Stokes and Shaffer have shown that 67 per cent. of the well treated cases of neurosyphilis have shown serologic reversal, while only 48.3 per cent. of a similar group have shown both serologic and clinical evidence of arrest. In other words, approximately 50 per cent. of these well treated cases do not show complete response to treatment. In our series, it was noted that 70 per cent. of the group in which the symptoms did not improve with the fluid, but in which treatment was continued, showed an appreciable response to the continued medication. In Group 2, the continued therapy relieved the symptoms in only 45 per cent. It would seem justifiable, therefore, to continue treatment in the face of positive symptoms irrespective of the negative serologic findings.

The estimated percentage of positive findings in the spinal fluid in tabes dorsalis varies from 52 to 100 in different clinics, and the number of cases of asymptomatic neurosyphilis varies from 18 to 48 per cent. in the same institutions.

Table 7 (Case 4).—*Observations in a Case of Serologically Negative Neurosyphilis* *

	Cerebrospinal Fluid				
Date	Wassermann	Nonne	Cells	Colloid Reaction	Blood Wassermann
6/18/20	—	—	1	....	—
7/10/22	—	—	3	....	—
4/ 3/25	42———	+	27	000000000000000	1

* In the examination of a woman, aged 29, suffering from renal lithiasis, in 1920, it was discovered that the pupils were unequal and markedly reduced to light, but normal for accommodation. The knee jerks and the Achilles reflexes were absent. No sensory disturbances were noted. The patient's husband gave a definite history of syphilis, but as he was ill with active pulmonary tuberculosis, his spinal fluid was not tested. The patient returned again in 1922, when the fluid was negative, and in 1925, it was positive. The neurologic findings at this time showed that the disease was advancing.

An important group, the "burnt out" or imperfect group, in which no symptoms were manifested at the time of examination or on subsequent visits, were excluded from this report. The diagnosis in this group is essentially a neurologic problem aided at times by the recognition of dermatologic or visceral evidence of syphilis. The neurovascular type which predominates in the serologically negative neurosyphilitic group was likewise omitted from this study.

The fact that a single negative reaction in the spinal fluid in cases of clinically positive neurosyphilis is not evidence of arrest of the disease has been noted a number of times. The symptoms may persist as they were at the time the reaction in the fluid was reversed, or the patient may progress to complete incapacity or manifest new signs and symptoms. We were unable to recognize any criteria in the tests of the spinal fluid that would act as a prognostic sign. The type of complaints and the patients' general condition, as noted over a period of six months or more, seemed to be the best index. Not only was it noted that the symptoms would progress in the face of negative serologic findings, but there were ten cases in the first and second groups, after the reaction of the fluid had been negative for two years or more, in which there was a reversal to positive and back to negative again under treatment. This observation confirms that of Solomon and Klauder. These reversals may or may not be associated with exacerbation and progression of the clinical symptoms. In the interpretation of such findings, it is necessary, of course, not to mistake changes in the serologic technic for evidence of the return of activity in the cerebrospinal fluid. In a number of cases encountered during this study, the Kolmer modification of the Wassermann reaction gave positive results, although the former technic had given negative findings for several years. Not only the Wassermann reaction but also the cell count should help to indicate renewed activity. The increase in the cell count, after a period of negative findings in the fluid, may be more significant than a reversal of the Wassermann reaction or its modifications. The globulin and colloidal gold tests, or a modification of the latter, seemed to follow rather than precede such recurrences. In our present state of knowledge, we are not justified in discharging, as arrested, neurosyphilitic patients who have had one negative spinal fluid test or who are not free from symptoms. The single negative report on the spinal fluid is of no more significance than a single negative Wassermann reaction in the serum which, as is well known, does not overrule a clinical suspicion of syphilis. It would seem to us that repeated tests of the spinal fluid at stated intervals of approximately a year are advisable (Tables 6 and 7).

The effect of continued treatment for the relief of the persistent symptoms in the group of patients with serologically negative reactions without previous treatment was attended with definite benefit in 45 per cent. of the cases. The results of continued treatment, however, were more encouraging in the group whose spinal fluid reactions reversed as a result of medication, in contrast to those cases in which reversal was the result of the patient's resistant forces; 70 per cent. of the former showed some improvement.

Treatment of neurosyphilis showing negative serologic reactions included more than the direct attack on the syphilis; the infected bladders must be cared for by lavage or drainage. The intravenous use of arsphenamin probably has a definite effect in controlling the frequently associated pyelonephritis. The dietetic control of the nephritis or nephrosis, with discontinuance of the mercurial preparations, has been of material help. It has recently been called to our attention that the prostate, and also the teeth, tonsils and uterus, may be the seat of the focal infection that aggravated the neuritis of tabes dorsalis. Again, hypertension and cardiovascular disease may account for some of the complaints. We have nothing new to offer in the treatment of patients with negative serologic tests who suffer from persistent gastric crises other than chordotomy, as suggested by Frazier,[13] which seems to hold out more hope than any form of treatment that has been offered thus far. Paravertebral injections of local anesthetics have afforded only temporary relief, while the injection of alcohol has been unsuccessful. Particular care of the patient's own resistant forces is very necessary, and for this, neo-arsphenamin in very small "tonic" doses has been useful. Rest, mental and physical, is almost as essential in the treatment of this phase of neurosyphilis as it is in tuberculosis.

CONCLUSIONS

1. Attention is again called to the fact that neurosyphilis may be clinically progressive in the presence of completely negative serology.

---

[13] Frazier, C. H.: Surgery of the Spine and Spinal Cord, New York, D Appleton Co., 1918, pp. 695-720.

2. Continued treatment for the symptoms that persist after the spinal fluid has become negative is attended with benefit in 70 per cent. of the patients whose spinal fluids reversed to normal as a result of treatment, and in 45 per cent. of those in whom the spinal fluid reversed without treatment.

3. A single negative spinal fluid report in the clinically positive but asymptomatic neurosyphilitic is not sufficient evidence to warrant the discharge of the patient as cured.

4. Spinal fluid examinations in addition to complete physical examinations should be made at yearly intervals, or thereabouts, in the neurosyphilitic patient whose spinal fluid has reversed to normal as a result of or without treatment.

5. Although our present knowledge on the subject of the significance of negative and positive spinal fluid findings in neurosyphilis is far from complete, we are justified in seeking to obtain a reversal of the serology to negative by the present day modern methods of treatment, bearing in mind that a small percentage of the well treated cases will have persistent symptoms irrespective of the serologic results.

6. The type and severity of the persistent symptoms, when considered in conjunction with the patient's general condition, offer the best guide as to the value of continued treatment in the serologically negative neurosyphilitic.

7. Because the serology has been found to reverse to positive, and the clinical signs of the disease develop in the asymptomatically and serologically negative neurosyphilitic, it hardly seems justifiable to allow these patients to rely solely on their own resistance mechanism, something about which we know very little.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. KNOWLES, LUDY AND DECKER; WILE AND KEIM; STOKES AND SHAFFER, AND O'LEARY AND NELSON

Dr. Harold N. Cole, Cleveland: Dermatologists have not stopped at treating diseases that go no deeper than the skin. Possibly a few things could be learned from the work that some dermatologists are carrying on. These papers show the necessity of making an early diagnosis in these cases of syphilis of the central nervous system. The therapeutic results are much better if treatment is started early. When the medical schools will give more time to dermatology and syphilology, emphasizing the importance of the early diagnosis and treatment of syphilis, then, and then only, shall we see less syphilis of the heart, of the spinal cord, and so on, ad nauseam. Practically all central nervous system syphilis has its inception during the first year or two of the disease. Dr. Wile's report shows that their best results were achieved in the early stages of the cerebrospinal involvement, and we all have found that if we get the cases in the early years the disease is easy to deal with; but as the older symptoms come on, the bladder symptoms, the crises, the paralyses and so on, the fewer the cases that will be benefited.

Dr. J. E. Moore, Baltimore: The point Dr. Cole brought out has interested us for many years; namely, the treatment of early syphilis. For this reason I was particularly interested in Dr. Knowles' paper because I have been trying to find out what has happened to our cases of primary and secondary syphilis treated by a method unlike that of Dr. Knowles', but depending on treatment carried out continuously and for a long period of time. We find, as Dr. Knowles does, that many uncooperative patients do not fulfil our treatment requirements. During the last five years we have been making intensive social efforts to get back to the clinic the patients treated during the past ten years, and have succeeded in studying 417 of them. In all these we have records not only of repeated physical and neurologic examinations, but also of routine examinations of the spinal fluid. From the standpoint of the amount of treatment given, we have divided our material into four groups, the first including those patients who had eight or less doses of arsphenamin, with no mercury. Of these, 10 per cent. were cured and 90 per cent. were not. In the second group, those who received two courses of arsphenamin with mercury, approximately 70 per cent. developed recurrences. Those in the third group, with three courses of arsphenamin plus mercury, show approximately 60 per cent. cured. In the fourth group, those who followed our ideal course of treatment, 80 per cent. are cured and 20 per cent. have had recurrences. It is fair to say that included in this last 20 per cent. are a considerable number of cases that might be regarded as reinfections rather than recurrences. Under the best methods of early treatment available in Europe and in this country, I feel that, given a cooperative group of patients, it is possible to achieve a permanent cure in about 90 per cent. of the cases. If adequate early treatment could be carried out everywhere, it should be perfectly possible to cut down materially the incidence of the late grave complications of the disease.

Dr. Julius Grinker, Chicago: I am gratified to learn that the dermatologists have learned more neurology and are doing better work in neurosyphilis than the neurologists themselves are doing. More than that, the field of neurosyphilis has been gradually slipping away from the neurologists because we are following up our cases, and thus the end-results do not reach the neurologists as frequently as formerly, which, of course, is much better for the patient. The general practitioner should have availed himself of this symposium. If he had, mistakes would be prevented. Some points, particularly those regarding the negative Wassermann reactions, are absolutely unknown to the general practitioner. We are often referred to patients from physicians with the statement, "This man has a negative Wassermann reaction; therefore I know he has no syphilis," but on clinical examination we find evidences of tabes, or cerebrospinal syphilis or even paresis. The average practitioner of today, aside from the dermatologist and neurologist, still believes that the negative Wassermann reaction means "no syphilis." I think the correct knowledge should be disseminated, so that patients will be treated who need treatment most.

Dr. F. J. Eichenlaub, Washington, D. C.: Two things in the symposium impressed me. Dr. Knowles' statistics about clinic patients are very interesting and they parallel, in great part, my own experience. As a matter of fact, they parallel more or less our experience with private patients. Some little time ago I figured out how many patients in a large free clinic in the District of Columbia took enough treatment, and the percentage was less than 10. Dr. Cole's point about the early diagnosis of syphilis is very important and should be stressed, but I do not believe that in the lifetime of any of us the stressing of this point will make a very material difference in the amount of late syphilis seen. I do not believe so because of what Dr. Knowles brought out, that so few of the patients, even when the importance of this matter is impressed on them, will take sufficient treatment to prevent the late complications. One has many interesting experiences. I had one patient who had five clinical recurrences of syphilis and yet the importance of long continued treatment was not impressed on him. Even physicians who surely should know the value of continuing treatment have abandoned their treatment after a short time. My experience does not agree with that of Drs. Stokes and Shaffer regarding optic atrophy. We have quite a number of referred cases, and many of these patients are materially improved and their optic atrophy is checked by the routine treatment, and more often still by the addition of routine intraspinal therapy.

Dr. John H. Stokes, Philadelphia: Dr. Eichenlaub's remarks suggest that failure to draw the distinction between primary and secondary optic atrophies may explain a portion of the improvement sometimes claimed for optic atrophy in general. Secondary atrophy following chronic inflammatory changes in the optic nerve responds in accordance with the general rule that the amount of improvement is determined by the proportion of active inflammation to degeneration. The typical pale, sharply defined disk of primary atrophy has a much more unfavorable prognosis. We feel a little inclined to apologize for the therapeutic detail in our paper. This emphasis was intentional, however, and we wish to reiterate that a mastery of detail is necessary for successful treatment in late syphilis. Routine treatment may be successful, but individualization is much more often needed. Those who review our results should realize that the attempt to reduplicate them, for example by a substitution of mercuric salicylate for mercuric succinimid, will not yield the desired results. We do not offer our technic with any intentional egotism, for better methods will undoubtedly be devised. We merely state the definite results secured by a definite procedure, one that should be reduplicated if judgment is to be passed on it.

Dr. J. Frank Schamberg, Philadelphia: Dr. Grinker said that the dermatosyphilologists were perhaps contributing more to syphilis than the neurologists. I think this is due to the fact that the dermatosyphilologist has been pursuing syphilis as a morbid entity from the time of its inception to the end, and this has necessitated a number of studies on the spinal fluid and the blood. I believe the dermatosyphilologist has been more successful because he has not started out with the extremely pessimistic opinion of the neurologist. The neurologist and psychiatrist has seen the cases beyond hope of correction. We have had a series of theses which represent, in a sense, a sort of therapeutic inventory. We have heard what one may hope to accomplish. We have learned that in the early meningitic forms the cases are more hopeful and in the late cases less and less hopeful. I cannot refrain from reiterating the statement that the treatment of neurosyphilis is chiefly prophylactic; that in order to prevent the late complications the patient must have early, vigorous treatment, followed by serologic control. In the early treatment our methods should be conservative, the more radical methods being reserved for the bad cases. I believe that many patients will get well without intraspinal medication. Many will get well under intravenous treatment, and in even some of the late cases recovery will occur under such treatment. I have in mind a patient who has been under my care for fifteen years, coming with late syphilis of the meningovascular type, with Argyll Robertson pupils. That man is now in good health. So, we must not take too pessimistic a view of meningovascular syphilis. We must remember that there are distinct limitations to the use of the metallic arsenicals. They do not reach the nerve tissue in sufficient amount to bring about an effect. Nonspecific therapy may be of great aid. Our attention has been called to the value of malarial infection in the treatment of paresis. While nothing definite can be given at this time, I think the consensus of opinion is that it permits longer remissions and return to vocational activity than any treatment that has been brought to us for many years. As time goes on and we are able to study our cases earlier, and see them in their incipience, more of them can be arrested. All cases of parenchymatous syphilis begin with meningitic involvement. I think we should look forward with research and study to the possibility of achieving better and better results.

Dr. Henry F. Stoll, Hartford, Conn.: I have sometimes been impressed with how much easier it is to make a tabetic patient with an infected bladder come back for treatment for the tabes, than to persuade him to have the bladder washed. I hope some plan of treatment may be suggested for the patients with negative blood and spinal fluid tests. Should they have regular courses of treatment, for ever, or should one wait for them to develop symptoms?

Dr. Henry H. Hazen, Washington, D. C.: There is one very serious problem in the treatment of syphilis, and that is the dispensary patient who will not consent to take the full course. That becomes very largely a public health problem. About the only thing we can do for these people who drift off after from ten to eighteen weeks is something like the following: Have the patients visited by a visiting nurse in the first week. If the nurse has a sufficient amount of intelligence she can get a fair idea as to whether that patient is apt to discontinue treatment. If he is the sort who will probably leave the dispensary it seems an excellent idea, instead of giving him a course of eight arsphenamin injections, to be followed by mercury, to give that patient at least twelve injections of arsphenamin combined with mercury. I wonder whether it would not be wise to undertake these rather radical methods in the case of patients we are apt to lose.

Dr. Frank C. Knowles, Philadelphia: This subject is tremendous. Naturally, only one phase of the subject has been discussed. I think we have to follow a routine treatment if we give in the neighborhood of 10,000 injections a year. Fortunately, at the Pennsylvania Hospital we have enough physicians to study our cases carefully. We have advocated a routine treatment of syphilis, but that does not mean that other drugs and other methods are not used. We have used foreign proteins, colloidal mercury, bismuth and various other preparations. We use, however, special methods of treatment usually in consultation and cooperation with the neuropsychriatric group at the hospital. If there are special indications for treatment, we follow these out. Certain patients cannot be given arsenic; certain cases of neurosyphilis are made worse by it. What I mentioned in my short article are simply the results on completed tests and in the routine treatment. It is not the advocacy of routine treatment in all cases, but careful study in all cases, and if there is a contraindication for this treatment or a special indication for any other treatment we follow it out. Our clinic is organized with six physicians, two full-time social service workers, a trained nurse, and an orderly.

Dr. Loren W. Shaffer, Philadelphia: The use of bismuth in treatment was not taken up. It has been used for a period of two years but we are not yet in a position to make any final statement as to its place. The references to the literature are in the final paper. As to the duration of treatment, we feel that lifelong observation is preferable to continuous treatment. It is practically impossible to continue treatment throughout life, and if a patient will not cooperate, it is better to wait for some symptom and then treat that drastically rather than to treat subthreshold throughout life.

Dr. Paul A. O'Leary, Rochester, Minn.: I agree with what Dr. Shaffer has said in regard to Dr. Stoll's question. Frequent routine examinations, particularly of the cardiovascular and nervous systems, when taken in conjunction with the active symptoms, offer a guide as to the need for continued treatment after the serologic findings have become negative. I agree heartily with all that has been said regarding the early treatment of syphilis and neurosyphilis, but the group that does not respond to these modern methods of treatment needs special consideration. There is a tendency at present to use fever therapy in addition to mercury and arsphenamin for the treatment of these resistant cases. Whether malaria or a foreign protein is to accomplish the desired effect we as yet do not know, but it has opened up an additional therapeutic attack which in our present state of knowledge is worthy of further trial.

Therapeutic Value of Light.—I have pointed out that there is good evidence for believing that light, mustard leaves, and mustard gas ultimately produce their effects in the same way; therefore it might be argued that those who are tolerant or supersensitive to the one stimulant should be so also to the others. This is definitely not the case, and the reverse is not uncommon, though negroes are tolerant to all three; this suggests that some other factor may be necessary to produce erythema apart from the light. This factor might well be the Bence-Jones quinoidine, since it is known that skins of the supersensitive are particularly fluorescent, and that fluorescent substances under the influence of light exhibit remarkable properties, such as the artificial production of supersensitiveness. This view is entirely different from that expressed by Dr. Peacock, speaking recently in the name of Professor Russ and himself, in which he regarded the fluorescence of the skin surface as a protective phenomenon, though on what evidence I do not know, except, of course, that outside the body fluorescent substances absorb ultraviolet rays.—Dixon, W. E.: Discussion on the Therapeutic Value of Light, *British Medical Journal* **2**:499, Sept. 19, 1925.

THE GASTRO-INTESTINAL SYMPTOMS OF NEUROSYPHILIS

DIFFERENTIAL DIAGNOSIS [*]

MAURICE FREMONT-SMITH, M.D.
AND
JAMES B. AYER, M.D.
BOSTON

In the sixty years since Charcot [1] first described the gastric crisis of tabes, increasing recognition has been given to syphilis as a cause of gastro-intestinal disturbance. Only in the last ten years, however, have we emphasized the less typical gastro-intestinal symptoms of neurosyphilis, and learned to appreciate the difficulties in the way of diagnosis.

Edsall,[2] in 1914, reported fifteen cases of gastric disorder, diagnosed ulcer or cancer and only later proved syphilis of the central nervous system. Operations were performed in four of the earlier of these fifteen cases.

Nuzum,[3] in 1916, studied 1,000 cases of tabes, and found mistaken diagnoses responsible for ninety-seven unnecessary laparotomies. In this group nineteen useless operations were performed for supposed gallstones, nineteen for supposed ulcer, eighteen for appendicitis, eleven for salpingitis, seven for adhesions and nine for exploration. His article stresses the unwisdom of making a diagnosis of intra-abdominal pathologic conditions unless tabes is excluded.

Woltman,[4] last year, reported 120 cases of gastric crisis in which sixty-three futile operations had been performed: twenty with reference to the appendix, fourteen on the gallbladder and twelve on the stomach. Some of these patients had been submitted to repeated operations.

Crohn,[5] and Full and von Friedrich,[6] however, have pointed out that peptic ulcer is of not infrequent occurrence in the tabetic patient, and have discussed the possibility that vagus degeneration may predispose the tabetic patient to ulcer of the stomach or duodenum.

Our purpose here is to show how great may be the difficulty in deciding between peptic ulcer and tabes, even when both conditions are in mind, and to emphasize the care necessary in interpreting roentgen-ray findings when these two conditions are to be differentiated.

A study has been made of fifty cases of neurosyphilis in which gastro-intestinal symptoms were prominent. All the patients were suffering from a late degenerative type of the disease, the majority showing evidence of tabes dorsalis. The symptoms for the most part were gastric in type. Twenty-six cases have been classified as frank gastric crisis, on the basis of acute attacks, beginning and ending abruptly and characterized by pain or vomiting, or both; fourteen cases presented less typical gastro-intestinal symptoms, such as knife-like pains through the abdomen, or sporadic vomiting. In one case, intestinal spasm was apparently proved by operation. (Schlesinger [7] has reported colonic spasm demonstrated by the roentgen ray during an acute abdominal tabetic crisis.) Two cases in which the predominant symptoms were rectal have been included. Eight further cases with probable intra-abdominal pathologic conditions, in addition to neurosyphilis, are discussed.

In this group of fifty cases, twelve patients were operated on under mistaken diagnoses, eleven in other hospitals and one in the Massachusetts General Hospital; and one case diagnosed tabes by us later barely escaped operation for ulcer in another city. In one recognized tabetic patient, a duodenal ulcer was allowed to perforate before the surgeon would consent to operate. *A definite gastric pathologic condition was proved* by operation or indisputable roentgen-ray evidence in five cases; ulcer, in four; cancer in one (figures corresponding with those reported by Exner and Schwarzmann,[8] who at necropsy found peptic ulcer in five and gastric carcinoma in three of seventy-five tabetic patients), and decision as to presence or absence of ulcer was not made in three cases.

Two types of mistake in diagnosis are possible: Tabes may not be recognized and the symptoms attributed to an intra-abdominal pathologic condition:

CASE 1.—S. G., a man, aged 42, during six months had had several attacks of dull gnawing epigastric pain, lasting from six to eight days, without relation to food. He had been entirely well between attacks. The pupils reacted to light. The reflexes were normal. There was no history of syphilitic infection, and the blood Wassermann reaction was negative. Roentgen-ray findings were consistent with a pathologic condition of the gallbladder with possible adhesions about the appendix. The surgeon's preoperative note says, "Gallstones most likely; I do not feel sure that there is not ulcer of the duodenum." Operation disclosed no intra-abdominal pathologic condition except an appendix adherent at its base. A positive spinal fluid was later reported from another hospital. The history, typical neither of gallstones nor of ulcer, should have suggested the necessity of a lumbar puncture before operation.

Or tabes only may be recognized, and an accompanying ulcer disregarded:

CASE 2.—D. J. S., a man, aged 48, noticed one year before admittance that he staggered. For eight months he had had pain in the umbilical and epigastric regions, coming on from a few minutes to many hours after meals, and definitely relieved by food. Soda had not been taken. There was no history of jaundice. The pupils showed no reaction to light. The knee jerks were unequal. There was a positive Romberg's sign. The roentgen ray showed irregularity of the antrum and of the first portion of the duodenum, with several projections visible in the region of the duodenum. The blood Wassermann reaction was positive. The surgeon decided against operation on the basis of the positive Wassermann reaction, in spite of food relief and a roentgen-ray finding characteristic of ulcer.

Five months later the patient experienced sudden severe abdominal pain lasting forty-eight hours, and followed by the vomiting of a few spoonfuls of dark material. The knee jerks were now absent. There was definite tenderness and spasm of the upper abdomen. The preoperative diagnosis was duodenal ulcer with probable chronic perforation. An operation showed a minute perforation of the anterior wall of the duodenum, through which gas escaped. The duodenum had become adherent to the under wall of the liver. A roentgenogram three years later showed a well functioning stoma and persisting irregularity of the duodenum. Gastric symptoms were not at once relieved by gastro-enterostomy, but when last heard from four years after operation, the patient reported no further pain.

In the first group, the usual source of error is the unfamiliarity of the physician with the earliest symptoms and signs of tabes. In view of the fact that crisis may be the initial symptom of tabes, the history and examination are unquestionably of highest value in differentiating ulcer from tabes. The following points should be recognized:

1. As is well known, symptoms of ulcer of the duodenum occur usually in well marked cycles—a comparatively long period of discomfort followed by a shorter or a longer period of well being; tabetic symptoms, on the contrary, occur with pronounced irregularity. In the fifty cases studied, absolute irregularity is stressed in thirty-nine cases.

2. Food relief, relief from soda, and food-time relation, usually present in both gastric and duodenal ulcer, are typically rare in crisis. It must be recognized, however, that the pain of ulcer may be persistent and unrelieved by food or alkali. Such cases are usually of the penetrating type. We have seen one case with symptoms very suggestive of gallstones, which proved at operation to be a penetrating ulcer of the duodenum.

3. Vomiting is far more conspicuous in the tabetic patient than in the patient with ulcer, appearing with or without pain in forty of our series. In ulcer, vomiting is often obstructive and preceded by a history of discomfort or pain. In crisis it is frequently the initial symptom. Hematemesis occurred six times in our series, twice in cases with accompanying ulcer, and four times in cases without ulcer. It is well recognized that blood may appear in the vomitus of patients experiencing gastric crises. In these cases, however, the blood is usually small in amount and appears at the end of a long spell of vomiting, in contrast to ulcer, in which massive bleeding is sometimes the initial symptom, and hematemesis of moderate amounts not uncommon.

4. The pain of ulcer is usually epigastric, radiating, if at all, to the back; in our series of tabetic patients, pain (present thirty-seven times) was likewise epigastric in all cases. Radiation was specifically noted in fifteen cases only. In one case in which ulcer was present, and in four uncomplicated crises, the pain was referred to the back and shoulders; in the remaining ten cases (all crisis) the pain radiated laterally about the chest in seven instances, to the shoulders and chest in one case, to the shoulders and inguinal regions once, and across the abdomen once. In other words, radiation usually around the chest, i. e., atypical of ulcer, occurred in ten out of fourteen cases of pure crisis in which this symptom was noted. A case described by Crohn[5] presented this typical lateral radiation of pain. More careful observation of tabetic crisis may well disclose a higher percentage of lateral radiation.

5. A rather characteristic finding in tabetic patients subject to crisis is an area of hyperesthesia about the trunk, often most marked over the back in the middorsal region. Increased sensitiveness of the skin to cold is also found. Such hyperesthesia was noted in seven cases and could probably be demonstrated in a far larger proportion of cases if searched for.

6. It is our opinion that, with sufficient care, other concurrent symptoms of tabes may be discovered in most patients experiencing tabetic gastro-intestinal disturbances. Of our cases, twenty-eight of the fifty were found to present, along with or preceding the gastric disturbance, one or more other symptoms of tabes. (Lightning pains were noted twenty-one times; urinary symptoms, fifteen; cranial nerve palsies, ten; unsteadiness, ten; numbness of the legs and hands, seven; and sex disturbance, one.) Seven patients of this group had undergone needless operation. It is evident that in the presence of abdominal pain or vomiting, other symptoms of tabes are too often overlooked or disregarded.

7. Of the signs, the most constant neurologic abnormalities found were with reference to the pupils, which were regular, round and equal in only three instances out of the fifty. Irregularity and inequality were each noted twenty-four times; light reflex was described as absent in twenty-nine cases, sluggish in eighteen and normal in three. In contrast to this consistent abnormality in the pupils, the knee jerks were normal in fifteen of our series; the ankle jerks in nine. In the exclusion of tabes, therefore, four times as much reliance may be placed on normal pupils as on the presence of normal knee or ankle jerks.

8. The blood Wassermann reaction was positive in twenty-four cases and negative in sixteen. The spinal fluid (examined in forty-nine cases) showed abnormal findings in all but one case. The Wassermann reaction was positive forty-one times, negative eight. In six of the eight cases showing negative spinal fluid Wassermann reaction, the blood Wassermann was positive, and characteristic changes were noted in the pupils and reflexes. A completely normal spinal fluid (normal cell count, colloidal gold and protein content by quantitative estimation) is strong evidence against gastric crisis; only one case in this series presented a normal fluid.

9. Gastro-intestinal roentgen-ray examinations were carried out in twenty-four cases, in which abnormal findings were observed at some time in fifteen. Of these fifteen abnormal findings, five were correctly attributed to the presence of a gastric or duodenal pathologic condition. Ten represent abnormalities probably due to spasm. It is interesting to examine some of these roentgen-ray findings in detail. One report reads, "Sphincter irregular, a definite deformity of the duodenum." A later examination showed a normal duodenum. Another, "A constant defect in the pyloric end of the stomach, suggesting spasm but may be ulcer." This case showed a normal stomach and duodenum at operation. A third, "Duodenum flattened; the deformity could possibly be ulcer." A later roentgen-ray examination was negative. Again, "Duodenum poorly filled. A constant defect in outline present. Ulcer of the duodenum." An examination after atropin showed normal findings. In one case pyloric obstruction reported by roentgen ray led the surgeon to advise operation; a later roentgen-ray examination showed normal emptying time.

It is not in tabes only that roentgenograms suggestive of ulcer may give rise to false interpretation. Baetjer[9] says, "Sometimes marked hypertonicity may arise reflexly from gallbladder adhesions or a chronic appendix [he fails to specify tabes], and there may be with it a pseudospastic defect that simulates an ulcer." Anxiety, nausea or a cold barium meal may cause pylorospasm, with consequent incomplete filling of the duodenal cap. Abnormal roentgen-ray findings are, however, sufficiently frequent in neurosyphilis to justify extreme care in interpreting atypical findings. If a definite deformity, filling defect or niche cannot be demonstrated, examination should be repeated after thorough saturation with atropin, and a careful effort made to catch a completely filled duodenum. The surgeon contemplating operation for ulcer should feel no added diagnostic security from a roentgen-ray report merely "suggestive of ulcer." Eusterman[10] says, "One should not be too quick in accepting the roentgen-ray diagnosis of a lesion in association with tabes for, as Exner has pointed out, the vagus may undergo degenerative changes in this disease, which in turn may bring about spasm defects through faulty innervation." On the other hand, a definite diagnosis of ulcer is frequently possible by roentgen ray. This finding should be respected even though frank tabes coexist.

---

[9] Baetjer, F. H., quoted by Tice, Frederick: Practice of Medicine, Hagerstown, Md., W. F. Prior Company, Inc. 7: 250, 1924.

10. Another method of differentiating symptoms due to neurosyphilis from those due to intra-abdominal pathologic conditions is the effect of antisyphilitic treatment. In certain of our cases the immediate reaction to intravenous arsenic was a flare-up of the lightning pains or gastric crisis. On the other hand, the subsequent response to a course of antisyphilitic treatment may be definitely favorable in effect on the gastro-intestinal disturbance of the neurosyphilitic patient, although we must admit that in some cases such treatment is entirely ineffective.

In differentiating crisis from possible gallbladder disease or appendicitis (next to ulcer the most frequent causes of error in diagnosis), emphasis must again be placed on the frequency with which the tabetic patient will present history or signs of neurosyphilis in addition to the outstanding abdominal condition; the position of pain; the atypical radiation, and the area of hyperesthesia often demonstrable in crisis. In a rather small proportion of cases, the spinal fluid alone makes differential diagnosis possible.

Concerning the mechanism of the gastro-intestinal symptoms occurring in tabetic patients, and the spasm seen by the roentgen ray, we have nothing new to offer. Whether the physiologic disturbance of the sympathetic nervous system is based on a pathologic condition of this system or is dependent on the recognized pathologic condition of the spinal cord and roots is not known.

CONCLUSIONS

Mistakes in diagnoses in this group of cases are still being made. These mistakes are not limited to the rural communities, but occur even in the large general hospital with its complete medical, surgical, neurologic and roentgen-ray equipment.

While the usual mistake is the unwarranted diagnosis of ulcer or gallstones in the tabetic patient, the error may be reversed, and a coexistent ulcer in a neurosyphilitic patient may be ignored and even allowed to perforate before diagnosis is made.

There are various degrees of gastro-intestinal disturbance caused by neurosyphilis, ranging from crisis, on the one hand (characterized by sudden onset of epigastric pain or vomiting, or both), to the least forms of gastric disturbance, on the other. These minor forms present occasional vomiting, pains occurring in any part of the abdomen, or attacks of epigastric discomfort merely, with or without gaseous eructations. Other forms of gastro-intestinal disturbance are constipation, diarrhea and rectal tenesmus. Such symptoms are too often treated by the physician without a suspicion that they may be due to neurosyphilis.

Though we recognize that crisis may be the first symptom, we believe crisis is rare without some accompanying signs or symptoms of tabes. Of these, abnormalities in the pupils are the most constant. We wish to emphasize that a negative blood Wassermann reaction is of no significance in eliminating the possibility of neurosyphilis, our findings in this regard being in agreement with those of Edsall.[2]

Irregularity of the pylorus or duodenum, demonstrated by roentgen-ray examination, is of rather common occurrence in neurosyphilis in the absence of gastric or duodenal pathologic conditions. Such irregularities, in order to constitute presumptive evidence of ulcer, must be confirmed after thorough atropin saturation.

ABSTRACT OF DISCUSSION

Dr. Julius Grinker, Chicago: Dr. Nuzum's paper was based on the records of the Cook County Hospital, the surgical division. All the patients were operated on without a consultation with neurologists. Many of these patients were brought in at night as emergency cases, and surgeons went no farther in their inquiry than to follow their inclination to operate and ask for consent to operate. The state of affairs at present is quite different. When a patient is admitted in the daytime and is examined by the intern, this sort of mistake is very infrequent. Surgeons hesitate to make their own diagnosis, but they refer cases to the neurologist more often than formerly. But in spite of it, many mistakes are made by surgeons because of their neglect to take reflexes and to examine neurologically. I think the excellent paper to which we listened would do much good if it were read before a meeting of surgeons, who are in great need of such good advice, as it contains. I agree with the author that the roentgenographic findings do not offer criteria for operations in the majority of cases. They are often misleading. I saw patients who were turned over to surgeons for operation after a glance at a roentgenogram. I argued against operation and perhaps saved their lives. The author has emphasized these mistakes sufficiently for us not to fall into similar traps. There is another reason why the tabetic patient occasionally falls into the hands of the surgeon, which needs emphasis. Especially in patients suffering from gastric crises are we apt to find the presence of knee jerks, also in tabetic patients suffering from perforating ulcer. What is more natural than for the physician to exclude tabes as a possibility and to rush the patient to the surgeon? And the general practitioner relies too much on a positive Wassermann reaction in the diagnosis of tabes, and consequently he excludes that disease when the test is negative, and then the surgeon is appealed to, who is mostly ready to respond. (Applause.)

Dr. James B. Ayer, Boston: In reply to Dr. Grinker, it might have been better to read this paper before some other section. There is, however, one point that can well be emphasized, even before neurologists. I refer not to pupillary and reflex changes, but to roentgen-ray findings in this group of cases. I think it is fair to say that we had ourselves to educate the roentgenologist in his interpretation in the first years of our work in this subject. In the earlier cases, his report would read, "Characteristic of gastric ulcer." We have changed this so that now it reads "Findings compatible with gastric ulcer." In that the roentgen-ray findings are of great importance in the differential diagnosis of gastro-intestinal disturbance, and in that very little mention has been made of the roentgen-ray findings in other papers on gastric crises, I believe that the paper is worth publication for this fact alone. One more point might be made: Our report shows a distinct lessening in frequency of gastric operations in tabetic patients. I am not saying this because we have apparently done well, but because it represents what has been going on in the community. In our series are patients who have been operated on before coming to us. Unquestionably, the same occurred in the series of Nuzum, Crohn and others, so that the statistics on the number of operations in neurosyphilis of this type form a good index of the neurologic diagnostic ability of the community at large. While we must admit that the subject under consideration is not a new one, it must be admitted that, until mistaken operations are reduced to zero, the subject is to be an ever present one.

---

THE CONTROL OF FOODS EATEN RAW *

HERMAN N. BUNDESEN, M.D.
Commissioner of Health
CHICAGO

Primitive man had only to reach out to Nature for his supply of life-sustaining foods. These he ate raw or only partly prepared, and, thus nourished, he was able to face the rough forces of the elements. There was little danger of his food supply becoming infected, for the simple reason that it passed through no other hands than his own. There was but little barter or exchange of food supplies at that period.

This state of individual economy was changed with changing conditions. As century followed century, in the swift and confusing turmoil of what is today termed "progress," man's dependence on his fellow creatures increased, and in like measure his food became subjected to handling by many hands before it finally reached his stomach. Only a few decades ago, man was still in a condition of semi-independence; he could go into his own or his neighbor's barnyard, orchard or vegetable garden and obtain his own foodstuffs, kill his own animals and milk his own cows. But with the advance of civilization, the eating of raw foods became confined principally to a few staple articles, such as milk, ice-cream, certain of the sea foods (such as oysters), vegetables, fruits and beverages. Those articles which are consumed in a raw state are so eaten largely because their flavor is injured by cooking, and, in some instances, in order to preserve their vitamin content.

Modern economic conditions make it necessary that foods, from the time they leave their source, through the processes of preparing, packing, shipping, unloading, wholesaling, retailing, sampling, displaying and, finally, delivery to the consumer, be handled by many hands. This naturally increases and multiplies the possibilities of contamination.

MILK

In 1907, Rosenau[1] tabulated 317 outbreaks of typhoid fever, fifty-one of diphtheria and 125 of scarlet fever transmitted by infected raw milk. Since that date much attention has been given to safeguarding the milk supply, especially the supply of the larger municipalities in the Northern states. As a result, milk-borne epidemics have been less frequent than before that time.

In Chicago there has been no case of typhoid fever, diphtheria, scarlet fever or other infectious disease traced to the milk supply since 1916, when universal pasteurization was put into effect.

In reviewing the experience of safeguarding the milk supply during this period, there are a few features that are worthy of mention.

First of all, the control of pasteurization is accomplished by a twofold check; namely, the bacterial examination of the raw and pasteurized product, and, secondly, the requirement that all pasteurizing machines be equipped with automatic temperature recording devices, the records of which are submitted to the department of health every week.

In addition to control of pasteurization, it is essential that strict attention be paid to the manner in which the milk is handled, with a view to preventing contamination subsequent to pasteurization. In this connection, it is important that all utensils, including the bottles in which the milk is placed, should be thoroughly sterilized and that the product should be protected against contamination in handling.

The principal source of such contamination is the hand bottling a[illegible] which is frequently practiced in the [illegible] As the workers carrying on these processes are not examined and may be typhoid carriers, the department of health of Chicago has entirely prohib[illegible] and believes that in this way the [illegible] contamination has been minimized.

The danger of subsequent contamination is especially great in restaurants in which milk is handled in the usual manner. The dipping of the milk is not only a source of bacterial infection but also results in a very unequal distribution of the butter fat in the product as delivered to the consumer.

Prior to Nov. 15, 1923, 33⅓ per cent. of the samples of milk and cream taken from restaurants were found below grade in butter fat, and the bacterial content of the milk served was found to be much higher than that of the bottled milk as delivered to the homes.

To remedy this condition, an order was made effective, March 15, 1924, requiring all milk served in restaurants to be bottled or to be dispensed from approved urns, insuring the proper refrigeration, protection and mixing of the milk dispensed. As a result of this requirement, the "below-grade-in-butter-fat" samples collected from restaurants have fallen to approximately 3 per cent., and the bacterial counts have improved.

CREAM

The control of the pasteurization of the cream supply of a large city is much more difficult than that of the milk supply, because cream is derived from more numerous sources, which, in many instances, are at great distances from the city.

Another reason for the difficulty experienced in keeping the bacterial content of pasteurized cream within safe standards is the fluctuation in the demand for this product. Milk dealers report that the end of each week brings an extraordinary demand for cream for domestic consumption, and that variations in the weather cause another great fluctuation in the demand, due to variation in the consumption of ice-cream during hot and cold periods. There results, therefore, a tendency, made necessary by the market conditions, to store the cream until it is needed.

It is apparently for this reason that the dealers in cream have been slow to comply with the requirement of the Chicago ordinance which stipulates that cream be dated, showing the day on which it was pasteurized. It is interesting to note that a review of the regulations as to the dating of cream in a number of the principal cities shows that in only a few of them is it required that the date of pasteurization be given on the caps and labels of cream containers.

As a result of the foregoing conditions, it is quite universally found that the bacterial content of cream is much higher than that of milk, and that colon bacilli are often found in 0.001 or 0.01 c.c. portions. The latter finding calls attention to the potential dangers that would arise in case such aged cream was primarily infected with typhoid bacilli or other infective organisms. In order to obviate this danger, notice has recently been given in Chicago that the dating require-

[1] Rosenau: Bull. 56, Hyg. Lab., U. S. P. H. S.

ment of the ordinance will be strictly enforced. As a result of such requirement, it appears that much of the cream will be pasteurized in the city, and arrangements have been made whereby cream pasteurized by the "flash" process in the country or otherwise partially heated may be received in the city and given a final, more nearly perfect pasteurization under the direct supervision of the department of health.

CERTIFIED MILK

Certified milk is prepared with a view to making it safe for consumption in the raw state.

The conditions under which it is produced, under the supervision of the Medical Milk Commission of the local medical society, are well known and need not be gone into at this time. There are certain problems, however, that must be solved in connection with the safeguarding of this product. The outbreak of streptococcus sore throat reported by C.-E. A. Winslow in Boston, transmitted by certified milk, has called attention to the matter.

In an analysis of seventy-one samples of certified milk derived from nine farms producing certified milk for the Chicago market, streptococci of the beta type, which were virulent to mice, were found in 5.6 per cent. of the samples. During April, 1925, this type of organism was found in the samples of three of the farms supplying the city. The physician for the milk commission reported that a careful examination had been made of all the workers and no streptococcus infection had been discovered. It was therefore thought desirable to examine the milk of the individual cows. The result of this analysis was as shown in the accompanying table.

Summary of Results Obtained from Tests of Milk from Cows on A, B, C and D Farms

	Number	Per Cent.
Cows tested	606	...
Cows showing beta type	37	8.5
Cows showing alpha type	185	30.5

It will be noted that 222, or 39 per cent., of the 606 cows tested showed streptococci of the alpha and beta types, thirty-seven, or 8.5 per cent., being of the beta type. The organisms of this type isolated from four of these cows killed two mice within forty-eight hours. It was reported that the veterinary examination of all the cows subjected to these individual tests were negative, including the four in which the virulent organisms were obtained.

The question of the infectiveness of milk containing streptococci has not been definitely determined. On the advice of the bacteriologists of the consulting staff of the Chicago Health Department, the following method of procedure has been adopted for the safeguarding of the milk containing streptococci:

> Hemolytic organisms found in certified milk should be regarded as of no significance unless conforming to the following characteristics:
>
> They should be streptococci of proper morphology, giving colonies of the beta type on blood agar.
>
> Production of hemolysin should be sufficient to produce full hemolysis of rabbit's blood corpuscles within two hours.
>
> They should kill both of two mice injected, acutely within forty-eight hours, and should be recovered from the animals and identified.
>
> Samples containing organisms conforming to these tests may be regarded as under suspicion, but these data are merely suggestive and not proof that the organism is dangerous to human beings. Any action which may be taken must necessarily be determined by practical circumstances. If, however, an absolute safeguard against the possibility of septic sore throat outbreaks is desired, pasteurization or a shut-off of the supply until subsequent samples prove negative is the only reliable procedure.

ICE-CREAM

Ice-cream, when properly prepared and safeguarded against infection, is a wholesome dairy product, and should be in the same category as milk, cream, butter and cheese as a daily article of diet. It is, however, a well known fact that the bacterial content of some of the ice-cream sold is so high that sanitarians and dietitians have refrained from recommending this product freely as a food. A close study of the industry shows that much improvement has been brought about in recent years in the sanitation of plants and in the sterilization of utensils and machinery, but that not enough attention has been given to the various ingredients entering into the ice-cream mixture. The cream used is often an old product which has been rejected by milk dealers supplying the domestic trade. During prolonged hot spells the cream is derived from more distant sources where dairy inspection is not rigidly enforced, and where it is difficult to control pasteurization.

The other ingredients entering into the mixture, such as the condensed milk, milk powder, gelatin, fresh fruits and even the flavors, may contain excessive numbers of bacteria, and even colon bacilli.

In order properly to safeguard the ice-cream supply it has been found necessary to require that the completed mixture should be properly pasteurized before freezing. This, of course, entails a repasteurization of some of the cream used. Here, again, it is permitted that this cream may be treated by "flash" pasteurization process in the country, simply for the purpose of increasing its keeping qualities in transit, and then be more properly pasteurized as a part of the general mixture.

It is also found that somewhat higher temperatures can be applied to the pasteurization of the product used for the manufacture of ice-cream than of milk to be used for domestic purposes, because it is not necessary in the case of ice-cream to preserve the cream line. Thus, with pasteurization of the final mixture at a temperature, say, of 150 F. for thirty minutes, a product should be obtained with a low bacterial content, and entirely free from infective organisms, provided proper precautions are taken to protect the finished product against subsequent contamination. To this end, steps should be taken to see that the product is handled in the plants by machine as far as practical, that such machinery and all containers are perfectly sterilized, and that wherever it is necessary to handle the products by human hands, the workers be examined to see that they are free from typhoid bacilli or other infective organisms.

OYSTERS AND OTHER BIVALVES

Recent experience has again shown the danger inherent in oysters and other sea food when eaten raw.

A comprehensive report on the typhoid epidemic last winter in New York, Chicago and Washington, made by Lumsden, Haseltine, Leake and Veldee,[2] and a report on the Chicago outbreak[3] covered the most recent experiences with outbreaks of typhoid fever traced to oysters consumed in the raw state. Since the report of the outbreak at Wesleyan University by Conn,[4] there have been fifteen records in the literature of other typhoid outbreaks traced directly to infected oysters. In view of this situation, it is imperative that steps be taken to safeguard this article of food.

---

[2] Lumsden, Haseltine, Leake and Veldee: A Typhoid Fever Epidemic Caused by Oyster-Borne Infection (1924-1925), Pub. Health Rep., Supplement 50.

I concur in the conclusions arrived at by a recent conference called by the Surgeon General of the United States Public Health Service in Washington, Feb. 19, 1925. Until these recommendations are put into effect, local, state and municipal health officers will be compelled to exercise such control over the oysters sold in their respective jurisdictions as will insure a safe supply. This can best be done by requiring all shippers of oysters to secure a permit before being allowed to sell their product, and to get reports from the local and state officials at the place of production, showing that inspections have been made at the place where the oysters are grown, shucked or otherwise prepared.

The danger of contamination of the oysters during the handling should also receive attention. This occurs especially in the packing and shucking establishments, and is shown by the difference in colon content between the fresh and the prepared product. Shucked oysters often show a score of a thousand and more, while the shell oysters usually score less than a hundred. The danger from typhoid carriers in these establishments has to be met. If the matter of inspection and control of the growing, packing and distribution of oysters is not assumed by the federal authorities in cooperation with the states in which these oysters are produced, then it will be necessary for the local health officers in places where they are distributed to exercise a stricter control, and to this end it is hoped that some process may be worked out whereby both the shell and the shucked stock may be purified by some means, such as washing or chlorination. Such purification might, to a large extent, supersede the inspection and control that the local authorities would otherwise be compelled to exercise over the growing and handling of oysters at the place of their production.

FRUITS AND VEGETABLES

Theoretically, fruits and vegetables may transmit typhoid fever and other infections, but practically it is very difficult to trace cases of disease to this source. The reason is that ordinarily contamination of fruits and vegetables occurs during handling. Only a few specimens become infected, and on account of the nature of these fruits and vegetables the infection does not multiply to any great extent. It is for this reason that cases of infectious disease developing are usually isolated, and from a practical standpoint are hard to connect with the source of infection. Another reason for the difficulty in tracing infection in fruits and vegetables is the promiscuous distribution of these products, as a result of which it can rarely be shown that one individual has received his supply for any length of time from any particular source.

In the recent outbreak of typhoid in Chicago, which was ultimately traced to oyster infection, special effort was made to determine the sources of certain vegetables, such as celery, lettuce and watercress, served in hotels and restaurants, where it appeared that the majority of the patients had contracted their infection. When the tracing of these commodities to their ultimate source was attempted, it was found that the ramifications were such that it was practically impossible to state definitely from what source the patients had derived the fruits and vegetables eaten during the probable infection period. The only thing which could be proved definitely was that there was no common source of supply for these foods in the series of cases investigated.

The investigation also disclosed that watercress should be given more attention as a source of typhoid infection than it is ordinarily given by health departments. This vegetable is grown in swampy places in which the water is apt to be contaminated with sewage matter.

Bacteriologic examination of fruits and vegetables has not proved of any value. In the majority of instances *B. coli* is found, but it is impossible to determine whether this is of human origin or derived from the soil, where it is found in large numbers. In certain shipments of lettuce recently examined by the Chicago Department of Health, it was found that the high colon count was due to contaminated ice used in the packing of this commodity.

On account of the location of the infective organisms on the surface of these vegetables, it has been found that a careful and thorough washing, especially in hot water, if practicable, is very effective in removing the superficial contamination. Attention to this matter is therefore recommended as the best safeguard against infection by fruits and vegetables.

CARBONATED BEVERAGES

The method of insuring the safety of carbonated beverages is comparatively simple, provided a pure water supply is available for their manufacture. The purity of the product made originally from a safe water supply can be maintained, if proper attention is given to sanitation of the plant and machinery, and the utensils and containers are properly cleaned and sterilized before they are filled.

Experience has shown that an alkali soak consisting of a 4 per cent. solution of sodium hydroxid, maintained at a temperature of not less than 130 F. for a period of not less than five minutes, is very effective in cleansing and sterilizing beverage bottles. After such sterilization, they should be thoroughly rinsed in pure water and filled.

It has been shown that the carbonic acid gas is a deterrent of bacterial growth, and it is possible that the saccharin which is frequently used as a substitute for sugar may also inhibit the multiplication of bacteria.

Beverages when thus prepared should have a bacterial content not much above that of the water from which they are derived.

RAW MEAT AND SAUSAGE

The parasites that make raw meat dangerous to health are *Taenia solium*, *Taenia mediocanellata*, *Taenia ecchinococcus*, *Bothriocephalus latus* and *Trichina spiralis*.

The public is not generally aware of the fact that there is no systematic microscopic inspection of meats in slaughter houses. The examination for parasites is apparently not made because it is assumed that meat food products are not ordinarily eaten raw in this country. There are, however, some nationalities and immigrants who persist in the habits learned in their native lands, such as the eating of raw ham and sausages, and, in some instances, even the eating of raw beef. It is among this class that the cases of trichinosis and tapeworm observed in this country occur.

---

[3] Bundesen, H. N.: Typhoid Fever Epidemic in Chicago Apparently Due to Oysters, J. A. M. A. 84: 641-650 (Feb. 28) 1925.

[4] Conn: Report of the State Board of Health of Connecticut, 1894, pp. 239-264.

Trichinosis is probably more common than appears in the records of reported cases of this disease. During the last three years, twenty-seven cases of the disease were reported to the Chicago Department of Health.

Although pickling and boiling are recognized means of rendering meat parasites innocuous, it is evident that these means cannot be relied on to be used in the home to safeguard the public against meat parasite infection.

The Bureau of Animal Industry of the U. S. Department of Agriculture has issued regulations in regard to the manufacture of sausage commonly eaten without cooking, requiring pork entering into their composition, if not prepared in accordance with certain smoking and curing methods which it has outlined, to be subjected to refrigeration for not less than twenty days at a temperature not higher than 5 F.

ABSTRACT OF DISCUSSION

Dr. Oscar Dowling, Shreveport, La.: While the milk of Louisiana is not what it ought to be, no milk can be sold until the cow is tuberculin tested.

Dr. J. W. VanDerslice, Oak Park, Ill.: *Streptococcus hemolyticus* is found constantly in raw milk. From 10 to 30 per cent. of cows in all herds will at times show *Streptococcus hemolyticus* of the beta type. These organisms may kill mice, but this is not evidence of their pathogenicity to man. There is no easy way by which the bovine type can be distinguished from the human type. The Chicago Medical Society Milk Commission is now making an exhaustive research on the problem, and any material of value will be given to the American Association of Medical Milk Commissions for publicity.

Dr. A. S. Hershfield, Chicago: Dr. Bundesen, commissioner of health of Chicago, has aroused the interest of the people of Chicago in public health. He keeps that interest alive in milk, food, water and other necessities by teaching positive health through *"Chicago's Health,"* a bulletin issued every week by the department of health. The campaign for safe milk that he inaugurated a year and a half ago was done with considerable trepidation, not knowing how the public would take it. But it was taken in the spirit it was meant, to the general advantage of the people. Again, in the case of medical examination of food handlers, a great deal of publicity was given to this health measure, and restaurant owners said they would cooperate with the health commission to protect the consumer. In other words, a sane, intelligent attitude toward public health and feeding it properly to the public is bound to bring the backing of the community; and also brings the realization that standing behind positive health measures is a guarantee of health safety.

Dr. William J. Hickson, Chicago: In regard to the personnel of many restaurants: We examine in the psychopathic laboratory in Chicago cases mentally, emotionally and physically, the flotsam and jetsam of a large city. Our reports will be published in the forthcoming annual report of the Chicago municipal court. We found the personnel of many restaurant workers in Chicago to be very low not only on the intelligence but also on the emotional side; therefore I think it very important that these measures of hygiene be strictly carried out because such personnel is too utterly irresponsible personally as well as to others about hygiene or damage they can do and I think the regulations in this direction cannot be too strict.

Dr. Louis I. Harris, New York: Dr. Bundesen touched on so many topics that he probably had to omit mention of many important items. I would emphasize the importance of pasteurizing butter. It enters so largely into the diet of children that it deserves especial comment. It should be legally required exactly as is the pasteurization of milk. I think the time will come when the sale of loose or dipped milk will be regarded as a disgrace for any community to permit it. The dispensing of any drink so that it slops over the hands of the person serving it should be prohibited. I recognize that the solution of the question involves many practical difficulties. The question of streptococcus standards interests us immensely. We should not be dogmatic and urge on small communities things that cannot be carried out because of the lack of adequate machinery. We must first be quite sure that we have worked out standards and methods of differentiating the type of streptococcus that is harmful from that which is not harmful before we give any kind of sanction, implied or direct, to milk containing streptococci, or urge the adoption of methods that cannot be carried over into small communities. Anatole France, traveling through Italy, was amused by a watermelon vender who cried, "Buy my melons; for three cents, eat, drink and wash your face." Dr. Bundesen in his campaigns quite properly gives force to his counsels by stressing the many advantages that will follow from heeding his advice. It is effective public health education. We must bear in mind that there is a great consumption of raw and uncooked foods. Exposure to dust should be prevented. The examination of food handlers, which, on the whole, is primitive in its present development, represents an effort in the right direction. Possibly, in the not distant future, such examinations will be conducted everywhere as efficiently as their importance merits. Food inspection may be ever so excellent, and yet be nullified by sanitary methods of distribution and service.

Prof. I. V. Hiscock, New Haven, Conn.: Many important problems are involved in the sanitary control of food supplies, as emphasized in Dr. Bundesen's paper. It is gratifying to note, however, in considering our most essential food, that milk supplies throughout the country have generally shown striking improvement in recent years. This has come about through the efforts of health officials, coupled with the cooperation of persons connected with the dairy industry. Today, in most of our large cities at least, all the milk is either pasteurized or comes from tuberculin-tested herds; and in many cases from 90 to 98 per cent. of the supply is pasteurized by the holding process. It is true that pasteurization was never intended to cover up the trail of dirty milk. As has been well pointed out, milk production must be supervised all the way from the source to the point of delivery. While I also believe that we need a certain amount of milk of certified grade, it seems to me we should not forget that certification does not necessarily guarantee safety. This fact has recently been ably demonstrateed by Dr. Huntington Williams, who has traced a paratyphoid epidemic in New York State to milk produced on a certified farm. During the last few months I have had the pleasure of visiting two splendid dairy farms, one in Michigan and one in Connecticut, where the milk of certified grade was pasteurized before being fed to calves.

Dr. F. C. Johnson, New Brunswick, N. J.: I wish to speak of an interesting case under the class of foods that Dr. Bundesen passed over quickly. Coming from California there are reports of an unusual specific infection of the gastro-intestinal tract which has been communicated by raw lettuce. We had a little boy in New Brunswick who was especially fond of raw lettuce. He developed colitis with diarrhea, and our technician, who had worked in California, recognized at once the eggs of the parasite and there is no reason to doubt that it was transferred to New Brunswick from California in raw lettuce. It was interesting to me from an agricultural standpoint, having been an agriculturist; and, being a pediatrician, I have advised not to feed lettuce or celery to children as the possibility of infections being carried by these raw vegetables is really great, in view of the large amounts of excreta of farm animals and sometimes of human beings that are used in fertilizing the crops of lettuce and celery.

Dr. Ferguson, Chicago: During the last six or seven months there seems to have been a rather severe attack on the certified milk industry by the health officers throughout the country. We are at a loss at the present time to know just why this has occurred, and I was very glad to hear Dr. Bundesen state that he favors certified milk, provided it is properly protected. I believe all medical milk commissions are striving to do this and that they are all alert to all dangers to the product, especially the finding of *Streptococcus hemolyticus* of the bovine type in the milk. In going over this situation with a number of health officers, we find that certified milk is not the only food product going into communities which has this streptococcus in it. We find it in pasteurized milk and butter and cheese. We believe certified milk is the ideal that we should continue to safeguard in order that we may have this ideal for other dairy products to live up to. In order to do that, we recognize that certified milk must be properly safeguarded by the Medical Milk Commission. In a very important conference which we had at Princeton, a few nights ago, there were some important points brought up which we hope to have brought out in book form, and which will help in distinguishing between bovine and human streptococci. Dr. Jones, who is Dr. Smith's co-worker at the Rockefeller Foundation, stated definitely that the bovine type is harmless to human beings and is found in butter and pasteurized milk and other dairy products. My plea therefore is for you not to make an attack on the highest product in the dairy industry, but help the medical milk commission keep that ideal in order that we may have something to aim at. Certified milk has held its place for thirty years and has brought the dairy industry up to where it now is.

DR. P. H. HOURIGAN, Buffalo: I was interested in the matter of food handlers and we are interested in handling food. We find benefit from the health department. Last year we took up the matter of milk and required food handlers to be examined. We required cultures from the nose and throat, a Widal test, smears from the vagina and urethra, and then a Wassermann test. That ordinance went into effect, January 1. Of about 100 Wassermann tests we found about 8 per cent. positive. I want just to bring up that matter to the doctor and ask what he thinks of that examination of the food handlers.

DR. W. H. SEEMANN, New Orleans: Three or four years ago, when a conference of health officers was held in Jackson, Miss., we were endeavoring in our small town way to improve the milk supply and have the tuberculin testing of cattle generally accepted. One of the most brilliant writers and one of the most persistent speakers and vitriolic impressionists I have ever listened to was there and, being a man of national, as well as international fame, he thoroughly convinced himself he was right, and insisted that it was puerile to talk of anything but pasteurization. When I got up the bills we demanded at the beginning that we should have tuberculin tested cattle, dairy utensils 100 per cent. in equipment, personnel to acquire cleanly habits, and then, if we wished, to pasteurize. I am heartily in favor of pasteurization, but I am glad to see we are getting at the source.

Influenza.—Epidemic influenza, so far as can be recognized by the meager historical descriptions, occurred at least as early as the fourteenth century. Since the beginning of the sixteenth century epidemic waves of this disease have swept over the world at more or less frequent intervals, the latest being the great pandemic of 1918-1919. The loss of life in the recent outbreak was enormous, amounting to over 450,000 deaths in the United States and to over 6,000,000 in India. . . . In the years between pandemics, for example, between 1890 and 1918, many deaths have been attributed to "influenza," but since recognition of true influenza in nonepidemic periods is hardly possible by either clinical or bacterial methods, the identity of the "influenza" of 1917 with the epidemic influenza of 1918 is uncertain. It is perhaps significant that the age-grouping of the "influenza" deaths in nonepidemic periods is very different from that in pandemics.—Jordan, E. O.: General Bacteriology, Ed. 8, Philadelphia, W. B. Saunders Company, 1925.

END-RESULTS IN TREATMENT OF KNEE JOINT TUBERCULOSIS.*

RUSSELL A. HIBBS, M.D.
AND
HERMAN L. VON LACKUM, M.D.
NEW YORK

In July, 1904, the Country Branch of the New York Orthopaedic Dispensary and Hospital was opened with a capacity of fifty beds for the treatment of joint tuberculosis in children. In 1908, it was enlarged to a capacity of 130 beds. In September, 1924, thirty more beds were added for adults, making the total capacity 165 beds.

The hospital is situated in the rolling country of Westchester County, 22 miles from New York, near White Plains, at an elevation of 400 feet above sea level. It was built for the definite purpose of furnishing a place in healthful surroundings where children with joint tuberculosis could remain for long periods under the continuous observation of the same surgical staff. The object was that more accurate knowledge might thus be obtained of the course of the disease as it affected the individual joint, its influence on the development of children, and the end-result obtained by treatment.

The organization was planned so that the full benefit might be secured for the individual case: life in the country, good air, sunshine, good food and good surgical care.

Only children were admitted in the earlier years of the hospital's activities, and the cases were those of tuberculosis of almost all the joints. Among them were seventy-seven children with knee joint tuberculosis who remained long enough under observation to make their study of value. There were other cases involving the knee that were not seen long enough to afford any information of value and they are not included in this study.

These patients were those admitted during the period from July, 1904, to July, 1921. The average duration of disease before the patients were admitted to the hospital was something over three years. In many instances the diagnosis had not been made, or had been inaccurate and none of the children had had any adequate treatment in the dispensaries in the city. Some of them had worn plaster, and had had massage, and various measures of this kind. The general condition of these patients was not conspicuously bad and seems to have had no particular bearing on their progress.

In estimating the end-result, joint tuberculosis was considered quiescent or clinically cured only when all muscle spasm or any other symptoms suggesting active disease had disappeared. Indeed, in most instances the patients were kept in the hospital for a year after all treatment had been discontinued, living perfectly free, active lives. They were then discharged to their homes and followed up through the outpatient department of the city dispensary.

Of the seventy-seven cases, fifty were discharged as quiescent; two patients died subsequently, and three other cases became quiescent soon after discharge. While as much information as is possible will be given of the remaining nineteen cases, it is chiefly with the fifty-one that we are concerned.

---

* From the Country Branch of the New York Orthopaedic Dispensary and Hospital.

* Read before the Section on Orthopedic Surgery at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

The ages of the patients varied from 9 months to 14 years, and the average age of onset of the disease was 4 years. The youngest patient was also syphilitic, and since the local condition had progressed in spite of treatment for syphilis it was thought justifiable to continue the diagnosis of tuberculosis as well. The knee is still very active although the patient's general condition is much improved. There were two other very young patients, the onset being at about 1 year of age. One of these cases is still active after five years, and the other became quiescent in seven years and has been quiescent for four years. Four patients had the onset at 1½ years of age; one case became quiescent after a duration of thirteen years, recurring in seven years, and is still active, ten years later. Another was treated at the country branch nine years, was discharged active, and is still active after eleven years. These two patients refuse to be operated on, although in neither case is there the slightest possibility of ever securing any function in the joint. One of the others became perfectly well in a year and has remained so; this certainly was not tuberculosis. The fourth failed to become quiescent in eight years of treatment and was fused by operative measures. The patient is now well. In one case the disease began at the age of 14. After five years of treatment by immobilization, the knee became naturally fused and has been well for thirteen years.

In considering the very young patients, it seems that they are much slower to respond to treatment and that the condition is more likely to recur early than in those patients who have sufficient resistance to reach an older period before the disease begins.

In reviewing the entire seventy-seven cases, it is striking to observe how few of them were normal persons, and the youngest patients, with one exception, showed definite evidence of enfeebled growth.

As to the question of the influence of trauma as a causative factor, it would appear from this study that there is no definite evidence that trauma other than that of normal activity has any relationship to the cause of the disease or its severity.

Cutaneous tuberculin tests were not carried out in many of the earlier cases, but when done were positive in all but two cases. The two children who did not react were definitely tuberculous, and their failure to react is believed to be due to the fact that mixed tuberculin was not used. Recent work has shown that the reactions vary with the bovine and human types, and on occasion reactions were given with only one kind.

The Wassermann test was used in about one half of the cases, and enough positive reactions were gained to indicate its need as a routine measure, proving as it does sometimes that the two diseases may exist in the same person. When the joint is tuberculous and syphilitic, antisyphilitic treatment is helpful only to the extent that it affects the general condition. There were only five cases that showed positive evidence of syphilis, so that there was no reason for believing that the majority of the cases had a syphilitic focus as a primary source.

Seven children are dead. Three died of the tuberculous lesions, three of pneumonia, and one following a laparotomy. Two of these had had quiescent joints for four and five years, respectively, at the time of death. In the first case, death was due to a tuberculous kidney and in the second to pulmonary tuberculosis.

Of the sixteen children who, for various reasons, were discharged from the country branch while the disease was active, the condition became subsequently quiescent in three, as noted above; four cases that remained active have been fused by operation, and nine are still active, from four to eleven years after discharge.

The history of these patients suggests that they are much better after undergoing treatment in institutions in the country than in city hospitals and dispensaries, and it further suggests that operative treatment is conservative rather than radical, especially in those patients who cannot be controlled.

In the fifty-one cases that were regarded as clinically cured, it required an average of six and one-half years to accomplish that result; the longest period in any single case was thirteen and one-half years, and the shortest was two years and eight months. The former recurred eight years later, and the latter is still quiescent, six years later. Sixteen of the fifty-one cases recurred after periods varying from nine months to ten years. Lowered resistance, for one reason or another, rather than gross trauma, appeared to be the cause of these recurrences. In making this statement, the constant slight traumatism caused by movement is not considered, although its removal is an essential part of the treatment. Four of them were fused immediately and six subsequently, and the patients are now well. Two of the cases became again quiescent after a period of immobilization, and the four others are still active, undergoing some sort of treatment, but operation still being refused. Adding to these the cases that remain from among those discharged as active, there are of the seventy patients still living thirteen with active knee joint tuberculosis at the present time. There are thirty-five cases, therefore, of the fifty-one that have remained inactive. Of this number there are ten children who, obviously, never had tuberculosis. Seven of them have perfectly free knees, and after an average of four years show no evidence of ever having had any knee disability. It took an average of three years to accomplish this result. One case is that of villous arthritis, and the other two are probably syphilitic. Of the twenty-five cases remaining, only five of them have ankylosed, three by bony ankylosis and two by fibrous tissue. There remain, then, twenty cases with motion which varies from 10 to 100 degrees, nine of these cases having less than 45 degrees. Four children have severe knock-knee deformity; two have severe subluxation, and nine have more or less flexion deformity.

In the entire series, sixteen were fused by operative means, and none of them have shown the slightest evidence of disease since that time. An average of seven months was consumed in gaining bony fusion, the time depending on the extent of the bone involvement, the bone-growing capacity of the patient, and the excellence of the operative technic. All were unmistakably tuberculous. Four were reported by the pathologist as chronic arthritis, illustrating the necessity of being very careful in selecting the tissue for examination, and the possibility of making mistakes in joints that are explored for the purpose of diagnosis. Of these sixteen cases, four are among those who never became quiescent. The total duration of the disease in these four averaged eight and one-half years, the longest being seventeen years and the shortest three and one-half. The other twelve were among those which became quiescent but relapsed. The average duration of disease in these was nine years, the longest eighteen and the shortest four years.

The influence of the disease on growth is shown in the fact that about one half of the cases show lengthening, and the patella is almost invariably enlarged on the diseased side. Growth of the femur is most easily stimulated. Some of the extremities were shorter and some longer. Although for a period of time there is stimulation of growth, more frequently of the femur as noted above, but sometimes of the tibia as well, in the end, the extremities tend to become of equal length. The average shortening of those that were short was about three-fourths inch, the femur being the bone most seriously retarded.

SUMMARY

Of the seventy-seven patients, seven are dead. Of the seventy remaining cases, sixteen have been operatively fused, of which twelve are cases that relapsed and four are cases that did not become quiescent. Fifty-three cases, including two in which the patients died, became quiescent. Fifty-one remain, in ten of which there never was tuberculosis, leaving forty-one. Of these, sixteen have already relapsed, twelve are fused, two are again quiescent, and four remain active. Add to these the nine that never became inactive, and there are now thirteen active cases in the whole series. Twenty-seven cases are inactive, three with bony ankylosis and therefore safe, two with fibrous ankylosis and unsafe, and twenty-two with varying degrees of motion and deformity, all of which are certainly unsafe.

The average age of onset was 4 years. The duration of time before the quiescent period was reached was, on an average, six and one-half years. The average age at which relapse has occurred in quiescent cases was 17 years, seven years after discharge. The relapses to date among the cases that became quiescent are well over one third of the series. The average period during which these patients have been observed is something over fifteen years, the longest twenty-four and the shortest six years.

CONCLUSIONS

This study gives convincing evidence that the methods of diagnosis used in these cases, although they were those practiced universally at the time, are wholly untrustworthy.

We know of no method of making a diagnosis in knee joint tuberculosis except by aspiration, with guinea-pig inoculation, or by exploratory operation with tissue examination and guinea-pig inoculation.

Without a positive means of diagnosis, we are subjecting patients who do not have the disease to long periods of treatment, having our suspicions confirmed by the bone and muscle atrophy that appears as a result of the treatment. Subjecting the joints, especially of growing children, to long periods of immobilization in many instances does permanent damage.

Is it not more scientific, as well as more humane, first to make a positive diagnosis, when this is possible, and in most instances it is, before we institute any method of treatment?

Whether any case of tuberculosis of the knee joint may be definitely cured with mobility, is doubtful. Surely such would be possible only in a case in which the diagnosis was made very early.

We are forced to the conclusion, from this series at least, that the conservative methods here used have failed to accomplish a cure in all but three cases that were fused by nature. The other cured cases, sixteen, were fused by operation.

The elimination of motion by fusing the knee by operation offers the only means we know of curing the disease, and it should be done early in the disease, and may be done as early as the sixth year without any disturbance of the growth of the leg.

ABSTRACT OF DISCUSSION

Dr. Charles F. Painter, Boston: I was somewhat surprised at the character of Dr. Hibbs' results. My general impression was that the prognosis of tuberculosis in the knee joints of children was somewhat better than that. The point that I think should be brought home to us is that the average period over which we may look for results, which we may perhaps class as cures, is longer than we are in the habit of thinking. The tendency to yield to the importunities of parents to get children out of apparatus and away from supports must be resisted, because the length of time that it is necessary to fix an affair of this sort is certainly longer than our good nature often lets us be convinced that it is. What Dr. Hibbs said about the duration of the period of treatment with the probabilities of having at the end of that time a satisfactory quiescence of the disease is the most significant point in his presentation of the subject. Another point that he made on which I think I should be very shy about agreeing with him is the advisability of any surgical intervention in cases of this sort at the period of time that he believes it is perfectly proper to interfere. I think that surgical intervention with tuberculosis in and about a joint, at the age that he speaks of, is not desirable, except, perhaps, in Dr. Hibbs' hands. The outlook for recovery from tuberculosis has to be based to a large extent on the character of the material being dealt with, and I do not believe that we can take material which is distinctly clinic material and which comes from poor surroundings and base our conclusions on it, or draw inferences from it, quite as well as we can from a more mixed material.

Dr. J. W. Sever, Boston: For years we have been treating tuberculosis of the knee in children in a conservative way by means of Thomas' splints and casts, often without an adequate diagnosis, and calling every swelling of a knee in a child "tuberculosis" of the knee. A certain number of cases may be an infectious arthritis, but we have no means of making a diagnosis without a biopsy on the joint. Lately we have been taking out sections that seem pathologic, and in some instances the pathologist reported, "chronic inflammatory." On the other hand, with the history of treatment continuing over long periods of years, with ultimate function or ultimate results good only in those cases which either have been fused surgically or fused themselves after seven or eight or ten years, with a diagnosis of tuberculosis established, why is it not surgically the best thing to do? Give them a stiff knee even at the expense of growth, and subsequent and consequent disability from treatment covering long periods of years. On the other hand, there are a certain number of cases of perfectly evident and frank tuberculosis in which eventually function in the knee resulted. What cases are we going to select to stiffen, and what cases are we going to select to leave alone, in order that these patients may have some useful function which will be better for them in the end? However, we must not lose sight of the fact that limited function with few degrees of motion is always a source of danger. There is always the possibility of these cases eventually becoming active and giving trouble, necessitating operation. It is a difficult question to determine. Are we going to fuse all cases with the possibility of eliminating eventual joint function, or are we going to take a chance on heliotherapy, with a moderate amount of fixation for a number of years, with the chance that we may or may not get eventually good motion in the knee, but always the possibility of later lighting up as they come into adult life and increased strain? I think Dr. Hibbs is right in theory.

Dr. Z. B. Adams, Boston: Years ago I had a chance to observe children with tuberculosis of the knee and I was strongly impressed with the fact that they did not any of them do well and that any that really had tuberculosis of the knee either went on for years and had a knee that produced abscess, and never got well enough to have any motion, or else fused, which takes a long time and does not occur in every case. I felt that if these children could be put under better conditions, such as they are put under in Dr. Hibbs' hospital, they would perhaps do better. I heartily agree with Dr. Hibbs that a great many of these children are much better off if a fusion is produced by surgical procedure. In these younger children, there is a question with some of them as to whether the tuberculosis is a primary synovial tuberculosis or a tuberculosis that involves the bone. Possibly some of these children that have a simple synovial tuberculosis can be gotten early and treated conservatively by splinting and heliotherapy. Some of them may get well with motion in the knee, but in a large majority of these cases in children, fusion is indicated as soon as the diagnosis of tuberculosis is made. A diagnosis based on the microscopic examination of tissue is not easy to make. Unless we get exactly the right portion of the joint, the pathologist will return a report of chronic inflammatory tissue. Adult cases, every one of them should be fused surgically. I do not believe that there is any such thing as curing an adult case of tuberculosis of the knee. One other point to consider is the growth of the child. If we tie these children up in plaster, at first, perhaps, there is an increase in length, from a stimulation of the epiphysis by the disease; but if we continue that fixation for a number of years, in many cases we get a decided shortening. We also know that if we do a fusion, unless we do it early we are extremely likely to destroy some, if not a good deal, of the epiphysis. That is the reason for doing the operation early: when we can do an erasion, take off the cartilage, the articular surface of the tibia and femur, take out the semilunar cartilages and bring the bones together without disturbing the epiphysis, get a solid fusion and resume use.

ROENTGEN RAY IN TREATMENT OF LOCAL INFLAMMATIONS, CELLULITIS AND CARBUNCLES *

FRED M. HODGES, M.D.
RICHMOND, VA.

Two definite types of carbuncle are recognized:[1] (1) the usual superficial type, which is very vascular, shows multiple skin perforations in the early stage, and after sloughing usually does not show a very deep crater; (2) the deep type, in which the mass appears to be fixed almost as in malignancy. In the latter, skin perforation and sloughing occur later in the disease, usually leaving a deep crater. Pus may burrow around through the tissues for several weeks before coming to the surface. This type occurs most frequently on the back of the neck.

Coyle,[2] Ross,[3] Dunham,[4] Richards[5] and Lewis[6] have reported excellent results from roentgenotherapy of carbuncles. Both Dunham and Richards state that nothing in all roentgenotherapy gives more satisfactory results than the treatment of carbuncles. In Lewis' report of sixteen cases only two carbuncles were operated on. He believes irradiation to be the method of choice in the treatment of practically all carbuncles.

Last year I[7] reported the results of roentgen-ray treatment of nine large carbuncles, three localized areas of infection due to other conditions than carbuncle, and one ischiorectal abscess. In all these, an excellent result was obtained. Since that time I have had seventeen other large carbuncles. Fifteen of this series responded beautifully to irradiation. All of these were seen after the carbuncle was well developed and contained, in several instances, one or more small openings in the skin. All were painful, some extremely so. In a few the infection was already limited when first seen. In the majority, however, the carbuncle had not reached this stage and was increasing not only in size but also in the severity of symptoms. In three patients, the pain was more severe for a few hours following the treatment, but this stage was followed by permanent relief from pain. In the other twelve cases there was almost complete relief from pain following irradiation. After treatment, the formation of a central abscess cavity with free drainage was the rule. In a few instances, drainage occurred through several small openings without a large central necrotic area ever forming. In no large carbuncle have I seen the tissues return to normal without some necrosis and drainage; but several authors, especially Dunham, have reported such cases. In all of these fifteen and the previously reported nine patients, pain was almost entirely controlled, and breaking down was more rapid than in carbuncles treated by other methods.

In two other cases, treatment not only did no good, but appeared to do harm. Both were in men between 50 and 60 years of age, in good general health, with no diabetes, increase in the blood sugar, syphilis, cardiorenal or other chronic disease. These two carbuncles were located high up on the back of the neck and ran such similar courses that only one will be reported in detail:

> A man, aged 54, seen after a carbuncle had been present for about one week, had practically no pain and only a slight elevation of temperature. There was a large elevated, indurated, red area which extended from about 2 inches above the hair line downward for about 4 inches, and about 2 inches to each side of the median line. In the center of this mass there was a very small bright red pimple. Just to one side of this pimple a crisscross incision about 1 inch long had been made. Several treatments were given over this area with no effect at all, as far as I could determine. After four weeks the entire area necrosed and sloughed out. Following this, there was a long drawn out recovery. At no time did he have any pain of consequence before or after irradiation. There were never any marked general symptoms. The hole in the back of the neck was very deep, showing that the infection had extended into the deep tissues.

Of course in these cases no one can know what would have happened if irradiation had not been employed, but it appeared that treatment may have delayed breaking down. The inflamed tissues had practically the same appearance for nearly four weeks. These two patients were seen in an earlier stage of development than any of the others I treated. When a large carbuncle involves the very deep structures, it may be that irradiation should not be given in the early stage before there has been any effort whatever at drainage. This applies particularly to carbuncles on the back of the neck. The tough thick skin in this locality seems to prevent the rapid breaking down, discharge and cure that follows radiotherapy of lesions located elsewhere. In these cases, treatment

helps to control the pain, but the duration of the disease is probably not materially shortened. In the early stage of this type, complete surgical excision is probably the treatment of choice. When the lesion is located elsewhere than on the back of the neck, the duration of the disease is probably shortened from 30 to 50 per cent.

In the complete series of twenty-six large carbuncles there was no mortality and there were only two cases in which marked benefit did not appear to follow irradiation.

Carbuncle probably kills at times by a long drawn out wearing down of the patient's mental and physical condition. In several instances the patients were not seen until after the condition had existed from four to seven weeks. Clinically, these patients were ill, very fretful, and were gradually losing ground. Locally, the carbuncles showed large craters, from the edges of which some serum and very little pus exuded. Irradiation appeared to be particularly valuable in this type of lesion. Within twenty-four hours there was a copious discharge, followed by local and general improvement.

In several cases of moderate sized carbuncles of the forearm, with red lines of lymphangitis extending nearly to the axilla, the pain was relieved and the red lines gone within from eighteen to twenty-four hours following treatment. I have no definite explanation to offer for the early relief of pain and the rapid disappearance of lines of lymphangitis extending some distance from the area treated, except the mechanical relief of tension in the tissues. This is probably brought about in several different ways. The increased discharge gives better drainage with lessened tension in the inflamed areas. When there are several pus pockets, they are under different tensions and some are more painful than others. Coalescence into one large abscess naturally lessens this tension to some extent. This does not, however, explain many cases in which the pain is entirely relieved before there has been but little softening or discharge. The lymphangitis in several cases has also entirely disappeared before the occurrence of either of the foregoing conditions. In some of the smaller carbuncles in which the pain was quickly relieved, the lesion gradually disappeared without any breaking down or discharge. Moderate doses of roentgen rays are supposed to cause a greater activity of the cells treated and to increase the phagocytic powers of the blood.

Maximow,[8] in a study of the changes in inflamed tissue following irradiation, states that the lymphocytes are probably destroyed almost immediately in an explosive manner. He found a marked depression of the usual reaction of the fibroblasts. Instead of almost immediately forming a new layer of connective tissue around the infection or irritation, they did not divide, or started late and usually divided abnormally. There was an intensive edema of the connective tissue. His study of the effect of irradiation on other tissues does not seem to have any bearing on the treatment of carbuncles. The doses used by Maximow were probably larger than any used in the treatment of carbuncles; therefore, in the latter a less depressing effect on the connective tissues would be expected, while on the other hand, stimulation might occur.

In my work, treatment appeared definitely to limit the infection, but no tissue studies were made. Whatever happens in a carbuncle after irradiation, the immediate effect in many instances is probably too quick for the effect of the ray on connective tissue to have anything to do with it. It may be that the rapid destruction of lymphocytes and the action of the ray on other structures may cause the liberation of a substance that has a marked effect on the inflamed tissues and possibly on the infecting organism.

I have treated only two cases of erysipelas. These were seen the first day that the lesions were noticed and before an area of skin more than 6 cm. in diameter was involved. After treatments, the inflammation rapidly subsided. I would not attempt to treat a severe advanced erysipelas, but believe that irradiation will prove to be of definite value in the early cases.

In chronic infections of the parotid gland, roentgen-ray therapy has given good results. A typical case was that of a child, aged 7, who for several months prior to treatment had had a chronic infection of the parotid with acute exacerbations every three to four weeks. The gland would swell up over night and become very painful. This would last for several days, returning to normal size after about a week. In the intervals between the attacks the gland was tender and somewhat painful. After the first irradiation the gland swelled up and was very painful for thirty-six hours. After a few days it was of normal size, with no pain or tenderness, and there has been no trouble for more than six months. Two other cases responded practically in the same manner. In chronic parotid infections I believe that irradiation offers a great deal, since as far as I have been able to learn, surgical treatment is not very satisfactory.

The following technic was used in the majority of cases: 4 mm.; 9 inch spark gap; eight minutes; 9 mm. of aluminum; 9 inches distance. Half this dose was repeated about the fourth day and again several days later if necessary. For the first treatment, the area included at least 1 inch of healthy tissue around the lesion. The later treatments were directed toward the central part of the lesion. A central necrosis is more apt to follow this technic than it is to follow a general application of the ray to the entire involved area. A small incision was made as soon as any part of the lesion showed softening. Larger incisions seem to delay the usual reaction following irradiation. In erysipelas and in some of the carbuncles, unfiltered rays were used with 4 milliamperes; 7 inch spark gap; three and one half minutes, and 10 inches distance.

SUMMARY

1. In the majority of carbuncles the roentgen ray acts almost as a specific, even in very extensive lesions, when the inflammation is limited largely to the skin and subcutaneous tissues. Pain is usually relieved, drainage enhanced, and a more rapid recovery follows.

2. The deep seated types, especially those occurring on the back of the neck, when treated after the carbuncle was well developed, responded almost as well to irradiation. In two early cases of this type on the back of the neck, no benefit appeared to follow irradiation, and probably a delay in breaking down and healing occurred. In these, complete surgical excision is probably the best method of treatment.

3. Chronic infections of the parotid usually respond to this type of therapy.

4. Roentgenotherapy is probably of definite value in the early stages of erysipelas.

them do well and that any that really had tuberculosis of the knee either went on for years and had a knee that produced abscess, and never got well enough to have any motion, or else fused, which takes a long time and does not occur in every case. I felt that if these children could be put under better conditions, such as they are put under in Dr. Hibbs' hospital, they would perhaps do better. I heartily agree with Dr. Hibbs that a great many of these children are much better off if a fusion is produced by surgical procedure. In these younger children, there is a question with some of them as to whether the tuberculosis is a primary synovial tuberculosis or a tuberculosis that involves the bone. Possibly some of these children that have a simple synovial tuberculosis can be gotten early and treated conservatively by splinting and heliotherapy. Some of them may get well with motion in the knee, but in a large majority of these cases in children, fusion is indicated as soon as the diagnosis of tuberculosis is made. A diagnosis based on the microscopic examination of tissue is not easy to make. Unless we get exactly the right portion of the joint, the pathologist will return a report of chronic inflammatory tissue. Adult cases, every one of them should be fused surgically. I do not believe that there is any such thing as curing an adult case of tuberculosis of the knee. One other point to consider is the growth of the child. If we tie these children up in plaster, at first, perhaps, there is an increase in length, from a stimulation of the epiphysis by the disease; but if we continue that fixation for a number of years, in many cases we get a decided shortening. We also know that if we do a fusion, unless we do it early we are extremely likely to destroy some, if not a good deal, of the epiphysis. That is the reason for doing the operation early: when we can do an erasion, take off the cartilage, the articular surface of the tibia and femur, take out the semilunar cartilages and bring the bones together without disturbing the epiphysis, get a solid fusion and resume use.

ROENTGEN RAY IN TREATMENT OF LOCAL INFLAMMATIONS, CELLULITIS AND CARBUNCLES *

FRED M. HODGES, M.D.
RICHMOND, VA.

Two definite types of carbuncle are recognized:[1] (1) the usual superficial type, which is very vascular, shows multiple skin perforations in the early stage, and after sloughing usually does not show a very deep crater; (2) the deep type, in which the mass appears to be fixed almost as in malignancy. In the latter, skin perforation and sloughing occur later in the disease, usually leaving a deep crater. Pus may burrow around through the tissues for several weeks before coming to the surface. This type occurs most frequently on the back of the neck.

Coyle,[2] Ross,[3] Dunham,[4] Richards [5] and Lewis [6] have reported excellent results from roentgenotherapy of carbuncles. Both Dunham and Richards state that nothing in all roentgenotherapy gives more satisfactory results than the treatment of carbuncles. In Lewis' report of sixteen cases only two carbuncles were operated on. He believes irradiation to be the method of choice in the treatment of practically all carbuncles.

Last year I[7] reported the results of roentgen-ray treatment of nine large carbuncles, three localized areas of infection due to other conditions than carbuncle, and one ischiorectal abscess. In all these, an excellent result was obtained. Since that time I have had seventeen other large carbuncles. Fifteen of this series responded beautifully to irradiation. All of these were seen after the carbuncle was well developed and contained, in several instances, one or more small openings in the skin. All were painful, some extremely so. In a few the infection was already limited when first seen. In the majority, however, the carbuncle had not reached this stage and was increasing not only in size but also in the severity of symptoms. In three patients, the pain was more severe for a few hours following the treatment, but this stage was followed by permanent relief from pain. In the other twelve cases there was almost complete relief from pain following irradiation. After treatment, the formation of a central abscess cavity with free drainage was the rule. In a few instances, drainage occurred through several small openings without a large central necrotic area ever forming. In no large carbuncle have I seen the tissues return to normal without some necrosis and drainage; but several authors, especially Dunham, have reported such cases. In all of these fifteen and the previously reported nine patients, pain was almost entirely controlled, and breaking down was more rapid than in carbuncles treated by other methods.

In two other cases, treatment not only did no good, but appeared to do harm. Both were in men between 50 and 60 years of age, in good general health, with no diabetes, increase in the blood sugar, syphilis, cardiorenal or other chronic disease. These two carbuncles were located high up on the back of the neck and ran such similar courses that only one will be reported in detail:

A man, aged 54, seen after a carbuncle had been present for about one week, had practically no pain and only a slight elevation of temperature. There was a large elevated, indurated, red area which extended from about 2 inches above the hair line downward for about 4 inches, and about 2 inches to each side of the median line. In the center of this mass there was a very small bright red pimple. Just to one side of this pimple a crisscross incision about 1 inch long had been made. Several treatments were given over this area with no effect at all, as far as I could determine. After four weeks the entire area necrosed and sloughed out. Following this, there was a long drawn out recovery. At no time did he have any pain of consequence before or after irradiation. There were never any marked general symptoms. The hole in the back of the neck was very deep, showing that the infection had extended into the deep tissues.

Of course in these cases no one can know what would have happened if irradiation had not been employed, but it appeared that treatment may have delayed breaking down. The inflamed tissues had practically the same appearance for nearly four weeks. These two patients were seen in an earlier stage of development than any of the others I treated. When a large carbuncle involves the very deep structures, it may be that irradiation should not be given in the early stage before there has been any effort whatever at drainage. This applies particularly to carbuncles on the back of the neck. The tough thick skin in this locality seems to prevent the rapid breaking down, discharge and cure that follows radiotherapy of lesions located elsewhere. In these cases, treatment

---

helps to control the pain, but the duration of the disease is probably not materially shortened. In the early stage of this type, complete surgical excision is probably the treatment of choice. When the lesion is located elsewhere than on the back of the neck, the duration of the disease is probably shortened from 30 to 50 per cent.

In the complete series of twenty-six large carbuncles there was no mortality and there were only two cases in which marked benefit did not appear to follow irradiation.

Carbuncle probably kills at times by a long drawn out wearing down of the patient's mental and physical condition. In several instances the patients were not seen until after the condition had existed from four to seven weeks. Clinically, these patients were ill, very fretful, and were gradually losing ground. Locally, the carbuncles showed large craters, from the edges of which some serum and very little pus exuded. Irradiation appeared to be particularly valuable in this type of lesion. Within twenty-four hours there was a copious discharge, followed by local and general improvement.

In several cases of moderate sized carbuncles of the forearm, with red lines of lymphangitis extending nearly to the axilla, the pain was relieved and the red lines gone within from eighteen to twenty-four hours following treatment. I have no definite explanation to offer for the early relief of pain and the rapid disappearance of lines of lymphangitis extending some distance from the area treated, except the mechanical relief of tension in the tissues. This is probably brought about in several different ways. The increased discharge gives better drainage with lessened tension in the inflamed areas. When there are several pus pockets, they are under different tensions and some are more painful than others. Coalescence into one large abscess naturally lessens this tension to some extent. This does not, however, explain many cases in which the pain is entirely relieved before there has been but little softening or discharge. The lymphangitis in several cases has also entirely disappeared before the occurrence of either of the foregoing conditions. In some of the smaller carbuncles in which the pain was quickly relieved, the lesion gradually disappeared without any breaking down or discharge. Moderate doses of roentgen rays are supposed to cause a greater activity of the cells treated and to increase the phagocytic powers of the blood.

Maximow,[8] in a study of the changes in inflamed tissue following irradiation, states that the lymphocytes are probably destroyed almost immediately in an explosive manner. He found a marked depression of the usual reaction of the fibroblasts. Instead of almost immediately forming a new layer of connective tissue around the infection or irritation, they did not divide, or started late and usually divided abnormally. There was an intensive edema of the connective tissue. His study of the effect of irradiation on other tissues does not seem to have any bearing on the treatment of carbuncles. The doses used by Maximow were probably larger than any used in the treatment of carbuncles; therefore, in the latter a less depressing effect on the connective tissues would be expected, while on the other hand, stimulation might occur.

In my work, treatment appeared definitely to limit the infection, but no tissue studies were made. Whatever happens in a carbuncle after irradiation, the immediate effect in many instances is probably too quick for the effect of the ray on connective tissue to have anything to do with it. It may be that the rapid destruction of lymphocytes and the action of the ray on other structures may cause the liberation of a substance that has a marked effect on the inflamed tissues and possibly on the infecting organism.

I have treated only two cases of erysipelas. These were seen the first day that the lesions were noticed and before an area of skin more than 6 cm. in diameter was involved. After treatments, the inflammation rapidly subsided. I would not attempt to treat a severe advanced erysipelas, but believe that irradiation will prove to be of definite value in the early cases

In chronic infections of the parotid gland, roentgen-ray therapy has given good results. A typical case was that of a child, aged 7, who for several months prior to treatment had had a chronic infection of the parotid with acute exacerbations every three to four weeks. The gland would swell up over night and become very painful. This would last for several days, returning to normal size after about a week. In the intervals between the attacks the gland was tender and somewhat painful. After the first irradiation the gland swelled up and was very painful for thirty-six hours. After a few days it was of normal size, with no pain or tenderness, and there has been no trouble for more than six months. Two other cases responded practically in the same manner. In chronic parotid infections I believe that irradiation offers a great deal, since as far as I have been able to learn, surgical treatment is not very satisfactory.

The following technic was used in the majority of cases: 4 mm.; 9 inch spark gap; eight minutes; 9 mm. of aluminum; 9 inches distance. Half this dose was repeated about the fourth day and again several days later if necessary. For the first treatment, the area included at least 1 inch of healthy tissue around the lesion. The later treatments were directed toward the central part of the lesion. A central necrosis is more apt to follow this technic than it is to follow a general application of the ray to the entire involved area. A small incision was made as soon as any part of the lesion showed softening. Larger incisions seem to delay the usual reaction following irradiation. In erysipelas and in some of the carbuncles, unfiltered rays were used with 4 milliamperes; 7 inch spark gap; three and one half minutes, and 10 inches distance.

SUMMARY

1. In the majority of carbuncles the roentgen ray acts almost as a specific, even in very extensive lesions, when the inflammation is limited largely to the skin and subcutaneous tissues. Pain is usually relieved, drainage enhanced, and a more rapid recovery follows.

2. The deep seated types, especially those occurring on the back of the neck, when treated after the carbuncle was well developed, responded almost as well to irradiation. In two early cases of this type on the back of the neck, no benefit appeared to follow irradiation, and probably a delay in breaking down and healing occurred. In these, complete surgical excision is probably the best method of treatment.

3. Chronic infections of the parotid usually respond to this type of therapy.

4. Roentgenotherapy is probably of definite value in the early stages of erysipelas.

ABSTRACT OF DISCUSSION

Dr. Ross Golden, New York: Our experience in the treatment of local nontuberculous infections includes twenty-five cases of carbuncle, sixteen of them on the back of the neck, approximately the same number of cases of furunculosis, and a few cases of cellulitis. Of the twenty-five carbuncles, the records of nineteen were available for study. The average time required for complete healing, that is for epithelization to become complete or practically complete, was forty days. The longest case required eighty days and the shortest eight days. The pain in these cases was usually not relieved after treatment for from twenty-four to forty-eight hours. Sedatives were usually required the first and in some instances the second and third nights. The fever, when it was present, lasted from two to four days. Extension after treatment occurred in three cases. Two pockets localized separately from the main sinus in one case and they had to be opened. Two of the patients were treated following incision. In one instance three incisions had been made, but the extension of the disease was not arrested until a roentgen-ray treatment had been given. The technic used is as follows: 9 inch gap; 3 mm. of aluminum filter; distance 10 or 16 inches, according to the size of the lesion. The amount of rays applied is from two thirds to three fourths of the so-called suberythema dose. To compare this treatment with the usual surgical methods, I analyzed about thirty records. Eleven of these lesions were on the neck, were treated by excision or incision, and had a reasonably complete follow-up. The average duration of postoperative treatment was forty-five days, the longest being seventy-eight and the shortest seventeen days. Two of the thirty surgically treated patients (diabetic patients) died. As a special effort was made to follow the cases treated with roentgen rays, I am inclined to think that the difference in average time of five days in favor of the radiation method is really too small. The records indicate that the time required for the healing of carbuncles varies directly with the size of the lesion, no matter what method of treatment is used. We feel that the roentgen ray has a very definite place in the treatment of carbuncles because (1) it requires no anesthetic, (2) there is much less scarring, (3) the slough separates earlier, (4) no skin graft is necessary, and (5) the healing seems accelerated a little. We apparently have not had the striking relief of pain obtained by Dr. Hodges in his cases. Our results with furunculosis, especially the recurrent cases, have been excellent. However, in two instances in which the process was located in the axilla, the roentgen-ray treatment seemed to be of little, if any, benefit.

Dr. I. S. Trostler, Chicago: I do not know of a condition wherein the results are as satisfactory, if we get our cases early, as in carbuncle. I have treated twenty-one cases of carbuncle. The technic that I used is considerably different from what Dr. Hodges or the other discussants have mentioned, and I rather think that my early relief from pain is a good deal due to the technic. Each case is a law for itself. I give approximately 30 milliampere minutes at 135 kilovolt peak, 8 inches anode skin distance, with 5 mm. of leather and 3 mm. of aluminum filter, and I give but one dose. I have had a few cases (three or four) of diffuse phlegmon. The technic was about the same as that just given, but I have not noticed any marked relief, except possibly from the pain. In furunculosis, particularly in the axilla, I have had six or seven cases with very satisfactory results. I use less filtration there and a little less milliampere minute dosage.

Dr. A. L. Gray, Richmond, Va.: My experience in the treatment of carbuncles is not large, but it has been without exception satisfactory. Since we know that roentgen rays are not directly bactericidal, we advance all manner of theories as to the cause of results in bacterial conditions. Until we do know, it is nothing but theory after all that we can advance, and we have to conclude what the best method is from our clinical experience. I am using a single dose of 9 inch spark gap voltage, 5 milliamperes, 3 mm. of aluminum filler, for about eight minutes at a 10 inch target skin distance. I believe that Dr. Hodges' results on the back of the neck would probably be better if he used a little heavier and little higher voltage dosage.

Dr. Dudley Mackey, Bloomfield, N. J.: I have treated eighty-four cases of carbuncle. I have had good results and a technic similar to Dr. Gray's except for using unfiltered ray. In dealing with the insane it is much more difficult to elicit symptoms; yet in several cases the pain was relieved the first night; in a number of cases from twenty-four to forty-eight hours elapsed before any definite results were obtained. Three cases of multiple sty of the eye were treated. In one case the patient had multiple sties of both eyes, recurrent for about one year, which later came in with swelling of the left cheek. One irradiation was given; the pain was relieved in less than ten hours, and no further treatment was given. After a year there was no return of sties or symptoms. This patient was referred to an oculist and treated by two other physicians before being irradiated, with no results. In four cases of herpes zoster, the pain of three of these cases was relieved within twenty-four hours after treatment. Dr. Hodges spoke of treating erysipelas. We have had in the Isolation Hospital at Essex County, in the last year, sixty-four cases under observation. We had two cases in the insane. Eleven of these cases were treated, while others were observed for comparison. The data are not absolutely accurate, as it would be impossible to select identical cases for control of this type. One patient had an erysipelas involving the face, eyelids, lobes of the ears, and the back to the waist line. In twenty-four hours after the first treatment, the pain was decreased with decided general improvement. This patient was normal mentally. Other cases treated showed decided increase in temperature the first twenty-four hours. After the twenty-four hour period there was a decided decrease in pain and drop in temperature. With the exception of one case, the temperature dropped to normal in thirty-six hours and remained normal until discharge. In observing the patients treated for erysipelas with the roentgen ray, pain was relieved. The time of disease was shortened as compared with cases that were not treated by this method. The data are not sufficient to afford a basis for any definite conclusions.

Dr. Guy R. Harrison, Richmond, Va.: I should like to stress one point made by Dr. Hodges and issue a warning. Speaking as one accustomed to doing surgery about the mouth, any satisfactory method, as far as I know, of handling certain chronic low grade infections of the parotid is not known. One of the parotid cases in which the history was given was a case of mine which Dr. Hodges was kind enough to treat for me, and the method certainly offers a great deal. The warning is this: One should select and treat cases of the parotid with great care. If not, there will probably be the complication of salivary fistula.

Dr. Fred M. Hodges, Richmond, Va.: In addition to the early relief of pain mentioned by Dr. Trostler, one of the most satisfactory things that we have had to deal with in roentgen-ray therapy is the late carbuncle which has already had surgical treatment, in which there is a gradual extension of the outer limits of the infection, with a serous discharge from the edges of the crater, but with very little pus discharge. We have had several carbuncles of this type, the lesion having been present for two months or more. Frequently within twenty-four hours after one treatment there is a heavy discharge of pus and the patient is in a better clinical condition. From this point on there is an uneventful recovery. We are glad Dr. Harrison could discuss chronic parotitis, since we believe that every one of these cases should be seen by an oral surgeon or some one perfectly familiar with this type of lesion, before irradiation is considered. We understand that it is very difficult in many cases to get a good result surgically and that occasionally branches of the seventh nerve are injured in attempting to remove a chronically infected parotid. As to technic, Dr. Richards of Toronto uses an unfiltered ray and seems to get better results than any one else. We have been trying this recently and believe that in the superficial carbuncles an unfiltered ray gives quicker relief from pain. In early erysipelas when only a small area of skin is involved, we believe that the roentgen ray offers a good deal, but would not attempt to treat an advanced serious erysipelas, with a large area of the body involved, a high temperature and a general infection.

OCULAR MUSCLE BALANCE FOLLOWING PROLONGED MONOCULAR OCCLUSION *

C. S. O'BRIEN, M.D.
INDIANAPOLIS

The use of prolonged monocular occlusion as a means of uncovering and diagnosing latent ocular muscle imbalances, as devised and employed by Dr. F. W. Marlow of Syracuse, N. Y., is undoubtedly, to my mind, one of the most useful and satisfactory tests added to the armamentarium of the ophthalmologist in years.

The various methods of testing for muscle imbalance and the many differences of opinion among ophthalmologists as to the treatment give proof that we should welcome any method which we think will add to our accuracy and which will allow us to make more comfortable many patients with asthenopia who have hitherto been unrelieved in our hands.

This test is comparatively new to most of us. It was devised by Dr. Marlow and employed by him for several years, although just recently has it been brought before the medical profession at large.

Orthophoria or muscle balance with a minimum of nervous impulse is a condition found about as rarely as emmetropia. However, a great percentage of the imbalances are low errors and are overcome without symptoms on the part of the person possessing them. It is only in cases presenting some other type of pathologic change, which affects the ocular muscles or their innervation, or in those in which the errors are great enough to necessitate a constant, marked spasm of the muscles in order to maintain binocular single vision, that we have need for employing this test.

OBJECT OF THE TEST

By the use of prolonged monocular occlusion we break up the necessity of and the desire for binocular single vision and consequently allow each eye to seek its own relative anatomic position of rest—this may be one of parallelism or not. It is unnecessary for the fusion center to send forth impulses to bring the two eyes into perfect alinement, there being no need for parallelism since we have only monocular vision. Thus, we break up the need for action on the part of the fusion center and bring out any latent imbalance that has not been manifest so long as the two eyes were in action at the same time.

Provided vision is good in either eye and the fusion sense is developed, there is always the desire for binocular single vision; and if there is any deviation from this we find the usual trend of symptoms ensuing; namely, blurred or double vision, dizziness, headaches, vertigo, even difficult locomotion and vomiting. If single vision is maintained with difficulty by the extra expenditure of nerve force and chronic cramp of one or more of the extra-ocular muscles, then there are presented symptoms of a muscular asthenopia. This seems to be more or less analogous to the constant cramp of the ciliary muscle seen in hyperopia and hyperopic astigmatism, in which there is a constant overexpenditure of nerve force necessary to keep the ciliary muscle contracted, in order that the individual may see distinctly even for distance.

Now in the case of the ciliary muscle—to arrive at what most of us think is the total error of refraction—we place the muscle temporarily at rest with a cycloplegic. Why not put the extra-ocular muscles, i. e., those contractions which are necessary to the maintenance of binocular single vision, at rest by closing one eye and consequently stopping all desire for binocular single vision and, in this manner, allowing each eye to seek its own relative anatomic position of rest? This must be the result of occlusion of one eye; if there is a latent deviation from parallelism, then this should and evidently does become manifest. That this does take place, usually beginning almost at once following occlusion, will be seen from the results of the tests for muscle imbalance.

INDICATIONS FOR USE OF THE TEST

A goodly number of persons with asthenopia fail to obtain relief when tested by capable refractionists, and many times we have been at a loss to understand just why a very careful refraction under a cycloplegic, accompanied by our usual muscle tests, has failed to bring the desired results. It is in just this class of cases that we get the most gratifying results from prolonged monocular occlusion. Oftentimes after a few hours occlusion we will note great relief and marked amelioration in the symptoms presented by the patient, and if this occurs we feel that we are on the right track.

It is neither necessary nor advisable to use this test as a routine measure in all cases of asthenopia presenting themselves to us. Experience teaches us, however, that it is wise to use prolonged monocular occlusion in those cases coming under the following types:

1. Those patients who have been wearing glasses which properly correct their refractive error, and yet continue to suffer from symptoms of asthenopia, headaches, etc. Of course, this may be accommodative, but we should certainly rule out the extra-ocular muscles.
2. Patients with transitory or prolonged blurred binocular vision, although each eye sees clearly when functioning alone.
3. Persons who have as much or more discomfort in distant vision as in accommodation. Accommodation does not seem to have a great bearing on the aggravation of symptoms produced by muscular imbalances, except in cases of convergence insufficiency.
4. Those who suffer from occipital headaches and pains, which extend into the back of the neck and shoulders.
5. Patients who have pronounced symptoms of ocular fatigue and asthenopia during or following the observation of motion pictures. In some of these cases the headache will follow the morning after having been to the theater.
6. Patients with very little or no refractive error, but who have pronounced symptoms. Many of these are in the so-called neurasthenic type of individual.
7. Those with headaches following a day in the stores and shops—the so-called "bargain counter headache."
8. Persons who are disturbed and have headaches, vertigo, etc., when riding on trains or other rapidly moving vehicles.

There is no doubt that different states of health determine the intensity of symptoms from muscle imbalances. Large errors in persons enjoying good health may be overcome and cause no symptoms. Small errors, which have been carried comfortably for years, may cause a great amount of trouble should the patient have an upset or contract some debilitating disease. Also the amount of use of the eyes determines to a certain extent the degree of discomfort experienced.

The menopause, nasal pressure, and sinus disease (especially of the ethmoids and sphenoids), as well as general asthenia and debility, are a few of the more frequent conditions causing discomfort from an imbal-

---

* Read before the Section on Ophthalmology at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

ance, which formerly has been carried by the patient without the manifestation of symptoms. Also, neurasthenic patients bear muscle errors badly.

METHOD EMPLOYED

Previous to deciding whether it is necessary to use prolonged monocular occlusion I take the muscle balance for distance and near in the usual way; i. e., with the Maddox rod cover test, checked by the parallax. This is done at the first visit, with the patient's manifest correction before the eyes. Again, the balance is taken at the next visit, with the full correction and the eyes under a cycloplegic. At the postcycloplegic examination, the balance is again taken with the correction that we intend to prescribe. By this time one has a good working idea of the state of the manifest ocular balance and usually can decide whether it will be necessary to use prolonged occlusion or not. If it is decided to use this method, I explain it fully to the patient, and, with his consent, I first use the short period of occlusion. This period is from two to three hours, and is usually carried out in the office. The patient wears his full correction in front of one eye and a patch over the other. I have no objection to the patients' leaving the office, but often they prefer to remain there on account of their appearance. If I desire to prescribe following this test I may do so; if I am not satisfied, I may ask the patient to allow me to use the longer period of occlusion.

Absolute monocular occlusion during the whole period of time consumed by the test is necessary, if one may rely on the results, and, although Dr. Marlow has adopted a method of making opaque one of the lenses which the patient wears, I feel that a black eye patch, a bandage or some other method of total occlusion is the better procedure. By this method one is sure that the patient does not see with the occluded eye; while if he wears only an opaque lens over one eye, there is nothing to prevent his looking above, below or to the side of the lens. If he does this it is just as necessary that he maintain binocular single vision as if his eyes were directed straight ahead; consequently he will get the excessive nerve impulse and overcontraction of the muscles and, if this should be the case, the whole value of the test is nullified. Also, if wearing only the lenses, one being opaque, there is an excellent opportunity to break up the test by failure to get the glasses in place before opening the eyes following sleep, and while washing the face. I make the patient wear the patch at all times, day and night, and if it becomes too uncomfortable it may be changed, but I do not allow the patient to do this.

The period of time over which the patient has worn the patch having elapsed, he is seated in a darkened room at a distance of 6 meters from the muscle light, and asked to close both eyes and keep them closed until notified to open them, the patch is removed, and the trial frame carrying the full correction is placed in position. Care must be taken to center properly each lens, for in lenses of moderate or high strength an artificial phoria may be created by the prismatic action of decentered lenses; especially is this true in cases of anisometropia and antimetropia. With the red Maddox rod before the better seeing eye, or over either if there is no appreciable difference in vision, and a small cardboard held in front of this, the patient is asked to open both eyes. He is directed to look at the light, then the cardboard is shifted to cover the other eye and he is told to note the red line. As soon as this is fixed in his mind, the card is shifted back in front of the originally covered eye. The patient is instructed that the card will now be removed momentarily, that he will see both the light and the line at the same time, and that you wish him to note the relative position of the two; i. e., whether the line is above the light or below it when testing for vertical imbalances, and to the right or left when testing for lateral errors. By using the Maddox rod cover test we expose the two eyes simultaneously for only one or two seconds, and our test is more accurate. I have found that by covering and uncovering the eye in front of which we have placed the Maddox rod it seems that the patient locates the light and line more readily, and hence the response is quicker. Prisms that cause the line to run through the light may now be placed before the eyes, thus measuring the error. A final check made with the parallax completes the test; i. e., in the primary position. This should be followed by repeating the test in the cardinal directions of the gaze, although I must admit that I do not always do this.

Ordinarily very soon (just a few seconds) after both eyes are opened, following completion of the test, binocular single vision is established, the manifest error becomes latent again, and we cannot make it manifest without reapplying the patch.

DURATION OF OCCLUSION

The period of time over which one should prolong the occlusion to get a working result is questionable and is undoubtedly different in each individual case. Dr. Marlow has established the fact that after one week's occlusion the results are found to be quite satisfactory in practically all cases. It has seemed to me that if this period of time can be shortened materially and yet much of the value of the test preserved, it will become a great deal more useful as a more or less routine procedure. Often there is great difficulty in overcoming the objections of patients to wearing the patch over a prolonged period of time. Some object on account of the appearance (especially women), some on account of the inconvenience, some from lack of understanding, and others on account of the itching that accompanies the patch or pad. These are probably some of the reasons for Dr. Marlow's substitution of the opaque lens. If we could get an attachment for spectacles, which would give us occlusion around the edges of the lenses, thus shutting off the uncovered portion between the lenses and the face, that would be more or less ideal.

I have kept the patch on for many different periods of time, varying from one hour's occlusion up to that of a week. I find in a great many cases that, following an occlusion of from two to three hours, I have been able to give a correction which has relieved all symptoms. With short periods of occlusion it seems to me that the vertical errors came out more readily than the lateral ones; also it has appeared that, as a usual thing, patients get more relief from the correction of these vertical errors than they do from the correction of the lateral ones, unless they are very marked. In fact, the correction of a vertical error often gives complete relief when a moderate lateral imbalance remains uncorrected.

I have found some cases in which the correction prescribed following the shorter period of occlusion did not give relief, but when the longer period was used I was able to prescribe glasses that did give complete comfort.

There is no hard and fast rule that one may recommend as to the time over which occlusion should be prolonged. It is better to use the longer periods of time, but there is so much objection to this on the part of a great many patients that often I am forced either to shorten the period or abandon the test altogether. For this reason I have tried to shorten the period of time consumed and have used the two to three hour method in the office in cases in which I was not allowed to use the longer period of occlusion. I have seen patients, examined in this manner, show a surprising amount of hyperphoria, exophoria or both following removal of the patch.

TREATMENT

In my limited experience it seems to me that the vertical errors are more potent in the production of discomfort than the lateral ones, and I have found very often that the partial or full correction of a vertical imbalance will have a beneficial effect in assisting Nature to overcome, without discomfort, any accompanying lateral imbalance; at any rate, there has been a lessening of the manifest lateral error, and the symptoms of muscular asthenopia have disappeared. Especially is this true if, after having corrected the vertical imbalance, I prescribe exercises for the lateral muscles. There is a doubt in my mind as to how much effect these exercises have on the lateral muscles; but they undoubtedly are of assistance in giving the patient something to do and to keep his mind occupied while he is becoming accustomed to new lenses.

In practically all cases of vertical imbalance, I make use of a prism grinding in one or both lenses. As to the amount of the hyperphoria, found following monocular occlusion, to be corrected, there is no specific amount to recommend. Generally I correct about two thirds of the error in the first prescription, but occasionally it is better to give only one half; then, again, it will be found necessary to give the full correction. As a usual rule, if the shorter period of occlusion is the one on which the prescription is to be based, I am inclined to give a full correction, feeling almost sure that the short period has failed to bring out the total latent error. In cases in which the longer period of occlusion has been used, it is better to make the first prism correction from one half to two thirds of the total error uncovered. It has been my experience that the correction of quite small latent errors will often give a patient great relief.

I often try out the prescription that I have decided is best by placing it (lenses and prisms) in a trial frame and allowing this to be worn for an hour or so. The prism may be varied during this time, and thus I may find the one that gives the patient most comfort; it is not by any means the rule that the full correction of a muscle imbalance is the most comfortable to wear. However, in some cases, prisms cause discomfort at first, but the continual wearing of them gives complete relief. I see patients who are wearing an accurate correction for their refractive error and in whom prolonged occlusion shows a latent imbalance. In order to determine the exact amount of prism to prescribe, I often place prisms from the trial case over one or both lenses and fasten them with small pieces of adhesive tape. Each prism may be worn any length of time desired and may be changed at will. In this way, I arrive at the correction that I think is best.

Occasionally, prolonged occlusion will uncover a very high error, very little if any of which has been manifest to the ordinary methods of examination. In some of these it is possible to get a better result from operative intervention, especially in the exophorias, than from the constant wearing of prisms. One can approximate parallelism by operation and use low degree prisms following this in order to get a more accurate correction.

Most of the cases of imbalance fall into the class which may be treated successfully by the constant wearing of prisms, and it is in these that we seem to get our most gratifying results.

SUMMARY

Prolonged monocular occlusion is a great aid in uncovering latent ocular imbalances. It makes it possible for us to give comfort to many patients who have suffered from a persistent asthenopia in spite of repeated careful refractions. In many cases it brings out a surprisingly high degree of imbalance, in which by the ordinary methods of testing we have been able to find only an orthophoria (functional).

Occlusion must be absolutely continuous over the whole period of time selected. I realize that usually the shorter periods do not bring out all the latent imbalance; but the amount they do bring out often gives us a basis on which to prescribe in such a manner that our patient is given complete relief from many distressing symptoms. Many patients will object strenuously to the longer periods of occlusion, and yet they will allow us to use the shorter ones. If we are to make daily use in our offices of this very valuable test, I feel sure that the shorter periods of time must be selected in the larger percentage of cases.

Another important point is in the actual testing of the muscle balance following occlusion. The correcting lenses must be properly centered in front of the patient's eyes before placing the Maddox rod. Care taken here will preclude the possibility of an artificially created phoria.

This test gives a basis on which to treat cases of extra-ocular muscle imbalance more or less similar to the basis for the treatment of refractive errors following cycloplegia. With the cycloplegic, we place the ciliary muscle at rest; with the monocular occlusion, we allow the eyes to seek their relative anatomic position of rest. It stands to reason that this position would be the one of comfort, and, if there be an imbalance, this would be the position to allow the eyes to approximate by the use of prisms, operations or what not if relief is to be obtained. If there is an imbalance, one certainly could not hope to find this position while both eyes were functioning simultaneously, for the desire for binocular single vision, provided the vision is good and the fusion center developed, is too great to allow the eyes to attain the position of rest. It is the prolonged monocular occlusion that allows the eyes gradually to seek the position of rest.

This test is not a routine one and is not necessary in all cases; but in selected patients it has proved to be an only means of relief and can be very highly recommended.

503 Medical Arts Building.

ABSTRACT OF DISCUSSION

Dr. F. W. Marlow, Syracuse, N. Y.: For some time after I began to use this method I was in doubt as to whether my failure to discover faults in the muscle balance was due to my lack of sufficient precision in the use of the ordinary tests, and whether other men of more skill and experience than myself might not be able to solve these problems by less clumsy methods than the "prolonged occlusion test." But

I found that other men had essentially the same experience as I had. In a large majority of these cases failure is due to the inadequacy of the ordinary tests to reveal the true state of the muscle balance. The test is not a routine one. It is called for only in cases of failure to relieve symptoms by the correction of demonstrable errors. I doubt the value of such short periods of occlusion as Dr. O'Brien describes, and I fear that if these short tests do not bring the "prolonged occlusion test" into disrepute, they will at any rate greatly lower its value. The difficulty of getting patients to adopt and carry out this test satisfactorily can easily be exaggerated. The essential thing is that they shall be made to understand the nature of it. It is my impression that the aversion to the prescription of lateral prisms, which seems to be prevalent, is ill founded. Some of my most striking cases have been those in which the prescription of such prisms was the means of solving the problem. The experience I have had with this test has entirely destroyed my confidence in the findings of the ordinary short tests, except in one respect. When exophoria is shown either by the screen and parallax, diplopia or rod test, exophoria is present, but its degree and the presence or absence of hyperphoria are still unknown. When the ordinary tests show orthophoria, the true muscle balance may be orthophoria or any form of heterophoria. Thus, of 154 cases of preocclusion orthophoria, only thirteen remained orthophoric at the end of the occlusion period. Finally, it seems reasonable to suggest that the origin of eye symptoms should be looked for first of all in the visual apparatus itself, and therefore it would seem advisible, before turning the case over to the rhinologist, the neurologist, the psychanalyst or the internist, and before the patient is tempted to resort to any of the prevailing cults, that an adequate prolonged occlusion test should be carried out.

Dr. S. J. Beach, Portland, Maine: Some criticisms of the prolonged occlusion test that I have seen give too much consideration to minor objections that do not hinder its practical usefulness. One is that the analogy to cycloplegia is inexact presumably because refraction with a cycloplegic becomes dynamic the moment the occluded eye is uncovered and binocular vision is resumed. It also might be questioned whether there actually exists "a stable condition of rest." Certainly the familiar variation from morning to night or after infectious diseases, in the deviation of an eye which is amblyopic and without possibility of fusion power, makes this doubtful. In spite of these theoretical considerations, I have found prolonged occlusion of practical value in some obscure cases. One use, the reverse of that pointed out in the paper, is to indicate the removal of prisms that are not needed. I have just seen a patient for whose relief several colleagues had prescribed vertical prisms of increasing strength until last fall she was wearing with constant distress 5 degrees split between the two lenses. This was apparently justified, as at that time my tests indicated a vertical imbalance varying from 4.5 to 8 degrees. Under prolonged occlusion, however, the error dropped to 2 or 2.5 degrees, an amount which many subjects carry without discomfort. This patient reports that for distance she has since been able to discard prisms much of the time and never requires more than 1.5 degrees for perfect comfort. I find that occlusion is liable in neurotic patients to exaggerate the previous complaint beyond endurance. We do not wish our patients so annoyed without assurance of benefit. Therefore, in determining more exact indications for this test, Dr. O'Brien has made a valuable contribution.

Dr. Walter B. Lancaster, Boston: There is another diagnostic point which has not been emphasized, and that is the value of the prolonged cover in deciding whether the defect in the balance of the two eyes is the cause of the symptoms, or not. By covering one eye, we eliminate the necessity of working the two eyes together. There is no longer any need of fusion when one eye is covered; hence there is no strain from producing fusion, because there is no necessity of overcoming the heterophoria. At first thought one might conclude that this would promptly relieve the symptoms due to that necessity; and, in fact, it does relieve them in many cases, but not in all. As Dr. Beach has intimated, the simple fact of wearing a cover in itself produces a good many symptoms in the neurotic cases; so that a negative result, that is, the lack of improvement on wearing a cover, is not by any means conclusive evidence that heterophoria is not causing symptoms. On the other hand, there are many cases in which one does get great relief; and the patient is then easily convinced that the working of the two eyes together is really at the bottom of the trouble. I have used the cover for the diagnosis of heterophoria more than twenty-five years; I do not remember where I got the idea. It does not seem to me to be quite as important as a diagnostic means as its advocates have asserted. In using the prolonged cover test, we must not conceive of the aim of the test as a device to secure complete relaxation, and so determine the position of rest analogous to the condition of relaxed accommodation under cycloplegia. The image falling on the retina stimulates the act of fixation, and the stimulus goes to both eyes. If we wanted to get the position of the eyes when relaxed or at rest, we could take the position under ether, or in sleep. All we want is to get the position of the eyes taken when stimulated by the normal reflex act. As Dr. Beach has said, it is not a condition of rest—it is a condition of binocular activity.

Dr. William Zentmayer, Philadelphia: Dr. Fink, a student in the university graduate school, took this subject for his thesis, and I would like to repeat some of his conclusions as I recall them. He found, as have Dr. Marlow and Dr. O'Brien, that the occlusion test certainly showed latent error in the majority of cases, and that this was probably the cause of the symptoms manifested. However, he had almost as large a group, I think, in a second class of cases that came to the hospital simply for the removal of a foreign body or a slight conjunctivitis. He used the occlusion test on this class, and found similar varying degrees of imbalance in those cases having no asthenopic symptoms such as he found in the group who had symptoms. This brings up the question as to whether these latent errors are really to be looked on as the cause of the symptoms in the vast majority of cases.

Dr. C. S. O'Brien, Indianapolis: As to the length of occlusion, I am frank to admit that the longer period of occlusion is the one that brings out a complete state of rest. However, the shorter the occlusion, the better the patient likes it. We have found in a number of cases that occlusion for two or three hours has given a satisfactory result to the patient, and it has also satisfied me. As to the amount of vertical phoria which the patient can carry, it has been my experience that a patient cannot carry these errors when they are of such high degree as we sometimes think. In other words, we find we get quite as good results in the smaller grades of error. The patients do not complain. If the patients complain too much, we have them return to the office and change it to the other eye. There is liable to be itching, and in hot weather perspiration and it makes them feel very uncomfortable. As to Dr. Zentmayer's remarks citing Dr. Fink's paper regarding the foreign body cases which showed almost the same percentage of vertical error, one of the points I brought out was that delicate persons were unable to carry an ordinary or a small amount of phoria comfortably. Perhaps these cases of foreign body came to the hospital from the Baldwin Locomotive Works and could carry more error comfortably than persons who came with an asthenopic condition.

Biochemistry.—In 1919 a chair of medical chemistry was founded at Edinburgh, and in the same year a chair of chemical physiology was endowed at Glasgow. . . . At Cambridge the Sir William Dunn Trustees have endowed the chair of biochemistry held by Dr. Gowland Hopkins, have built and equipped a fine school of biochemistry, and have given further endowment for upkeep and research expenses. At Oxford the Rockefeller Foundation of New York has given a new building for biochemistry which is already planned and begun. A new biochemical department has been provided also at University College Hospital, London, as a result of the munificence of the same foundation.—Report of the Medical Research Council for the Year 1923-1924.

IMMEDIATE METABOLIC DISTURBANCES FOLLOWING DEEP ROENTGEN-RAY THERAPY

II. PREVENTION AND TREATMENT OF UNTOWARD REACTIONS *

HOWARD P. DOUB, M.D.
ADOLPH BOLLIGER, PH.D.
AND
F. W. HARTMAN, M.D.
DETROIT

Rapidly developing tissue changes after exposure to intense irradiation are manifested by systemic reactions, such as nausea, salivation, vomiting, malaise and sometimes by chills and fever. These usually begin within the first hour and last from several hours to several days, being accompanied by complete loss of appetite. It is only these early effects that are to be considered in this communication. Although not dangerous to life, the acute illness is so disagreeable that the course of treatment may be seriously interfered with. Its occurrence and its relation to the areas treated are illustrated in Table 1.

Although the treatment of this reaction cannot be satisfactorily worked out until its etiology is demonstrated, it does justify therapeutic tests with various agents when these are of such nature that the response to them gives indirect evidence as to the factors concerned in etiology. In a preliminary communication [1] it was found that the compensatory acidosis following the initial alkalosis usually protected the patient against severe reactions on the second day. Further, it was demonstrated in a small series of patients and dogs that the immediate illness might be counteracted by substances which in physical and biologic systems protect the cell by decreasing its permeability, namely, ether anesthesia, morphin and calcium salts.

PRESENT STATUS OF THERAPY

1. *Symptomatic Treatment.*—Schmitz [2] emphasizes the importance of treating various symptoms as they arise. He suggests the elimination of toxic proteins through diuresis and catharsis. Acidosis is treated with sodium bicarbonate, physiologic sodium chlorid solution and glucose solution. Alkalosis is treated with mild acids, as orange and lemon juice. Nausea and vomiting are counteracted by large doses of bismuth subnitrate.

2. *Elimination of Noxious Gases.*—Pfahler,[3] Scholz,[4] Wintz [5] and Mallet and Coliez [6] all feel that ozone, or ozone in combination with other noxious gases produced by high tension currents, is responsible for the early reaction. Consequently, they eliminate these gases by the use of masks, ventilation of the room, and the placing of the roentgen-ray tube in a separate closed compartment. These measures have been helpful but have not eliminated the reaction, as is shown in our series of cases. Further, Pfahler's observations on patients and guinea-pigs receiving the gases but not the roentgen ray are in accordance with the more generally accepted view now that these gases are at most only one factor in the etiology.

3. *Alkali Therapy.*—Following the work of Lang,[7] in 1916, suggesting acidosis as the cause of the constitutional symptoms, alkali therapy was given a trial by Pfahler, Schmitz and others. Sodium bicarbonate was used both orally and intravenously. The results of this treatment were always questionable or definitely nonbeneficial. Our preliminary work,[1] showing that acidosis is only a compensatory reaction noted in the latter part of the first twenty-four hours when moderate dosage is used, makes alkali therapy illogical. It would, indeed, bear out the contention of patients that sodium bicarbonate brought on the reaction in many instances.

4. *Acid Therapy.*—The work of Hussey,[8] demonstrating an alkalosis following an intense irradiation, brought about the use of various agents to restore the normal acid base equilibrium, the most commonly used perhaps being hydrochloric acid given by mouth. As mentioned above, Schmitz recommended organic acids in the way of orange and lemon juice.

5. *Sodium Chlorid.*—Schlagintweit and Sielmann [9] demonstrated that the sodium chlorid content of the blood serum after roentgen-ray treatment was low, and on this basis treated irradiation sickness with a 5 per cent. solution of sodium chlorid intravenously. They found that sodium chlorid was ineffective as a prophylactic measure and that calcium chlorid was ineffective both in prophylaxis and in treatment. Cori and Pucher [10] emphasize the marked chlorid retention as compared to water excretion. This work has recently been confirmed by Cameron and McMillan,[11] who find that sodium chlorid prevents or lessens the acute illness

TABLE 1.—*Patients Showing Reaction*

Series	150	Abdominal area	16
Reaction	60	Reaction	14
Percentage	40	Percentage	87.5
Neck area	24	Pelvic area	47
Reaction	2	Reaction	25
Percentage	8.3	Percentage	53.2
Chest area	35	Other areas	28
Reaction	13	Reaction	7
Percentage	37	Percentage	25

Anderson and Kohlmann [12] find that both potassium and sodium pass from the blood into the tissues, and they are led to believe that this excess in the cells of the vegetative nervous system causes the illness. If this work is accepted, sodium chlorid in therapy would be contraindicated except as it might produce diuresis.

Nevermann [13] found sodium chlorid helpful especially when administered intravenously, but feels that cognac is a better remedy.

Sielmann [14] used salt enemas and a 10 per cent. solution of sodium chlorid intravenously, successfully. However, he found that a 25 per cent. solution of glucose gave an equally striking result. Prophylaxis with both salt and glucose failed. Along the same line,

Stegjskal believes that the action of sodium chlorid is only that produced by any hypertonic solution. Czepa and Hogler[15] do not consider the findings of Sielmann and his co-workers conclusive, and feel that the benefit derived from the use of sodium chlorid depends on the diuresis produced.

6. *Calcium Chlorid.*—Anderson and Kohlmann use this salt in therapy because they feel that it counteracts the storing of sodium and potassium salts in the tissues. Dodds and Webster[16] used calcium chlorid with some success, following the work of Anderson and Kohlmann, without drawing any conclusions. Pape used the same salt in combination with sodium chlorid and urea, reporting considerable success.

7. *Narcotics.*—Pape,[17] working on the theory of excitation of the vegetative nervous system, tried to reduce it by the use of sedatives and hypnotics, including calcium in combination with sodium chlorid, chloral hydrate and sodium bromid. In our preliminary animal experiments, morphin was found to prevent entirely the acute illness. Ether anesthesia prevented or reduced the illness. In the work of Hall and Whipple,[18] in which morphin was used as a sedative, the immediate reaction was not noted.

Simons[19] sought a drug that would decrease the excitability of the whole nervous region supplying the digestive tract, and found that the tincture of valerian gave some relief, in that the vomiting but not the nausea was controlled.

8. *Endocrine Therapy.*—Hirsch[20] is the chief exponent of endocrine gland therapy as a prophylaxis in irradiation sickness. He was lead to this line of therapy when he found that a stimulating dose over the hypophysis decreased the irradiation sickness following subsequent deep roentgen-ray therapy. Extracts of the anterior lobe of the pituitary body were found to decrease the symptoms. Epinephrin was also used with success, especially in combination with the extract of that ductless gland nearest the site of irradiation.

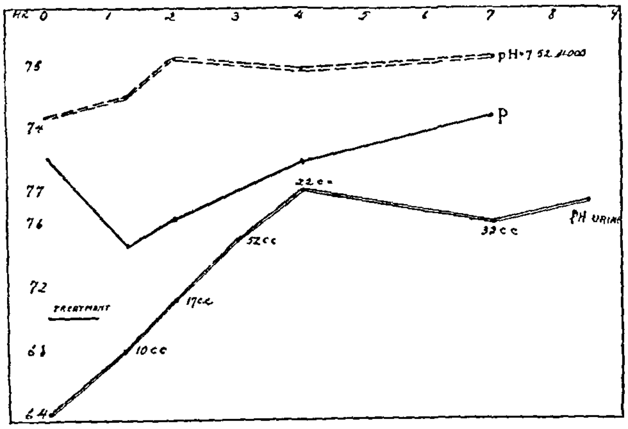

Chart 1 (normal dog) —A normal dog weighing 18 kg was given four human erythema skin doses over the left flank through an area 20 by 20 cm The usual salivation, vomiting and malaise were observed In addition there was elevation of the p_H of the blood to 7 52 The urine changed from acid to alkaline, with a p_H reaching as high as 7.7. There was a sharp dip in the inorganic phosphate curve of the blood, with recovery later. There was a reduction in the total output of urine and a slight decrease in the nonprotein nitrogen

Hirsch particularly emphasized that narcotics are absolutely to be avoided in treating irradiation sickness, since they have an inhibiting effect on the action of organ extracts if not entirely neutralizing it.

It is evident from the foregoing review that the rationale for the various forms of treatment is founded on various theories, some of which are altogether incompatible. This is particularly true of the various theories on which sodium chlorid therapy is used and the theories relating to the use of narcotics and endocrine extracts. Sufficient work has not been done to establish the metabolic changes produced by the roentgen ray, and no work has been done to find how these metabolic changes are altered when the various agents suggested are administered.

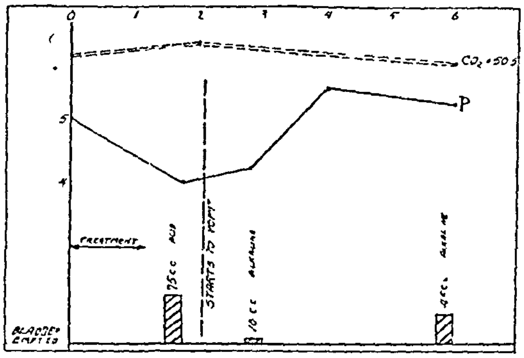

Chart 2 — Irradiation over chest: A normal dog weighing 18 kg was given eight and one half human erythema skin doses over the right chest The entire abdomen was protected from the rays. This heavy dose over the chest produced the immediate sickness, but with no later effects, as is seen after treatment over the abdomen The typical dip in the inorganic phoshorus is present The urine excretion was depressed two hours after treatment

In our preliminary communication[1] it was suggested that the immediate systemic symptoms, at least, were due to strong organic bases and other toxic decomposition products evolved from the nuclear injury or destruction. With this as a basis, work has been continued along three lines: (1) further investigation of alkalosis; (2) investigation of possible respiratory origin of this alkalosis, and (3) investigation of various agents to alleviate the illness.

1. *Further Investigation of Alkalosis.*—The previous work, that is the alkalosis of the blood determined by Meyer's colorimetric method, was confirmed. This alkalosis sets in within one hour of the irradiation and persists if the dosage is intense. Variations of 0.11 were observed, and the results were consistent, in that the change was always toward increased p_H.

Catheterized specimens of urine before treatment were invariably acid to litmus. Within a two hour period after treatment, the reaction became consistently alkaline and remained so for days.

The recent work of Rous,[21] using indicators to show the reaction within the tissues, was applied to find out what the tissue reaction to irradiation was and to see whether it supported the finding of alkalosis in the blood. Three indicators suggested by Rous were used; namely, litmus, cresol red and phenol red.

Litmus buttons were produced in six white rats and two white rabbits, the directions of Rous being followed closely. In each rat, at the end of four or five days, a rosy red hue developed in an area about the button from 2 to 4 cm. in diameter. With the rats, three were irradiated over the entire body and three were kept as controls. Within one hour of the treatment, the color surrounding the button changed to purple or orchid. The latter color was permanent and grew deeper, until at the end of five days it was a distinct blue such as develops in control animals after death.

[18] Hall, C. C., and Whipple, G H Am. J M Sc. **157**: 453 (April) 1919

[19] Simons, A: Strahlentherapie **14**: 106, 1922

[20] Hirsch, Henri. Zentralbl. f. Gynäk. **48**: 76 79 (Jan 19) 1924

[21] Rous, Peyton: J. Exper. Med. **41**: 379, 399 (March) 1925; **41**: 451 (April) 1925.

With the rabbits, similar technic was followed except that two buttons were made, one over the shoulders and another over the rump. Only the buttons over the shoulders were irradiated, after a rosy hue had developed at the end of five days. However, within an hour both buttons began to take on a purple tint, and at the end of twenty-four hours both areas were reddish blue. In ten days the areas were a distinct blue.

Cresol Red: Eight white rats were injected intraperitoneally with cresol red. Four were immediately irradiated and four were kept as controls. In the control animals the dye appeared in forty minutes, giving a light red color best observed in the ears, nose and eyes. The color persisted for only three hours. The four irradiated animals, after exposure of the entire body, showed good staining in twenty minutes. Fifteen minutes after the completion of the irradiation, the staining was distinctly of a darker hue than that observed in the untreated animals. The dye was also excreted earlier than in the untreated animals, apparently all disappearing within a two hour period.

Phenol Red: Eight white rats were injected with phenol red intraperitoneally and immediately exposed to deep therapy. At the end of twenty minutes the untreated animals were a yellowish red or eosin red, while the irradiated animals were bluish red or purple. The treated animals excreted all the dye in two hours, while it required three and one-half hours for the untreated animals to excrete it. This accelerated excretion of the dye corresponds with observations on the same dye administered to dogs intravenously when 59 per cent. was excreted in two hours before roentgen-ray therapy, and 66 per cent. was excreted in two hours twenty-four hours after therapy.

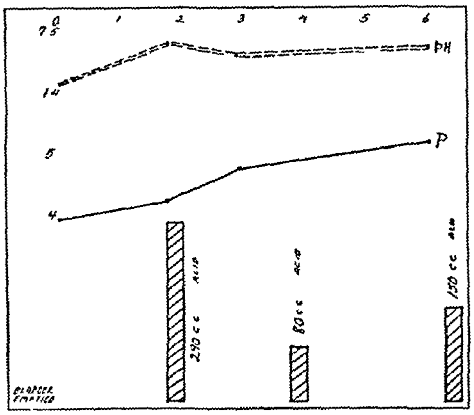

Chart 3.—Calcium lactate. A normal dog weighing 17 kg. was given four human erythema skin doses over the left abdomen. Before the administration of calcium lactate, the *p*H of the plasma was 7.42. After the administration of calcium lactate and irradiation with four human erythema skin doses, the *p*H of the plasma was 7.47 and after one hour and twenty minutes, 7.45. Inorganic phosphates of the serum before treatment were 3.93. After roentgen-ray therapy there is no dip in the inorganic phosphates but a gradual rise to 5.20 at the end of six hours. *Reaction of urine*: A catheterized specimen of urine is acid before the administration of calcium lactate and remains acid during a period of six hours' observation after the administration of calcium lactate and irradiation. Amount of urine excreted: After the administration of calcium lactate and irradiation, the amount of urine in the succeeding twenty-four hour period was increased over the twenty-four hour period previous to irradiation.

From this group of experiments we may conclude that the alkalosis observed in the plasma is secondary to the alkalosis in the irradiated tissues. It would seem that the reaction on the tissues is more marked than those observed in the plasma since changes of at least p_H 0.20 are required to affect litmus. They further confirm the findings that the early and persistent change after deep roentgen-ray therapy is an alkalosis.

2. *Investigation as to the Possible Respiratory Origin of This Alkalosis.*—Wels [22] has shown that nuclear and cellular division is dependent on oxygen but that the effect of irradiation does not center on oxidation. Swann [23] and others believe that oxidation is stimulated by small exposures and depressed by larger ones. The possibility of increased oxidation within the cell with resultant increased ventilation and washing out of carbon dioxid from the body is a possible source of the alkalosis observed. With this in mind, three patients were observed under precautions usually employed in the determination of basal metabolism. Their pulse, blood pressure, temperature and respiratory rate were determined, and, in addition, their expired air was collected for a period of ten minutes and the carbon dioxid and oxygen content determined. The same observations were made within a two hour period after deep roentgen-ray therapy for carcinoma. The results of these experiments are shown in Table 2. The production of expired air and the percentages of carbon dioxid, oxygen and basal metabolism are not materially

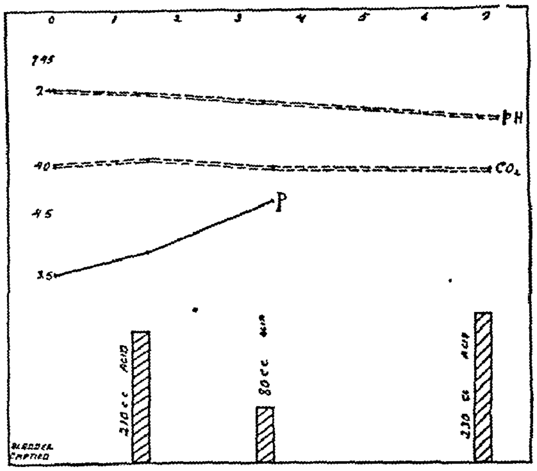

Chart 4.—Calcium chlorid. A normal dog with plasma p_H of 7.4 and weighing 16 kg. was given four human erythema skin doses over the left abdomen. Six hours after the administration of 40 c.c. of 2 per cent calcium chlorid solution intravenously and irradiation, the p_H was 7.36. The carbon dioxid content and carbon dioxid combining power of the blood showed no variation. The inorganic phosphorus curve in the same animal is low to start with, shows no dip immediately after treatment, and slowly recovers. Reaction of urine: A catheterized specimen of urine previous to the administration of calcium chlorid and irradiation was strongly acid to litmus and alizarin. *Urine, after calcium chlorid and irradiation*, is acid at the end of one and one-half hours and remains acid during the following five hours. Excretion of urine after the administration of calcium chlorid and irradiation shows marked increase during the period following irradiation, as compared to the twenty-four hour period previous to irradiation.

Table 2.—*Effect of Roentgen Ray on Oxidation*

changed, but the tendency is to decreased oxygen consumption with the lowering of basal metabolism rather than an increase. We may conclude, therefore, that the alkalosis is not the result of increased tissue oxidation.

3. *Investigation of Various Agents Used to Combat Acute Illness.*—In this investigation we first established a dosage, which, with our deep therapy equipment, would invariably produce an acute reaction in a dog manifested within one hour by salivation, nausea, vomiting, loss of appetite and malaise. In eighteen control dogs, fifteen treated over the abdomen and three over the chest, this dosage produced the symptoms suggested in every case. Using this established dosage the effects of hydrochloric acid, ammonium chlorid, sodium chlorid, calcium lactate, calcium chlorid and morphin were studied either alone or in combination.

EFFECTS OF HYDROCHLORIC ACID

Two hundred cubic centimeters of tenth normal hydrochloric acid was administered to dogs by stomach tube before, during and after irradiation. The animals became salivated and vomited repeatedly after the conclusion of the treatment. The urine, which was acid before treatment, contrary to the usual finding, remained acid during a four hour period of observation after treatment.

EFFECTS OF AMMONIUM CHLORID

Two dogs were given 12 gm. of ammonium chlorid daily for four days previous to irradiation. The carbon dioxid combining power of the plasma dropped as low as 29.5 per cent., and the p_H as low as 7.22. The treatment did not alter the acidosis thus produced, yet the animals were salivated, vomited repeatedly, and died in from four to six days.

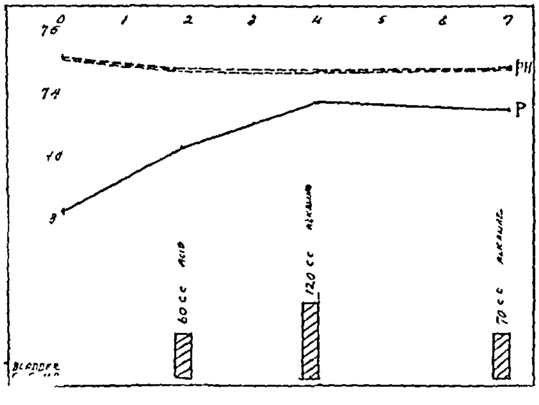

Chart 5.—Morphin: A normal dog weighing 14 kg. was given four human erythema skin doses over the left abdomen. The p_H of the blood previous to the administration of one-half grain (0.03 gm.) of morphin and irradiation was 7.46. Three hours after the administration of morphin and irradiation, the p_H was 7.43. There was a low inorganic phosphorus content of the blood to begin with, but no dip afterward. This gradually recovered. Urine, previous to the administration of morphin and irradiation, was strongly acid to litmus and alizarin. *Two and one-half hours after the administration of one-half grain (0.03 gm.) of morphin and irradiation the urine was acid, but four hours later it was found to be alkaline.* In the twenty-four hours previous to irradiation, the dog excreted 520 c.c. of urine. In the twenty-four hours after the administration of one-half grain (0.03 gm.) of morphin and irradiation, the dog excreted 1,620 c.c. of urine.

EFFECTS OF SODIUM CHLORID

Two hundred cubic centimeters of a 15 per cent. solution of sodium chlorid was administered by a stomach tube two days before treatment, also one-half hour before, and intravenously after treatment. Despite this, the dogs were salivated and vomited repeatedly. The urine excretion was increased after sodium chlorid and irradiation. The urine was acid before treatment but became alkaline after treatment, just as occurs in unprotected animals.

EFFECTS OF CALCIUM AND MORPHIN

Calcium lactate and calcium chlorid by mouth and intravenously were beneficial in alleviating the symptoms in both patients and dogs, but did not prevent or stop the illness in all cases. Morphin sulphate, in doses of from ½ to 1 grain (0.03 to 0.06 gm.) administered to dogs previous to irradiation, prevented all evidence of acute illness. With doses of from ⅙ to ½ grain (0.01 to 0.03 gm.) in patients the immediate effects of irradiation were prevented in most instances and alleviated in others (Tables 3 and 4). By studies on the p_H of plasma, the inorganic phosphates of blood, reaction of the urine, the amount of urine excreted and the amount of nonprotein nitrogen excreted when the animal was under the influence of calcium lactate, calcium chlorid and morphin, information as to the mechanism of the beneficial effects of these substances and indirect evidence as to etiology of the illness was sought (Charts 1, 2, 3, 4, 5 and 6).

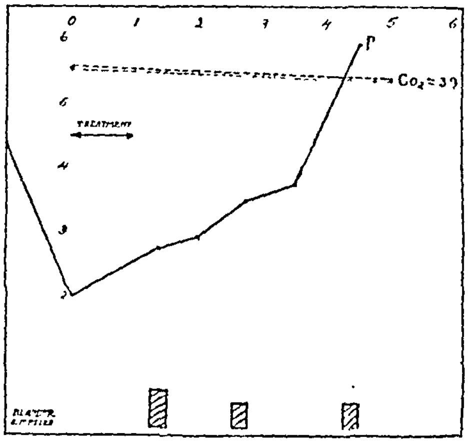

Chart 6.—Morphin protection: A normal dog weighing 21 kg. was given eight and one-half human erythema skin doses over the gastric area. The dog was previously given three-quarter grain (0.04 gm.) of morphin. Morphin entirely protected the animal against reaction for forty-eight hours, in spite of this extremely heavy dose. The inorganic phosphorus was strongly depressed by the morphin previous to the treatment. It recovered rapidly and increased over normal. The urine excretion during the hours right after treatment was not much diminished, but during the night an extensive polyuria took place. There was no disturbance in the carbon dioxid combining power. In the twenty-four hours before treatment there was an excretion of 624 c.c. In the twenty-four hours after treatment the excretion was 1,604 c.c.

Table 3.—*Patients Treated with Calcium Lactate*

Table 4.—*Patients Treated with Morphin*

Morphin used prophylactically	9
Complete protection	3
Protection for two days	3
Not protected	3

It is noted in the foregoing experiments that under the influence of calcium lactate, calcium chlorid and morphin the irradiated animal shows only a slight change in the p_H of the blood and this is usually toward the acid side, as contrasted with a change toward the alkaline side with irradiation alone. The total amount of urine excreted and the nonprotein nitrogen excreted in the urine during the twenty-four hours following irradiation are increased under the influence of these agents despite the irradiation which alone markedly decreases the excretion of urine and slightly decreases the excretion of nonprotein nitrogen. Thus the beneficial substances used, especially morphin, not only counteract the clinical symptoms but also maintain at normal level the metabolic processes of the body despite the irradiation therapy.

Some of the animals receiving calcium lactate, calcium chlorid and morphin before and after the roentgen-ray therapy lived through the acute illness and survived for months, while the control animals invariably died in from four to six days. Even those which did survive had bloody diarrhèa and refused food for days. Necropsy on the animals that received these substances showed about the same distribution and severity of lesions in the intestine. These findings would indicate that the local reaction to irradiation is the same, but that cells outside this area are protected against the toxic products evolved within this area.

Although there has been no opportunity to make studies of actual cases, the pathologic changes found in the irradiated areas of these protected animals indicated that the substances mentioned can be used in tumor patients without fear of their making the tumor cells more resistant to the roentgen ray.

SUMMARY AND CONCLUSIONS

In the study of 150 patients, treated with a modern deep therapy apparatus, including a water cooled tube, a high percentage of acute irradiation sickness was found, especially in those cases treated over the chest, pelvis and abdomen. The treatment of this reaction, as described by various workers, differs markedly probably because theories as to the etiology of the illness are so varied. The rapidly developing alkalosis, and the continuation of this condition after large doses, are confirmed by the determination of the p_H of the plasma and of the urine and by the use of indicators in the tissues. That this alkalosis is not a result of tissue oxidation or washing out of carbon dioxid is demonstrated in the study of the expired air of patients collected before irradiation and within a two hour period after irradiation. After the establishment of roentgen-ray dosage which invariably produces the acute illness in dogs, various agents for counteracting it were tested. Of these agents, hydrochloric acid, ammonium chlorid and sodium chlorid had but little effect. Ammonium chlorid and hydrochloric acid may combat completely the resultant alkalosis, but the experimentally produced irradiation sickness in dogs was not relieved by these drugs, demonstrating the fact that alkalosis is not the only factor concerned in irradiation sickness. Calcium chlorid, calcium lactate and morphin were beneficial in preventing or alleviating the symptoms. Morphin invariably prevented the reaction in dogs and was helpful in patients treated over the abdomen, in whom the treatment was invariably followed by irradiation sickness when unprotected.

ABSTRACT OF DISCUSSION

Dr. Henry Schmitz, Chicago: How large a dose of calcium chlorid or calcium lactate was used in these cases, and how large was the dose of morphin?

Dr. George E. Pfahler, Philadelphia: Since Dr. Doub published his recent paper, I have used calcium lactate in a great many cases, and I get the impression that it is helpful. We must make use of the morphin most cautiously or we shall get into other troubles, especially if we attempt to continue treatment over a considerable period of time, and we might even get involved with the Harrison act.

Dr. Howard P. Doub, Detroit: Relative to the dosage of calcium lactate and morphin, as I pointed out, we usually use one half grain (0.03 gm.) of morphin about one half to three quarters of an hour before the treatment. We used this only in cases in which we believed that very distressing sickness would result, that is, cases of carcinoma of the stomach, carcinoma of the gallbladder, etc., when we were treating over the gastric area. I certainly would not advocate using this medication in breast and neck cases, because I believe that where there is a chance of obtaining a cure of the cancer we should avoid producing the morphin habit. Of course, these patients never knew what they were getting, so far as we could keep them from knowing. In regard to calcium lactate, we used a 5 per cent. solution. In many cases, we injected intravenously from 20 to 30 c.c. immediately following their radiation. Later we used a considerable amount by mouth. In those cases we gave about 4 drams every half hour, for from four to six doses, and these series were frequently repeated. We would let them go an hour, and if they had any recurrence of the nausea this dosage was repeated. I do not believe that this substance has a deleterious effect on the patient.

NONSPECIFIC GRANULOMA OF THE INTESTINE CAUSING INTESTINAL OBSTRUCTION

T. HOMER COFFEN, M.D.
PORTLAND, ORE.

In 1909, Heinrich Braun[1] referred to a report by him, eight years earlier, of an inflammatory tumor of the mesentery, causing obstruction, and he reported "similar tumors of the intestines, whose recognition is important as to course and prognosis and especially because of their similarity to new growths." Up to that time there had been no record of these tumors in German medical textbooks or journals, but in reviewing the literature Braun found that Moynihan had seen the condition six times in three years and Mayo Robson had seen it five times in twelve years, never involving the small intestine. He thought that these tumors were sometimes unrecognized or mistaken for carcinoma, because microscopic examination had not been made, and he pointed out that they have nothing to do with the very circumscribed inflammatory tumors of tuberculosis or actinomycosis. They are sometimes diffuse inflammatory tumors in the vicinity of the sigmoid, usually associated with diverticula, or inflammatory pseudotumors of the mesentery, causing stenosis of the transverse colon. "Inflammatory tumors of other parts of the body are easily recognized as such," he wrote, "but in the abdominal cavity the differentiation from carcinoma (especially in elderly patients with cachexia, intestinal disturbance or signs of obstruction), from stones in the common or cystic bile ducts, or from masses in the female pelvis may be possible only by exploratory laparotomy." The reports from the literature by Braun are as follows:

Moynihan[2] reported intestinal obstruction in a man, aged 62, due to a mass the size of a coconut which was thought to be cancer. The tumor was not removed, but anastamosis was done, followed by recovery and no recurrence.

Robert Proust[3] saw a woman, aged 32, four months after ovariectomy, with lancinating pain in the left quadrant of the abdomen; a nut sized mass was felt. Operation revealed localized peritonitis, but the mass was not removed. When seen six months later, the tumor could be grasped in two hands, and operation showed an inflammatory tumor of the omentum, causing stenosis of the intestine. After removal, it was difficult to determine microscopically whether it was tuberculous or neoplastic, but a thorn was found embedded in inflammatory tissue and there were microscopic evidences of inflammation.

[3] [illegible] paraintestinale, Rapport par M. Lejours, Bull. [illegible] Paris 33: 1158, 1907.

Robson,[4] in 1906, saw an old man with a hard intra-abdominal tumor near the navel, suspected to be carcinoma. Operation revealed a tumor of the transverse colon, involving the omentum and small intestine; it was not removable. Anastomosis gave relief; he improved rapidly, and the tumor disappeared. Twelve years earlier, Robson had operated on a man, aged 70, for intestinal obstruction caused by a tumor of the ascending colon; anastomosis gave relief, and he was well when seen three years later. A third case was that of a patient seen two years before with an obstruction due to a large tumor in the region of the splenic flexure, resembling carcinoma. Anastomosis relieved it, and the patient was well when seen one year later.

Lejars[5] reported the case of a woman, aged 26, with pain in the gallbladder region and jaundice. Operation showed a mandarin sized tumor in the gallbladder region, involving the angle of the colon and mesentery; while it appeared to be malignant, microscopic examination showed it to be inflammatory.

Braun[1] reported two cases; one a woman, aged 54, with a mass in the lower part of the abdomen suggesting an ovarian tumor but found to be inflammatory. The other was a man, aged 60, with an obstruction tumor in the region of the cecum. Both tumors disappeared spontaneously after operation. In the discussion of Braun's paper, Jaffe reported two cases, both in the colon, mistaken for carcinoma; Reichel reported a similar case in the sigmoid; Franke said the condition should be differentiated from hyperplastic colitis, sigmoiditis and diverticulitis. Braun described the microscopic appearance of these tumors, and his paper is accompanied by colored plates of the microscopic sections. They agree with the description of Moschcowitz and Wilensky, which follow. The etiology of these inflammatory tumors was not determined by Braun.

In a paper by Moschcowitz and Wilensky[6] four cases were reported; summarized briefly, they are as follows: A man, aged 23, had diarrhea of one year's duration but was operated on for acute appendicitis. Six months later, a mass appeared in the right iliac fossa, which was a granuloma. He was well for two years, when he had acute obstruction with a granulomatous mass. Microscopically, there were numerous giant cells surrounding foreign bodies of unknown nature. A year later he had suppurative peritonitis, the origin of which was not determined at operation. When seen some months later he was well except for mild diarrhea. The second patient, a man, aged 33, had been operated on two years before for inguinal hernia, and the appendix was removed. He presented symptoms of appendicitis, but a large mass was found in the descending colon which, microscopically, was simple chronic granuloma. The third patient, a man, aged 44, had been operated on for acute suppurative appendicitis. Two years later a mass was found in the left kidney region, which, at operation, proved to be granulomatous obstruction of the splenic flexure, mainly in the mesentery, but involving the wall of the intestine and apparently not breaking into the mucosa. Microscopically, there was no evidence of tuberculosis, syphilis or lymphogranuloma. The fourth patient, a woman, aged 44, was seized with cramplike pain in the right abdomen. Three weeks later a large mass was found in the right iliac fossa. Resection, with a part of the ascending colon, showed simple granulomatous tissue.

The pathology of the cases of Moschcowitz and Wilensky was as follows:

Gross.—One specimen was a firm, dense, uncircumscribed tumor involving all coats of the large intestine and causing stricture of the lumen. There was some superficial ulceration, not beneath the mucosa. In three cases the ascending colon was involved; in a fourth, the splenic flexure. Another specimen involved the mucosa, submucosa, muscularis and serous layers of the small intestines, causing almost complete obliteration.

Microscopic.—There was uniform, extensive infiltration of all coats with cells of plasma or round cell type and fibroblastic transformation from comparatively richly cellular tissue to firm, dense fibrous scar. The number of polymorphonuclears varied. In one instance they were congregated sufficiently to justify the term abscess. New blood vessel formation was prominent in all specimens. Giant cells were absent in the first case. The mesenteric glands were not noteworthy.

The case here reported is presented because: 1. It is similar to those referred to above in the gross appearance, which suggested a tumor mass resembling tuberculosis or new growth, causing intestinal obstruction. 2. The patient has been under observation for nine years, in which time there have been three operations for granulomatous tumors, causing intestinal obstruction. He was fairly well in the intervals. 3. The first granulomatous obstruction followed an operation for appendicitis, subacute. Subsequent granulomas were associated with systemic evidences of focal infection (sciatica, arthritis, low grade fever, etc.). 4. The last operation showed coincidental suppurative cholecystitis, and the excised tissues and gallbladder gave a pure culture of streptococci. 5. The condition is rarely referred to in current medical literature.

REPORT OF CASE

A man, aged 20, with no former serious illness, had had more or less pain in the epigastrium, headache and moderate cough for a long time, and he was troubled with constipation for a year before I saw him in 1916. He was relieved of all these symptoms for four months, when he complained of pain in the left shoulder, constipation and rectal fissure. These symptoms responded to treatment, but one month later, after eating green corn, symptoms of appendicitis appeared that required operation, showing subacute inflammation. Exploration of the abdomen showed no further abnormalities. He was then well for about a month, when he had an attack of cramplike pain in the left upper abdominal quadrant, nausea and vomiting. These subsided in a few days, and he was well for about three weeks, when he had sharp abdominal pain and there were definite signs of obstruction, demanding operation. Eight inches of indurated thickened bowel was resected, thought at the time of operation to be tuberculous, but found to be granulomatous, as described above. Five months later he had acute obstruction, demanding operation, when 24 inches of ileum was resected by another surgeon during my absence in Europe. This was thought to be tuberculous but proved to be granuloma. The pathologist, at that time, not aware of the earlier history and the pathologic condition of the tissues removed at the former operation, thought it phlegmonous enteritis, due to chronic streptococcic infection as described by MacCallum.[7] His description was as follows: Microscopically, the specimens showed dense inflammatory tissue, with infiltration of the submucosa and mucosa. There was no ulceration and no evidence of tuberculosis or syphilis. The infiltration consisted of polymorphonuclear leukocytes, lymphocytes and many eosinophils. The gallbladder was septic at this time, streptococci being found in pure culture, also in the intestinal contents. Eight months later, another resection was done for the same condition, the patient having been comfortable up to a week before. It is nine months since the last operation for obstruction, and the patient is in fair health.

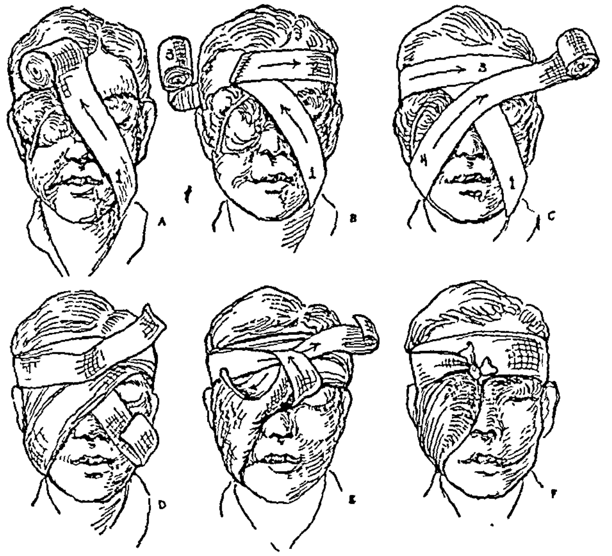
Clinical Notes, Suggestions and New Instruments

A USEFUL EYE BANDAGE

A. B. Reese, M.D., New York

An eye bandage, which I have used for some time and which possesses certain distinct advantages, may be described as follows:

The proximal end of the bandage for about 6 inches is placed obliquely over the eye that is not to be bandaged *(A)*; on the forehead over the eye to be bandaged, it is reversed *(B)*, and a turn or so is taken around the forehead in a direction away from the bandaged eye. Then it is brought up under the ear and over the eye to be bandaged, the first turn being made close to the nose *(C)*. The bandage is then completed by making alternate turns around the forehead and over the bandaged eye *(D)*. The last turn must be around the forehead *(D)* and the distal end is then tied to the proximal end *(E)* which frees the unbandaged eye *(F)*.



Eye bandage.

The advantages of the bandage are:

1. No adhesive plaster is necessary.
2. Pressure on the eye can be made to almost any degree, by varying the tightness with which the ends are tied.
3. The tying of the ends pulls the bandage in snugly and tightly along the nose *(F)* and makes it conform in a convex manner over the eye.

50 West Fifty-Second Street

PARATYPHOID BACILLUS B IN CANNED RIPE OLIVES *

William Royal Stokes, M.D., Baltimore

The following note is to record an observation that indicated the presence of an aerobic organism capable of producing food poisoning in canned ripe olives. Koser,[1] in a study of canned ripe olives, found viable organisms in eight of 181 samples of normal cans, and in 154 of 157 of swelled or springy cans. In 116 glass containers, eleven, or 9.5 per cent., showed the presence of living organisms, and all the twenty-six specimens that were obviously spoiled or had a bad odor contained living organisms. In studying the various species found, he observed members of the colon group, *Proteus vulgaris*, gram-positive staphylococcus and several aerobic spore-bearing organisms. He also found *Clostridium botulinum* in seven of the spoiled glass jars.

The observations reported here were made on a glass jar of ripe olives that was opened when received and from which olives had been eaten by a man and a woman who were patients of Dr. C. W. Judd. About twenty-four hours after eating the olives, they both were seized with fever, vomiting and diarrhea, but no special symptoms of botulism were observed. The olives had been in a refrigerator for several days after the attack, before they were brought to the laboratory.

A careful investigation failed to reveal the toxin or organism of botulism. In the experiments, one guinea-pig was inoculated subcutaneously in the abdominal wall with 1 c.c. of the unfiltered juice of the olives. This animal was dead twenty-four hours later, and there was a hemorrhagic area at the site of inoculation and enlargement of the spleen. The cultures from the site of inoculation and the spleen gave a large number of organisms corresponding to the paratyphoid B bacillus, and this organism was agglutinated by a dilution of 1:800 of the paratyphoid B agglutinative serum, the titer of which with the stock organism is 1:1,600.

The patients had recovered by this time, and examination of the stool failed to reveal any paratyphoid organisms. The colon bacillus and *Proteus vulgaris* were isolated also from the juice and tissue of the ripe olives.

CONCLUSIONS

It seems not improbable that an acute intestinal infection was caused by a paratayphoid organism in ripe olives. Experiments failed to demonstrate *Clostridium botulinum*, but revealed in the olives an aerobic organism recognized as paratyphoid bacillus B, which is capable of causing intestinal infection in human beings.

New and Nonofficial Remedies

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application. W. A. Puckner, Secretary.

VACCINE VIRUS (See New and Nonofficial Remedies, 1925, p. 341).

Eli Lilly & Co., Indianapolis.

Vaccine Virus.—Marketed in packages of one capillary tube containing sufficient material for one vaccination accompanied by a bulb and needle, and in packages of five capillary tubes each containing sufficient material for one vaccination accompanied by a bulb and needles.

TYPHOID VACCINE (See New and Nonofficial Remedies, 1925, p. 360).

The Gilliland Laboratories, Inc., Marietta, Pa.

Typhoid-Paratyphoid Bacterial Vaccine Immunizing (See New and Nonofficial Remedies, 1925, p. 361).—Also marketed in hospital size packages of ten complete immunizations. Each immunizing treatment consists of three 1 Cc. vials, the first dose containing 500 million killed typhoid bacilli, 250 million killed paratyphoid A bacilli and 250 million killed paratyphoid B bacilli and the second and third each containing 1,000 million killed typhoid bacilli, 500 million killed paratyphoid A bacilli and 500 million killed paratyphoid B bacilli.

ANTIRABIC VACCINE (See New and Nonofficial Remedies, 1925, p. 342).

E. R. Squibb & Sons, New York.

Rabies Vaccine (Semple Method)-Squibb.—An antirabic vaccine prepared according to the general method of David Semple (phenol killed). The brains of rabbits killed on the sixth day after inoculation with fixed virus rabies, are ground in a ball mill with physiological solution of sodium chloride containing 1 per cent. of phenol to yield a 10 per cent. suspension of brain substance. The mixture is incubated at 37 C. for twenty-four hours and then diluted with an equal volume of physiological solution of sodium chloride so that the finished product contains 5 per cent. of brain substance. Marketed in packages of fourteen syringes, each containing 2 Cc. The content of a syringe is administered daily over a period of fourteen days.

BATHS AND DIURESIS

Balneotherapy has as yet scarcely reached a stage of development at which the term "scientific" can properly be applied to it. Casual observation extending over generations has furnished guides for practical procedure and may presently transform the consideration of bathing from empiricism to a real science. Meanwhile, one must be content with such unsatisfactory platitudes as the "general healthfulness" of bathing and the assurances of the benefits or the reverse that the bath in one form or another may have conferred on a host of patients. The subject is obviously not a simple one. Temperature and pressure changes are applied to the body in the bath. The circulation and respiration have long been known to respond in varied ways to such alterations in the environment. The indirect consequences may be of considerable therapeutic as well as hygienic value. We need merely recall the remarkable nervous relaxation often induced by neutral baths, so that they become effective in the management of acute mania as well as in cases of ordinary sleeplessness. Cold baths are widely employed in the treatment of fevers.

Several years ago, Bazett and Haldane[1] observed a considerable diuresis to occur in baths of varied sorts. The effect was evidently not dependent on temperature. That cold, including cold baths, might produce a diuresis has long been known; but the results were equally striking when the possible temperature decrease was excluded. There is no evidence of any water absorption through the skin. Whereas the circulatory and respiratory changes observed on immersion in hot or warm baths appear to depend mainly on changes in body and skin temperature, no such dependence can be demonstrated for the diuresis. The increased secretion of urine is induced by immersion of the trunk in water without the limbs being immersed, but is not caused by immersion of the lower half of the body up to the level of the umbilicus.

It has been suspected that the pressure of the water on the abdomen raises venous pressure, causing secretion of urine and absorption of fluid. This hypothesis is supported by experiments of Griffith and Hansell[2] at the University of Pennsylvania, which indicate definitely that abdominal pressure without the accompaniment of the bath can produce a diuresis, and that for any subject there is probably an optimal value, so that pressure above this may cause no increase or actually a decrease in urine volume. The effective pressures employed by the Philadelphia physiologists were about comparable to the hydrostatic pressure on the abdomen in the baths. It seems inevitable that the venous pressure in the abdomen would be raised as the result of the external pressure. Slight increase in the pressure in the renal vein is known to produce diuresis in experimental animals. Consequently, the cause of the diuresis in the bath is presumably to be sought in a similar phenomenon.

PROTEIN HYPERSENSITIVENESS

In the earlier years of the development of our knowledge, anaphylaxis, as Duke[3] has pointed out, was looked on by the medical profession at large as an interesting laboratory phenomenon, responsible at most for an occasional human death following the use of therapeutic serums. As a result of two decades of intensive study by a large number of investigators, facts have been disclosed that show a condition, in human beings, very similar to anaphylaxis, as a common cause of illness. According to Duke, it affects, in slight or marked degree, possibly as many as 15 per cent. of persons.

Among the agents that may become responsible for hypersensitiveness and its manifestations, foods are included. It is far easier to understand how alien substances may bring about the untoward reactions. Ordinary foods, such as the conventional dietary proteins, do not seem so "foreign" to the organism. It should be remembered, however, that even the familiar proteins of the daily regimen induce toxic reactions when they are introduced directly into the blood stream and thus distributed unchanged to the tissues. Alimentary introduction of the same products differs in that it provides a preliminary digestion of them. They then enter the circulation as amino-acids or other nonantigenic products.

Hypersensitiveness to food proteins has therefore raised the question as to whether proteins are always absorbed solely as nonprotein digestion products. Or does an unchanged protein molecule occasionally traverse the alimentary barrier and thus either sensitize or intoxicate the individual concerned? Various investigators have attempted to learn whether readily soluble proteins, such as egg albumin, can be absorbed unchanged. The latest[4] observers have used specially sensitized animals as test objects. No signs of anaphylactic shock could be discovered on the direct intestinal injection of the sensitizing protein; but symptoms were elicited when the latter was introduced under conditions of stasis leading to pressure or when the mucosa was damaged. Consequently, the conclusion is reached that, under unusual conditions of increased intra-intestinal pressure, proteins may reach the blood stream to some extent in undigested form; at any rate, in quantities large enough and at rates rapid enough to sensitize a normal animal or for the intoxication of one previously sensitized. Like most defensive mechanisms of the body, the alimentary tract with its protective membranes and potent digestive secretions may fail at times under the stress of some unusual condition.

COUNCIL ON PHYSICAL THERAPY

The report of the organization and first meeting of the new Council on Physical Therapy of the American Medical Association, which appears elsewhere in this issue, places on record one of the most significant steps taken by the Association in its attempts to advance modern therapy. For many years, pioneers have been working empirically with various electrical and mechanical devices; indeed, some have recognized the suggestive power of such methods and in many instances exploited them unduly to credulous physicians and to the more credulous public. It has become apparent that physical methods have a definite field both in the diagnosis and in the treatment of disease, and that it was incumbent upon some unbiased and scientific body to define the exact merits of these devices. This sentiment was crystallized in the resolution introduced into the House of Delegates at the last annual session of the Association, in Atlantic City, by Dr. Joseph F. Smith of Wisconsin. That resolution reads:

> WHEREAS, From time to time there are offered for sale to members of the medical profession and to hospitals many nonmedicinal agents of alleged therapeutic value consisting of electrical devices, mechanical contrivances, colored lights, various kinds of lamps, etc., the exact nature and action of which the individual members of the profession at large, because of the lack of the necessary technical skill, adequate facilities and instruments of precision, are not in a position to evaluate correctly, and
>
> WHEREAS, The purchase of such pieces of apparatus, often on the misrepresentation of persons offering them for sale, results in great financial loss to the members of the profession annually, and
>
> WHEREAS, The use of such devices and apparatus without adequate understanding and control on the part of the physicians employing them tends to deteriorate the physicians' alertness in making a diagnosis, thereby resulting in loss of time and money to patients; therefore, be it
>
> *Resolved*, That the trustees of the American Medical Association be empowered to appoint a Council on Nonmedicinal Agents similar to the Council on Pharmacy and Chemistry consisting of at least two physicists, two physiologists, two pathologists and two clinicians whose duty it shall be scientifically to investigate and report on the value and merits of all nonmedicinal apparatus and contrivances offered for sale to physicians and hospitals and to publish in THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION from time to time the results of its investigations.

In due course the resolution was approved by the Reference Committee and by the House of Delegates and referred to the Board of Trustees, with a request for action. At its last meeting, the Board of Trustees nominated the members whose names appear under the heading of Association News.

The Council, as will be observed, includes representatives of fundamental sciences closely allied to medicine, whose services are necessary in order to evaluate properly the worthiness of physical apparatus. The physicists, the physiologists and the pathologists will cooperate with representative clinicians who have made basic investigations in the field of physical therapy to determine whether or not heat produced by electricity, by external application or by light, or, indeed, by the use of drug irritants, is a desirable procedure in any given instance. They will endeavor to assign proportionate merit to each of these methods under various circumstances. Manufacturers of apparatus have been urged to submit to the Council's opinion the thousands of devices now available, and to submit also the advertising material, with a view to offering to physicians only such apparatus as may be sold with due regard for established fact. The whole-hearted cooperation with which many of the larger manufacturers have entered into the scheme is in itself a tribute to the high position earned by the Council on Pharmacy and Chemistry of the American Medical Association, established more than twenty years ago. It is also a recognition of the value attaching to acceptance of advertising claims by that council, by THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION and by the journals of the various state medical associations which have adopted the approval of the Council on Pharmacy and Chemistry as their standard.

The initial discussions of the new council indicate a desire to be of the widest possible service to scientific medicine. The plans include not only investigation and approval of physical apparatus, but inquiry into such methods as massage and manipulation, hydrotherapy and exercise. If the views now held are carried to fruition, physicians will have available shortly, through the work of this council, a statement of the present status of each of the physical therapeutic methods now known, including its history, its underlying physiology, its actions and its uses. Fellows of the American Medical Association will, it is hoped, appreciate the manner in which members of this council have taken hold of the tremendous problem, and at the same time recognize the fact that their work is given to the organization without idea of any compensation other than the regard of fellow scientists.

THE GLUCOSE CONTENT OF NORMAL URINE

It is a well attested fact that the sugar characteristically present in the urine in diabetes is the carbohydrate glucose. The chemical nature of the latter has been established by dependable methods of investigation. It has also been known for some time that the urine of presumably healthy persons gives certain reactions that suggest the presence of carbohydrates closely allied to, if not identical with, the familiar sugars. Thus, under suitably arranged conditions and with sufficiently sensitive reagents, so-called "reduction tests" can be conducted with positive outcome on normal urines. The evidence that some carbohydrate material, however small in amount it may be, regularly escapes into the urine need not be reviewed here. There are indications that it consists of a mixture of substances; and the possible significance of this normal carbohydrate "leakage" through the kidneys has excited considerable discussion.

The impression is widespread that part, at least, of the "normal" urinary carbohydrate consists of glucose, the quantity being so small, however, as to escape detection by any except the most delicate tests. If this is correct, as has repeatedly been maintained by biochemists of repute, the difference between the diabetic and the healthy person with respect to sugar output through the kidneys is essentially one of quantity or proportions. Diabetic glycosuria or even alimentary glycosuria may then be looked on as an exaggerated "glycuresis."

The detection of small amounts of glucose among other carbohydrates, and particularly reducing sugars, is not easy. Renewed investigation of the normal urine sugar problem has brought forth challenges of the presence of glucose. Among the critics, Greenwald, Gross and Samet[1] allege that the sugars excreted in normal urine are made up of nonassimilable carbohydrates or carbohydrates assimilable with difficulty, and of reducing substances derived from the protein of the food and from endogenous sources. The nature of those in the former group depends on the diet. This group may include lactose from milk, pentoses from fruits, and caramelized sugars and dextrins. The amounts of all these are usually small. On ordinary diets, at least half of the sugars of the urine originate from the protein of the food or from endogenous sources. Apparently, they do not arise from nuclein metabolism. It is suggested that they may be pentoses, which, it is argued, are always formed from protein and, in pentosuria, are either formed in larger quantities or escape further catabolism.

It is admitted that glucose may appear in the urine of normal persons after the ingestion of quite large quantities of glucose or after the ingestion of a carbohydrate meal immediately following a period of carbohydrate-free diet. Just as with any other function, there are probably all gradations in the ability of individuals to assimilate glucose. There are those who are unquestionably normal and those who are frankly diabetic, just as there are those who have unquestionably normal hearing and those who are totally deaf. Just what shall be called "normal" is a matter of statistics and of definition. Not nearly enough of the variations in the ability to assimilate glucose is as yet known. Höst[2] also is convinced that the sugar in normal urines is not identical with the blood sugar, glucose. The latest investigators,[3] at Addenbrooke's Hospital in Cambridge, England, proceeded from the thesis that if glucose, a fermentable sugar, is present in urine, the products of its fermentation should be detectable when this reaction is attempted. The most delicate tests available failed to demonstrate production of carbon dioxid when normal urine was treated with yeast. This points clearly to the absence of glucose from normal urine.

Current Comment

FEBRILE PLEIOCHROMIC ANEMIA

The description of heretofore unrecognized disease entities is no longer so frequent that a novelty fails to arouse interest. On more than one occasion, precise formulation of observations on anatomic or functional irregularity has served to awaken enthusiasm and brought to light unsuspected additional illustrations of the malady involved. All too few practitioners are thoroughly prepared by training or temperament to "sense" the unusual. We use this expression advisedly; for the highest diagnostic skill requires the contributory help of all the physician's senses. This is illustrated in the illuminating study of an undescribed disease reported by Moschcowitz[4] of New York. In its pathology it was characterized by widespread hyaline thrombi in the terminal arterioles and capillaries. The pathogenesis of this peculiar type of thrombosis, so far as the appearance of the thrombi is concerned, was discovered long ago by Flexner in masses of agglutinated red blood cells. He concluded that when red cell thrombi are old or when agglutination is compact, the plugs have the appearance of hyaline thrombi. In the disease leading to this unusual pathologic morphology,

[2] Höst, H. F.: J. Metabol. Res. **4**: 315, 1923.

[3] Lund, G. S., and Wolf, C. G. L.: The Glucose Content of Normal Urine, Biochem. J. **19**: 538, 1925.

[4] Moschcowitz, Eli: An Acute Febrile Pleiochromic Anemia with Hyaline Thrombosis of the Terminal Arterioles and Capillaries, Arch. Int. Med. **36**: 89 (July) 1925.

Moschcowitz believes that death resulted from some potent poison having both agglutinative and hemolytic properties. There are indirect indications that transfusion of blood may be a palliative measure. In former days the reviewer would presumably have referred to the new entity as Moschcowitz's disease rather than attempt the discoverer's more cyclopedic designation of "acute febrile pleiochromic anemia with hyaline thrombosis of the terminal arterioles and capillaries."

THE E. R. A. HAZARD

Some minds are impregnable to scientific evidence. Among their unfortunate possessors are those who believe that the "Electronic Reactions of Abrams" have some basis in fact. To argue with such persons is hopeless. All attempts on the part of the medical profession to enlighten them are rendered abortive by the preconceived belief that scientific medicine is hidebound and will not see the light. Minds of this kind, however, are more open to the practical facts of business. They will sit up and take notice when a business man tells them that his experience is thus and so. To these individuals we would commend a circular recently sent out by an insurance company that specializes in insuring professional men and women against professional loss. The special feature of this insurance company is protection of those who practice the healing art against malpractice suits. The company has two premium rates, one covering physicians and one covering those who employ the Abrams fakery. They are known respectively as "General Premium Rates" and "E. R. A. Premium Rates." The premium charge for a physician indemnifying him for $5,000 a year is $12.50. The premium charge for the Abrams disciple, indemnifying him for the same amount, is $50!

THE INDEX OF INSULIN ACTION

The four years that have elapsed since the use of insulin in clinical medicine was instituted have not sufficed to supply any adequate explanation of how the pancreatic hormone enables the body to utilize glucose. Efforts to secure an answer to the important problem at hand have assuredly not been lacking. One by one a number of possibilities that present themselves have been tested, for the most part succeeding only in narrowing somewhat the remaining fields of inquiry. The blood itself is evidently not the seat of the predominant reaction. Various organs have been tested for their possible complicity in the function of carbohydrate utilization through the influence of insulin. Some of them have been extirpated without any disappearance of sugar metabolism. Others have been studied in isolation by the method of perfusion, without showing any unexpected results. One of the latest investigations, by Mason and Matthew[1] of the University of Michigan, has served to demonstrate that insulin acts independently of the central nervous system, the sympathetic nervous system, and the parasympathetic system. At any rate, in experimental animals administration of the hormone still produces characteristic decrease in the content of blood sugar after destruction of the central nervous system, administration of atropin in doses that paralyze the parasympathetic endings, or the use of drugs that interfere with the function of the sympathetic ganglions. A heretofore unemphasized feature has been recorded by Foshay[2] of the Lakeside Hospital, Cleveland, who observed that insulin may cause a reduction in the quantity of glucose in the erythrocytes disproportionate to the decrease in the whole blood. According to him, overdosage, the source of danger in insulin therapy, may lead to cytoglycopenia—a status of glucose impoverishment within the red blood cell. Hence it may happen that untoward symptoms arise before their cause is betrayed by an examination of the whole blood alone. If the exhaustion of erythrocytes with respect to sugar is indicative of what happens to the tissue cells in general, a step toward a better understanding of the exhaustion seen after insulin overdosage will have been taken.

ARE CALORIES OLD FASHIONED?

In his presidential address delivered before the American Neurological Association in Washington last May, Peterson[3] recalled the saying of Hippocrates that there are ills, no less dreadful than those of repletion, arising from deficiency of diet. Twentieth century medicine has had its attention attracted to such deficiency disorders in striking ways. It is being admonished that, "in a land literally flowing with milk and honey, several million children in the public schools suffer from malnutrition." Peterson advanced the thesis that neurasthenia, a common ailment having a professionally unpopular designation, has failed to receive the critical consideration which its widespread occurrence dictates, and that it deserves to be studied from the standpoint of nutrition and fatigue. As if to point a promising direction for the desired research, the neurologist remarks: "We are just beginning to realize that the calories have gone out and the vitamins have come in." One who has read these columns of The Journal in recent years must admit that the newly recognized food factors have found consideration and that the promise which they hold for the advancement of practical therapy has not been overlooked. Mendel[4] has well remarked, however, that we are living in a period of hectic anticipation of novelties, when much is expected of science; and the momentary enthusiasm for the new is apt to bring about indifference to the old. The fact is that the appreciation of the calory idea in nutrition has not gone out but, on the contrary, has become a permanent part of everyday science. Lest we forget, it may be worth while to recall what an adequate appreciation of the energy factor means for present-day medicine. Basal metabolism and its variations in disease are measured in terms of calories. The formerly unappreciated large food fuel needs of the growing child are dealt with in the same terms. As Mendel has expressed it, the better appreciation of the nutritive needs of those destined to become the rank and file of our nation when they are grown up—an appreciation based alike on experimental studies and on statistical data as to food habits—is not the least of the contributions which the science of nutrition has made to public welfare during the last decade. The food dictators of the future will no longer be excused if they estimate the food needs of peoples in the once conventional terms of "man values" wherein the requirements of the child population were calculated as a fraction of the adult needs proportional to the smaller weight and stature of the young. The high-calory diets in fevers have revolutionized the management of the typhoid patient in determinable ways. The reduction of obesity has become an experiment in rational low-calory feeding.

Association News

COUNCIL ON PHYSICAL THERAPY

Report of Organization Meeting

The Council on Physical Therapy held its first meeting, for organization purposes, at the headquarters of the American Medical Association on Friday, October 16. The Council is composed of two physicists, four clinicians, two physiologists and two pathologists.

There were in attendance at the meeting: Dr. W. T. Bovie, assistant professor of biophysics, Harvard University, Boston; Dr. Arthur Compton, professor of physics, University of Chicago; Dr. Ralph Pemberton, internist, Philadelphia; Dr. Harry E. Mock, assistant professor of surgery, Northwestern University Medical School, Chicago; Dr. Arthur U. Desjardins, department of radium and roentgen-ray therapy, Mayo Clinic, Rochester, Minn.; Dr. George Miller MacKee, associate professor of dermatology and syphilology, Columbia University College of Physicians and Surgeons, New York; Dr. W. B. Cannon, professor of physiology, Harvard Medical School, Boston; Dr. A. S. Warthin, professor of pathology, University of Michigan, and Dr. Francis Carter Wood, pathologist, director of the Institute of Medical Research, Columbia University, New York; also the ex-officio members: Dr. Olin West, Secretary and General Manager of the Association, and Dr. Morris Fishbein, Editor.

The major portion of the discussion was devoted to the scope of the work of the Council and methods of procedure. Three committees were appointed: (1) committee on organization; (2) committee on education; (3) committee on field, scope, nomenclature and present status of physical therapy. The last mentioned committee will have charge of the preparation of a series of fundamental reports on therapeutic methods and on the apparatus used for carrying out such methods. These three committees are to formulate reports for presentation at an early meeting of the Board of Trustees.

Ovarian Extract Useless as Therapeutic Agent.—The commercial preparations of ovary and parathyroid at present on the market are, according to the majority of competent observers, physiologically inactive, and in all probability useless as therapeutic agents. In the case of both these organs (as also of the pancreas) some special method of extraction is necessary in order to obtain a preparation containing the active principle.—Vincent, Swale: *Proc. Royal Soc. Med.* **18**:31 (June) 1925.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

Osteopaths Cannot Be School Physicians.—The state attorney general's office has notified the state board of osteopathic examiners that school boards could not employ under the state law osteopaths to examine children in the public schools.

Hospital News.—The Kaspare Cohn Hospital, Los Angeles, in planning to build a 200-bed hospital, to be occupied before 1927. Its capacity now is fifty-five beds.——Construction will begin about January 1 on a new $1,500,000 unit to be erected at the Sawtelle Soldiers' Home. The new building will provide accommodations for 700 beds.

Illegal Practitioners Fined.—Andrew H. L. Kikkert, Pasadena, was found guilty, September 11, of violating the state medical practice act and was sentenced to pay a fine of $100 or in lieu thereof to serve thirty days in the county jail. W. Roy Graham, an unlicensed chiropodist, Alhambra, was found guilty of the same charge, August 24, and was sentenced to pay a fine of $100. Both fines were paid.

Appointments to State Board of Medical Examiners.—Governor Richardson appointed, October 7, Dr. Wilburn H. Smith, Los Angeles, a member of the state board of medical examiners to succeed Dr. Robert A. Campbell, Los Angeles, whose term expired, and Dr. Andrew W. Morton, San Francisco, to succeed Dr. Harry E. Alderson, San Francisco. Drs. Percy T. Phillips, Santa Cruz, and Charles B. Pinkham, San Francisco, secretary, were reappointed for four-year terms. Drs. Campbell and Alderson have been members of the board since its organization in 1913.

Lane Medical Lectures.—Dr. Vittorio Putti, professor of orthopedic surgery, University of Bologna, and director, Rizzoli Institute of Bologna, will lecture at Lane Hall, Stanford University Medical School, Sacramento Street, San Francisco, 8:15, November 9, on (1) "Congenital Dislocation of the Hip"; (2) November 10, "Arthroplasty—History and General Considerations"; (3) November 11, "Arthroplasty—Technic"; (4) November 12, "New Conceptions of the Pathogenesis of Sciatic Pain"; (5) November 13, "The University of Bologna in the History of Medicine."

DELAWARE

Arm Band for Whooping Cough Victims.—According to the *Atlantic Medical Journal*, the Delaware State Board of Health recently ruled that all persons having whooping cough would be compelled to wear a bright yellow band around the coat sleeve bearing the words "Whooping Cough State Board of Health." The band is supplied by the state. This preventive measure has been used with success, it is said, in the state of Connecticut and the city of Newark, N. J.

DISTRICT OF COLUMBIA

Personal.—Surg. Gen. Hugh S. Cumming, U. S. Public Health Service, sailed, October 10, for Plymouth, Cherbourg and Bremen.

Society News.—The first meeting of the newly reorganized Society of Dermatologists of Baltimore and Washington will be at the District Medical Society Building, Washington, November 12. Dr. Henry H. Hazen, Washington, has been elected chairman; Dr. Lloyd W. Ketron, Baltimore, vice chairman, and Dr. Harry M. Robinson, Baltimore, secretary-treasurer.

FLORIDA

Malaria Survey.—The U. S. Public Health Service will make an extensive survey in Polk, Hillsborough and Citrus counties of malaria. Headquarters of the investigation will be at Lakeland under the direction of Bruce Mayne, assistant technical engineer, who investigated the malaria situation in this community in 1917. The present survey will require several months.

Dr. Levy Welcomed.—The Hillsborough County Medical Society, Tampa, held a formal welcome, October 6, for Dr.

Ernest C. Levy, who recently accepted the position of health officer of that city. Dr. Levy made a plea for cooperation between the local physicians and his department. Among the guests were Dr. Burdett L. Arms, state health officer, and Dr. Henry Smith of the state board of health.

ILLINOIS

Chiropractor Fined.—H. F. Kovski, Athens, a chiropractor, was found guilty of practicing medicine without a license and fined $100 and costs, October 8. Kovski was recently held to the grand jury on a charge of manslaughter following the death of a child in his office while undergoing "an adjustment," it is reported. No indictment followed.

Dr. Wightman Succeeds Dr. Lowry.—Dr. Grace S. Wightman, Chicago, has been appointed chief of the division of child hygiene and public nursing of the Illinois Department of Health, to succeed Dr. Edith B. Lowry, who held the position on a temporary appointment. Dr. Lowry did not compete in the civil service examination for a permanent appointment. Dr. Wightman was formerly director of the field department of the Chicago Municipal Tuberculosis Sanitarium.

Society News.—At the fifth annual meeting of the Tri-County Medical Society, Monmouth, October 1, Dr. David S. Hillis spoke on "The Use of Forceps in Obstetrics"; Dr. John L. Tierney, St. Louis, "Problems in Cardiovascular-Renal Diseases"; Dr. Vernon C. David, Chicago, "Fractures of the Femur in Children," and Dr. J. H. Hutton, Chicago, "Goiter." Among the other speakers were the Hon. John Lugg, mayor of Monmouth, and Dr. Olin West, Secretary and General Manager of the American Medical Association.

Outbreak of Snakeweed Poisoning.—It is reported that about fifty cases of an obscure ailment and one death occurred a few days ago in the vicinity of Collinsville and Maryville, and that the cause of the outbreak was attributed to the use of dairy products from cows that had eaten snakeweed. It was noted in a family in which there were eleven victims of the disease that the family cow also was sick. An investigation by veterinarians and physicians concluded that the cause of the outbreak was snakeweed eaten by the cows from which the human victims obtained butter and milk.

Entire Medical Society on Hospital Staff.—At the request of the board of directors of Highland Hospital, Belvidere, the Boone County Medical Society became the staff of the new hospital. The president of the medical society, Dr. Alden Alguire, becomes the chief of staff of the hospital; the vice president of the medical society, Dr. Robert B. Andrews, becomes assistant chief of staff; the secretary of the society, Dr. Frank S. Whitman, becomes secretary of the staff of the hospital and every member of the society becomes a member of the hospital staff.

Telephone Information Rules.—The Chicago Medical Society has maintained a telephone information bureau for its members for four years. The policy of the bureau to requests from the public has been not to give out names or recommend physicians. The result, says the official bulletin of the society, is that the bureau does not meet its requirements to the public. The question of changing the policy toward telephone requests for physicians was taken up by the council at its last meeting, which decided to appoint a committee of five to draw up a proposal for placing the Telephone Information Bureau at the disposal of the public. The proposal will be reported to the council, November 10, and will then be submitted, corrected or approved, to the branch societies at their December meetings. It will then be submitted with the replies from the branches, back to the committee, which will report it to the council for final disposition at the January meeting.

Chicago

Spurious Medical Diplomas.—It is reported in official correspondence that a so-called University of Trinity College, Chicago, has conferred the degree of Doctor of Medicine on two Japanese gentlemen and that a similar degree was also recently conferred by Lincoln-Jefferson University. Investigations show that although these so-called universities are "legally chartered," they have no buildings and equipment such as all reputable medical schools possess. The University of Trinity College is not listed in the Chicago telephone directory.

Medical Arts Club Reorganizes.—The Medical Arts Club announces a reorganization with the following officers and directors: president, John S. Nagel; vice presidents, John H. Cadmus, D.D.S., Robert H. Hayes; secretary, Frederick R. Green, and treasurer, William Allen Pusey. The new board of directors includes Drs. John S. Nagel, Robert H. Hayes, Hugh N. MacKechnie, J. H. Walsh, Charles E. Humiston, Arthur D. Black, M.D., D.D.S., A. A. Goldsmith, John H. Cadmus, D.D.S., Harry B. Pinney, D.D.S., M. M. Printz, D.D.S., Otto U. King, D.D.S., William Allen Pusey and Frederick R. Green. Plans are being developed looking toward early construction of a permanent home on a downtown site.

Society News.—Dr. James B. Herrick addressed a meeting of the woman's board of the Chicago Heart Association, October 20, on "What Women Can Do to Help in a Campaign Against Heart Disease"; Dr. Walter W. Hamburger on "Some of the Factors in a Comprehensive Cardiac Program," and Dr. Harrold A. Bachmann on "The Child with Heart Disease." Mrs. Morris Woolf is chairman of the woman's board of governors of the Chicago Heart Association; Dr. Herrick is president of the Chicago Heart Association.——Sir William Arbuthnot Lane, London, England, will address the Chicago Medical Society, November 4, on "Present Treatment of Fractures," and Mr. Philip Franklin, London, on "Newer Developments in Laryngology."——Dr. Malcolm L. Harris, chairman of the Judicial Council of the American Medical Association, was installed as president of the Chicago Medical Society at a banquet in the Hotel LaSalle, October 14.——Prof. Alfred N. Richards, Ph.D., professor of pharmacology of the University of Pennsylvania School of Medicine, Philadelphia, will address the Chicago Society of Internal Medicine and the Institute of Medicine of Chicago, at a joint meeting at the City Club, October 26, on "Experiments Concerning the Nature of the Function of the Kidney." There will be a dinner preceding the meeting in honor of Professor Richards.

Postgraduate Instruction at Rush.—A great program of postgraduate medical training is being developed in the new buildings of Rush Medical College and in the Presbyterian Hospital, Central Free Dispensary, John McCormick Memorial Institute for Infectious Diseases, the Children's Memorial Hospital, the Home for Destitute and Crippled Children, the Cook County Hospital, and the Country Home for Convalescent Children. Rush will take a prominent part in this program with three major objectives: (1) To afford recent graduates an opportunity to carry on research; (2) to provide clinics to enable practitioners to specialize, and (3) to provide intensive clinics conducted by leaders from one to three weeks to furnish review courses for general practitioners. For several years it will be necessary to carry on the last two years of undergraduate work of the University of Chicago medical schools at Rush Medical College. The new Rawson Building, occupying the site of old Rush College, has been completed; the laboratory building on Harrison Street has been reconstructed for clinical investigation and research, and a new program of development is in progress at the Presbyterian Hospital. The University of Chicago has furnished for about twenty-five years the buildings, equipment and teachers for the premedical courses and the first two years of medical training at Rush at a cost of about $250,000 annually, and in the campaign for medical funds in 1916-1917, Mr. Rawson, the late Dr. Bridge and others gave large sums for west side improvements. The university has underwritten a deficit of $170,000 in the construction of the Rawson Building and contributed $25,000 to the Rush budget for the current year. The Rush Alumni Association is a department of the alumni council of the university. The Rush alumnus has all the rights and privileges of alumni of the University of Chicago. It is natural that he should be loyal to the program of development of the university's medical schools. The number of Rush alumni is about 4,696, of whom 545 have subscribed to the development fund $155,632. There remains to be raised about $95,000 of the amount which the Rush Alumni Association agreed to secure. Dr. Ralph W. Webster, '98, Chicago, is president of the Rush Alumni Association; Dr. Charles A. Parker, '91, Chicago, secretary, and Dr. Carl O. Rinder, '13, Chicago, treasurer.

INDIANA

Children's Hospitals Meeting.—Dr. Isaac A. Abt, professor of diseases of children, Northwestern University Medical School, Chicago, addressed the children's hospitals meeting at the James Whitcomb Riley Hospital for Children, Indianapolis, October 24, on "Prophylaxis of Contagion in Children's Hospitals," and Dr. Howard C. Carpenter, Philadelphia, on "The Children's Hospital as a Community Center for Health

Teaching." Dr. Vilray P. Blair, associate professor of clinical surgery, Washington University School of Medicine, St. Louis, held a clinic on plastic surgery of the face, and Dr. Abt on acute and subacute conditions in children's diseases. There was a round table discussion in which hospital superintendents and chiefs of departments of hospitals took part.

KANSAS

Personal.—Dr. Martin V. Robbins, Cherryvale, has been placed in charge of the medical department of Armour and Company and the Fowler Packing Company of Kansas City. Dr. Robbins was formerly on the medical staff of Morris and Company before the Armour-Morris merger.——Dr. John O. Murrin has been appointed physician to the State Orphans' Home at Atchison to succeed Dr. Virgil Morrison.

KENTUCKY

Society News.—At a recent meeting of the Third District Medical Society in conjunction with the Barren County Medical Society, at Cave City, Dr. John D. Trawick, Louisville, spoke on "Kentucky's Crippled Children"; Dr. Herbert H. Hagan, Louisville, on "Conservative Treatment of Head Injuries," and Dr. William A. Weldon, Glasgow, on "The Use and Abuse of Atropin by the General Practitioner."

State Medical Election.—At the annual meeting of the Kentucky State Medical Society, Louisville, Dr. Robert L. Woodard, Hopkinsville, was installed as president; Dr. Irvin Abell, Louisville, was made president-elect, and Drs. James T. Reddick, Paducah, Thomas E. Craig, South Park, and William P. Cawood, Harlan, vice presidents; Dr. Harry A. Davidson, Louisville, delegate to the American Medical Association; Dr. James A. Orr, Paris, orator in medicine; Dr. Charles C. Garr, Lexington, orator in surgery, and Dr. Arthur T. McCormack, secretary (reelected). The next annual meeting will be at Frankfort.

MASSACHUSETTS

Personal.—Dr. John H. Gibbon, Philadelphia, delivered the annual address on the seventy-ninth anniversary of Ether Day at the Massachusetts General Hospital, Boston, October 16.

Pioneer Work in School Clinics.—Massachusetts established by law, a few years ago, school clinics throughout the state for the mental examination of every child who was three years or more retarded in the public schools. The object was to discover mentally defective children and to provide for them a kind of training that would make them self-supporting and safe members of society. Fourteen clinics have been established and in the last five years about 15,000 children examined. The examinations are not compulsory; 121 municipalities have requested the examination and 116 municipalities have thus been examined. Special classes are formed for these children and, according to the director of the division of feebleminded of the state department of mental diseases, no schools have discontinued these classes once they are formed.

MICHIGAN

Gift for Health Center.—Announcement has been made of the gift of $75,000 by Mrs. Leopold Wineman for the purpose of converting the North End Clinic in Detroit of the United Jewish Charities into the Wineman Memorial Health Center. The institution will be built on Holbrook Avenue near Oakland, and ground will be broken within a few weeks.

Hospital News.—A psychopathic hospital costing about $100,000 is being built at Ann Arbor as a unit of St. Joseph's Mercy Hospital on an 80-acre estate, 1½ miles from the city. It will accommodate fifty patients, and Dr. Theophil Klingmann will be the director.——Plans are being made for a $3,000,000 addition to the Herman Kiefer Municipal Hospital, Detroit.

Tuberculosis Clinic.—Twenty-nine members of the Berrien County Medical Society at Niles endorsed plans, September 17, for a permanent tuberculosis clinic in Berrien County presented by the County Tuberculosis Association. According to arrangements, a tuberculosis clinic will be held monthly, alternating in St. Joseph and Niles, and the cost will be covered by the Michigan State Tuberculosis Association. Dr. Benjamin A. Shepard, Kalamazoo, will conduct the clinics. At the conference in Niles, Dr. Samuel W. Becker, Mayo Clinic, Rochester, Minn., spoke on "Pernicious Anemia"; Dr. Milo K. Miller, South Bend, Ind., on "Chest Conditions in Children," and Dr. Harry L. Cooper, South Bend, on "The Value of Routine Physical Examinations."

MINNESOTA

Dr. Berglund Elected Professor of Medicine.—The University of Minnesota announces the election of Dr. Hilding Berglund, a native of Sweden, as professor and head of the department of medicine to succeed Dr. S. Marx White, who will devote his full time to private practice. Dr. Berglund came to this country in 1920 to study under Dr. Folin at Harvard University, and since 1923 has been assistant professor of medicine in Harvard University Medical School and an associate in medicine at the Peter Bent Brigham Hospital, Boston.

MISSOURI

Court Orders License Restored.—A circuit court judge in St. Louis ordered the Missouri State Board of Health, October 5, to restore the license to practice medicine of Dr. Walter E. Abell. The court held, it is reported, that Dr. Abell had satisfactorily completed his medical course, contrary to the findings of the board last August.

Ruling on Liquor Reversed.—The ruling of a county court prohibiting physicians who have state and federal liquor permits from having liquor in their offices was reversed in circuit court at Bloomfield, September 23, in the case of Dr. Dawsey Ryan of Bernie. Dr. Ryan, it is reported, was arrested and fined for having liquor in his office after the county had withdrawn the liquor permits of all physicians; he appealed, claiming that his state and federal permits allowed this privilege despite the rule of the county court. The court of appeals at Springfield reversed the decision and the case was dismissed.

Society News.—Dr. William Engelbach addressed the St. Louis Medical Society, October 13, on "Treatment of Ductless Gland Disorders Having Their Chief Complaints Referable to Other Systems."——The Jackson County Medical Society, Kansas City, October 13, held a symposium on the use of serums and vaccines in the contagious diseases of childhood, Dr. Charles J. Eldridge discussing infantile paralysis; Dr. Joseph B. Cowherd, diphtheria; Dr. Harry M. Gilkey, whooping cough; Dr. John Aull, scarlet fever, and Dr. Frank C. Neff, measles.——More than 1,000 physicians attended the annual fall conference of the Kansas City Clinical Society and the Medical Association of the Southwest, October 5-9. Among the visiting physicians on the program were Drs. William J. Mayo, Rochester, Minn.; Alexander Lambert, Benjamin S. Barringer, Russell A. Hibbs and John E. Weeks, all of New York; Arial W. George, Boston; Charles F. Hoover, Cleveland; Robert C. Coffey, Portland, Ore.; John O. Polak, Brooklyn; Roy B. Canfield, Ann Arbor, Mich., and Hugh T. Patrick and Isaac A. Abt, Chicago. Dr. Frank D. Dickson is president of the clinical society and Dr. Edward H. Skinner director of the clinics.

New York City

Postgraduate Course in Physiotherapeutics.—Columbia University offers a six weeks' clinical course in physiotherapeutics, with lectures, for graduates in medicine from November 9 to December 18, at the Beekman Street Hospital. The course will be limited to ten members and will not be given unless five applications are received. The aim is to include such work as to qualify students to practice the different forms of physiotherapy. The fee is $200, payable in advance. Communications should be addressed to the dean of the School of Medicine, 437 West Fifty-Ninth Street.

Academy Retires Librarian.—After forty-four years of service as librarian at the New York Academy of Medicine, Mr. John S. Brownne has been retired from active duty with the title of consultant librarian. In appreciation of his courteous and faithful service, a committee presented to Mr. Brownne a purse raised among the members and a beautifully engrossed resolution. The library has grown, during Mr. Brownne's term, from 10,000 volumes to 138,000 books and 100,000 pamphlets, and the staff from one to seven members; his most notable service was the development of the General Library Fund from nothing to about $42,000.

Clinics for General Practitioners.—The Hospital for the Ruptured and Crippled has arranged clinics especially for general practitioners, to be held the second and fourth Wednesdays of the month at 4 o'clock from October to May. Visiting physicians may examine the cases and confer with the surgeon in charge of the clinic in regard to any orthopedic condition. Notices of the meetings will be mailed on request to Joseph D. Flick, superintendent of the hospital, 321 West Forty-Second Street. The October 28 clinic will be given by Dr. Richmond Stephens, assisted by Dr. Toufick Nicola on (1) "Delayed Union of Fractures," (2) "Osteomyelitis," (3) "Rachitic Deformities" and (4) "Paralytic Deformities of the Feet."

Hospital News.—A group of physicians and business men will construct at once the "Park West Medical Building" on Seventy-Sixth Street just east of Amsterdam Avenue, which will open May 1, 1926, and be, it is said, the first private general hospital on the West Side with certain advantages announced. The building will be eight stories high, fire and noise-proof, with a capacity of seventy-eight patients and for general use except contagious diseases. About twenty-five physicians are intimately interested in the project, but the service and equipment will be at the disposal of all ethical physicians. The project has been financed by S. W. Straus & Company, and will cost $250,000.——The president of the Knickerbocker Hospital announced, October 3, that the new $500,000 building on Convent Avenue will be ready for occupancy Nov. 1, 1926, and that about half of the funds needed for its construction is now available. An entire floor in the new building will be devoted to the dispensary department.——Miss Mable Davies, who was decorated by the British and French for work as a nurse during the World War, has been appointed superintendent of the Beekman Street Hospital.——The Lutheran Hospital, Brooklyn, will soon begin the construction of a $700,000 service building.——The annual appeal of the United Hospital Fund will occur during Thanksgiving week. The fund will undertake to raise $1,000,000 to help care for persons unable to pay for treatment in its fifty-six nonmunicipal hospitals.——The cornerstone of the new Downtown Community House, 107 Washington Street, was laid, October 1. This organization, according to *New York Medical Week*, practically forms the social service department of the Beekman Street Hospital, there being an interlocking directorate.——The Booker T. Washington Sanatorium, One Hundred and Thirty-Eighth Street and Seventh Avenue, will move shortly to One Hundred and Thirty-Seventh Street and Edgecomb Avenue, where it has purchased two brick buildings.——The Bronx Hospital will conduct a campaign for $1,000,000 for a new building, November 10-20.——A new fireproof extension, accommodating twenty-eight patients, has been added to the Bay Ridge Sanatorium.——The Metropolitan Hospital of the Department of Public Welfare celebrated its semicentennial at the Hotel Plaza, October 15.

NORTH CAROLINA

Change of Date of Meeting.—The Medical Society of the State of North Carolina announces that the house of delegates has voted to change the place and time of the next annual meeting from Wilmington, April 20-22, to Wrightsville Beach, June 15-17. A new board of medical examiners will be elected at this session.

OHIO

Report of Medical Board.—Among the items in the annual report of the state medical board for the year ending June 30, 1925, is that the board licensed by examination in the last year 255 physicians and surgeons and by reciprocity 106. Applications for license were rejected on examination to twenty-three and on reciprocity to one. The board which has only two inspectors for the state in its enforcement division, in the last year investigated 425 cases, of which 159 were brought to arrest and of these 110 convicted; three of these cases were still pending and fifteen have been dismissed. During the same period twenty-six violators of the medical practice act left the state to avoid arrest and forty-five others ceased practice.

Stream Pollution Board.—A law became effective in July authorizing the state department of health to organize a stream pollution board. Already most of the municipalities and basic industries which contribute toward the pollution of streams and lakes have been organized into groups and the problems facing each group presented to them. Group meetings were held throughout the summer bimonthly and groups which have already organized to eliminate industrial waste and sewage include cities and the steel, dairy, paper and chemical industries and mines. The law authorizes the state health department to appoint a representative of cities, industries, agriculture and of sportsman groups to serve as a member of the state stream pollution board. The remainder of the board is made up of the members of the state public health council and it is empowered to study streams and lakes and classify them according to their importance as sources of water supplies and to map out definite plans for the gradual elimination of pollution. Before a city, industry or individual begins construction of additions to existing plants or new drainage systems, the plans must now first be submitted to the state board of health and be approved.

Medical Defense.—Since the Ohio State Medical Association placed its medical defense plan in operation in 1916 there had been 122 suits and ninety threats filed with the committee up to August 20, and the total cost of the plan had been $12,947.68. A report of the Medical Defense Council, July 1, showed that there were then twelve suits pending. Defense is not granted to a member of the state association who does not forward his application blank to its office within ten days after the service of summons, nor to physician who do not keep on file roentgenograms in fracture cases when alleged malpractice arises for such a case, or for a physician who has brought a "cross complaint" by suing to collect a bill within one year of the termination of his services. In a summary of the malpractice situation, the *Ohio State Medical Journal* assigns the increase in malpractice suits to such causes as careless remarks of other physicians, economic need (more suits are filed by the indigent) ambulance chasing lawyers, professional jealousy, and greatest of all the uncontested settlement of nuisance suits. The number of malpractice suits and threats in Ohio has remained about the same the last five years owing, it is said, chiefly to the plan of fighting to the finish and to the fact that physicians have grown more careful in their comments.

Cincinnati's Negro Health Problem.—The death rate last year among Cincinnati's negroes was almost double that among its white population; in the previous year the death rates were 15.1 and 26.3 per thousand inhabitants, respectively, and in 1922, 14.2 and 22.5. While the negroes of Cincinnati constitute only about 9 per cent. of the population, they contribute 28 per cent. of the deaths from tuberculosis; more than four times as many colored people as white people die of tuberculosis per thousand population. Of the colored children, almost three times as many of them die during the first year of life as among the white children. Negroes contributed more than 70 per cent. of the smallpox in the city last year; yet in one school (the Harriet Beecher Stowe School, which is exclusively for colored children) there was no smallpox because the children had been vaccinated. The board of health recently considered the negro health problem, and with its recommendation there has been started the Michael W. Shoemaker Health Center for negroes, conducted under the auspices of the Public Health Federation and the Negro Civic Welfare Association. The health activities of the center have been placed in the hands of a committee which will cooperate with the college of medicine and the department of health, and as the institution grows general clinics will be established.

OKLAHOMA

Personal.—Dr. Carroll M. Pounders has been appointed medical inspector of Oklahoma City schools.——Dr. John M. Dodson, executive secretary, Bureau of Health and Public Instruction, American Medical Association, will address the Oklahoma County Medical Association, October 24, on "The Work of the A. M. A. Headquarters," and on the preceding day addressed the Oklahoma Public Health Association at the Skirven Hotel, Oklahoma City.——Dr. George Boresky has resigned as assistant city physician of Oklahoma City.

PENNSYLVANIA

Pay for Repeated Vaccinations.—The state board of health informed the Huntsville Board of Health, October 6, that in instances in which there have been two previous unsuccessful vaccinations, the third vaccination must be done at the expense of the city.

Personal.—Dr. John A. Biever has been reelected president of the board of health of Columbia.——Dr. Edward B. Heckel has been elected president of the Pittsburgh Ophthalmological Society for the fourteenth consecutive year.——Dr. Clifford C. Hartman has been reappointed editor of the *Pittsburgh Medical Bulletin* of the Allegheny County Medical Society.

Slit-Lamp Society.—The Pittsburgh Slit-Lamp Society was formally organized, October 12, for the purpose of promoting the study of slit-lamp microscopy of the eye. Dr. William W. Blair, professor of ophthalmology, University of Pittsburgh School of Medicine, was elected president; Dr. George H. Shuman, secretary, and Dr. Adolph Krebs, treasurer. The society will meet monthly.

County Society Clinic.—More than 100 physicians attended the annual clinic of the Fayette County Medical Society, Uniontown Hospital, Uniontown, October 1. Dr. R. H. Jeffrey, the president, presided; among the speakers were Dr. David Riesman, professor of clinical medicine, and Dr. George P. Muller, professor of clinical surgery, both of the University of Pennsylvania. Dr. Muller also spoke at the banquet on "Newer Methods of Pedagogy at the University of Pennsylvania Medical School."

Hospital Room for Teachers.—The late Simon Gratz, formerly president of the board of education of Philadelphia, set aside in his will $50,000 to establish a private room in Jefferson Hospital for the use of school teachers free of charge. Mr. Gratz bequeathed to the trustees of the hospital $7,000 to be awarded to the graduate who is adjudged as having done within five years from graduation the most in the advancement of medical or surgical treatment of disease or in research work; also a bequest of $15,000 to Jefferson Hospital to establish three beds as a memorial to his mother, aunt and sister, and $5,000 to establish a bed as a memorial to his wife.

Society News.—Dr. Robert H. Ivy, professor of maxillofacial surgery, University of Pennsylvania Graduate School of Medicine, Philadelphia, addressed the September meeting of the Dauphin County Medical Society on "The Surgery of Facial Deformities."——Dr. Jesse O. Arnold, clinical professor of obstetrics, Temple University Department of Medicine, Philadelphia, addressed the Fayette County Medical Society, Uniontown, on "The Challenge of Higher Ideals in Practical Obstetrics."——Dr. Ulrich D. Rumbaugh addressed the Luzerne County Medical Society recently on "Toxemia of Pregnancy."——Sufficient funds have been pledged to the Fayette County Medical Society to assure the completion of its new home.——Dr. John H. Stokes, professor of dermatology and syphilology, University of Pennsylvania School of Medicine, Philadelphia, addressed the Northampton County Medical Society, Bethlehem, October 16, on "Skin Diseases."——Dr. Cortlandt W. W. Elkin, Pittsburgh, addressed the Allegheny County Medical Society, October 20, on "The Present Conception of Acidosis."

Philadelphia

Fees for Testimony.—Judge Joseph H. Taulane, of the court of common pleas, has ruled that a physician subpenaed in a court case to testify must do so under the same conditions and for the same fee as paid to other witnesses. If, however, a physician is called to give expert testimony he is entitled to a larger fee.

Popular Science Lectures.—The Philadelphia College of Pharmacy and Science, which recently opened its one hundred and fifth session, will give a series of thirteen popular science lectures at the Y. M. C. A. on alternate Thursday evenings, beginning October 8, which will be broadcasted in abstract form on the following Saturday evening from Station WIP.

Professor Janet Holds Clinic.—Dr. Pierre Janet, professor of psychopathology in the Collège de France, Paris, held a clinic at the Philadelphia General Hospital, October 12, and the following day addressed graduate students of the department of psychology at the University of Pennsylvania; a reception in his honor was given at the home of Dr. S. DeWitt Ludlum, professor of psychiatry, Graduate School of Medicine, University of Pennsylvania. Dr. Janet has been in Mexico as an exchange professor.

Sesqui-Centennial Fund Oversubscribed.—The campaign to raise $3,000,000 by the sale of participation certificates to expedite the construction of buildings for the Sesqui-Centennial celebration went over the top, October 10, the total amount subscribed having been exceeded on that date by about $6,000. The campaign to raise funds started ten days ago and a number of prominent physicians of Philadelphia took part (The Journal, October 17, p. 1232).

Child Guidance Clinic Opened.—An organization known as the All-Philadelphia Child Guidance Clinic has been established with headquarters at 1711 Fitzwater Street, prepared to spend $100,000 in the interest of children's welfare. The funds are being furnished by the New York Branch, which plans a permanent clinic here at the end of two years to assist children presenting problems in behavior and personality. Dr. Frederick H. Allen, formerly resident psychiatrist at Johns Hopkins University, is director of the clinic.

RHODE ISLAND

No Essays on Plastic Surgery.—In the ninetieth annual report of the Fisk Fund to the Rhode Island Medical Society, the board of trustees reported that no essays were submitted for the 1925 prize, the title offered being "Plastic Surgery." The trustees offer for 1926 a prize of $300 for the best essay on "Recent Progress in the Prevention and Treatment of Scarlatina, Measles and Diphtheria."

Dr. Coll's License Revoked.—The secretary of the state board of health writes that the license to practice medicine and surgery in Rhode Island of Dr. James P. Coll was revoked, September 24, on charges of (1) gross unprofessional conduct, (2) conduct of a character likely to deceive and defraud the public, and (3) deception in obtaining certificate. The only James P. Coll of which the American Medical Association has a record was located at Blandford, Mass., and is said to be the head of the Electro-Medical Doctors' Institute at Springfield, Mass. He was found guilty, Sept. 15, 1924, in the district court of Massachusetts of practicing medicine without a license (The Journal, Aug. 16, 1924, p. 539, and Oct. 4, 1924, p. 1084).

SOUTH CAROLINA

Personal.—Dr. Roderick MacDonald, Blackstock, Fairfield County health officer, has resigned and will go to Philadelphia, October 1, to take up postgraduate work.——Dr. George D. Heath, physician to the Clemson College, Clemson, for more than four years, has resigned to take special work at Johns Hopkins University, Baltimore.

Society News.—At the annual meeting of the Seventh District Medical Association, Sumter, September 10, Dr. Henry M. Stuckey, Sumter, was elected president and Dr. Carl B. Epps, Sumter, secretary-treasurer. Dr. Robert S. Cathcart, Charleston, president of the South Carolina Medical Association, spoke on subjects pertaining to the state association, and among others, Dr. Richard M. Pollitzer, Greenville, on "Acute Poliomyelitis; with Case Reports"; and Dr. Stewart R. Roberts, Atlanta, Ga., on "The Classification of the Blood Pressures." The next annual meeting will be at Kingstree the second Thursday in September, 1926.

TEXAS

School for Sanitarians.—Under the auspices of the Texas Association of Sanitarians, the annual short school for sanitarians, met in Waco, October 7-10, under the direction of W. Alfred Buice, professor of public health, Baylor University, and the presidency of Dr. Arthur H. Flickwir, Houston. Among the lecturers were Elliot H. Gage, U. S. Public Health Service, and Dr. Clarence S. Drake, Chicago.

Reserve Officers on Duty.—Forty-one army medical reserve officers recently completed fifteen days of active duty with the Second Medical Regiment of the regular army at Fort Sam Houston. Among other duties was the actual physical examination of about 1,100 applicants for entrance to the citizen's military training camp at Fort Sam Houston; in conjunction with regular army officers, the forty-one reserve officers examined about 300 boys per hour.

Freshman Class at Texas University.—The dean of the University of Texas Department of Medicine, Galveston, writes that there were 113 applicants for admission to the freshman class this year, which was limited to sixty, and that selections were made on a scholarship basis. The lowest general average of any freshman in his premedical college work was 75. The selections are made, August 10, and Texans are given preference. The medical school has just opened a new $300,000 laboratory building.

WEST VIRGINIA

Court Ruling on Term of Health Officers.—The attorney general has ruled that county health officers cannot remain in office after their terms have expired until their successors are appointed, and that the county court has no authority to pay any salary to a health officer after the expiration of his term. The ruling was made in the case of Dr. Joseph R. Hughart, health officer of Monongalia County, whose term expired, June 30, and who has since been acting as health officer, although not reappointed.

PHILIPPINE ISLANDS

Committee on Treatment of Leprosy.—The clinical investigation of leprosy at the San Lazaro Hospital, Manila, is carried on by a committee, which keeps a record of each patient, noting the treatment given, the course of the disease and the final outcome. The committee has recently been reorganized with Dr. Jose P. Bantug, chairman, and Drs. Leoncio Lopez-Rizal, Regino Padua, Manuel V. Arguelles, Samuel Tietze and Proceso Gabriel, members.

Demonstration in Sanitation.—At the recent town fiesta in Santa Ana, Pampanga, members of the Philippine Health Service cooperated with the local health officer in giving a sanitary demonstration by moving pictures which showed the life history of the fly, the diseases it transmits and how to exterminate the fly. A similar demonstration was given of the mosquito. There was a large and enthusiastic audience, some of whom propounded questions on these subjects. The demonstration was accompanied by a discussion of typhoid fever.

Personal.—According to the *Journal of the Philippine Island Medical Association,* Dr. Sulpico A. Chiyuto has been appointed chief of the Culion Leper Colony, effective, Aug. 1, 1925, to succeed Dr. Avellana Basa, resigned.——The Philippine delegates to the Sixth Congress of the Far Eastern Association of Tropical Medicine at Tokio, Japan, October 12-31, were Major Arthur P. Hitchens, Army Research Board, Drs. I. Oto Schobl, Bureau of Science, Agerico B. M. Sison of the College of Medicine, and Leoncio Lopez-Rizal and Cristobal Manalang, both of the Philippine Health Service.

GENERAL

Typhoid Outbreaks.—Recent press dispatches note that outbreaks of typhoid fever have occurred at Hutchinson, Kan., forty-five cases (October 6); at Kingston, N. Y., twenty-two cases and four deaths (September 24); at Montgomery, Pa., twenty-eight cases and one death (October 5); at Bridgeville, Pa., fourteen cases (October 7), and at Barnsboro, N. J., twelve cases (October 10).

Travel Study Club.—The Travel Study Club of American Physicians has decided on a 1926 study tour to London, Paris, Switzerland, Munich, Vienna and Berlin. The tour will be limited to members and friends recommended by them. Dr. Louis L. Seaman and Dr. Richard Kovacs, New York, were reelected as president and secretary-treasurer, respectively, at the ninth annual reunion of the club, and Drs. Edward B. Heckel, Pittsburgh, John P. Lord, Omaha, and Fred H. Albee, New York, vice presidents.

Commission on Medical Education.—The commission initiated by the Association of American Medical Colleges to survey medical education in the United States met at Buffalo, October 19, and elected A. Lawrence Lowell, president of Harvard University, Cambridge, Mass., chairman; Dr. Willard C. Rappleye, director of study, and Dr. Fred C. Zapffe, Chicago, treasurer. It was decided that the director should collect data and other material bearing on the subject of medical education, and that this material would be studied at a meeting to be called by the director. In furthering the the work of the commission, the Rockefeller Foundation has subscribed $50,000, the Carnegie Foundation $40,000, the medical colleges which are members of the Association of American Medical Colleges $26,000, and the American Medical Association, $15,000.

Academy of Ophthalmology and Otolaryngology.—The thirtieth annual meeting of the American Academy of Ophthalmology and Otolaryngology will be at the Hotel Sherman, Chicago, October 19-24, under the presidency of Dr. Horace Newhart, Minneapolis. The American Board for Ophthalmic Examinations and the National Board of Examiners in Otolaryngology will hold examinations Monday morning, October 19, preceding the opening of the academy, at the Cook County Hospital. There was a list of 123 candidates for fellowship in the academy submitted. The ophthalmologic exhibit was under the direction of Major James F. Cupal, U. S. Army. Joint scientific sessions were held Tuesday and Wednesday mornings, and papers in ophthalmology presented Tuesday afternoon and Thursday morning and in otolaryngology Wednesday and Thursday afternoons. An opportunity at each session was given for the presentation of cases and the demonstration of new instruments. A golf tournament was arranged for October 19 at the Flossmoor Country Club. The usual banquet was held, October 21.

Society News.—At the recent annual meeting of the Association of Military Surgeons of the United States, New York, Surg. Gen. Edward R. Stitt, U. S. Navy, was elected president, to succeed Surg. Gen. Hugh S. Cumming, U. S. Public Health Service; Surg. Gen. Merritte W. Ireland, U. S. Army, Col. Frederick H. Vinup, Maryland National Guard, Asst. Surg. Gen. Claude H. Lavinder, U. S. Public Health Service, and Brig. Gen. William H. Wilmer, Baltimore, vice presidents; Col. Jefferson R. Kean, U. S. Army, retired, secretary, and Major Edgar E. Hume, U. S. Army, treasurer. George E. Vincent, president, Rockefeller Foundation, addressed the association at a dinner at the Waldorf-Astoria, October 9; among the foreign delegates were Medical Inspector General of France J. F. A. Rouget; the medical principal of the French War College, Colonel Speare; Rear Admiral Edward Sutton of England; Dr. Dolybe Coryllos of Greece; Capt. Wao Nagimo, and Commander Kakuenara Marchimo of Japan; Major Giuseppe Rolando of the Royal Italian Navy, and Lieut. Col. Bolidan Hulewicz of the general staff of the Polish army.——All the present officers of the Medical Association of the Southwest were reelected at the recent annual meeting in Kansas City. They are Dr. Truman C. Terrell, Fort Worth, president; Drs. Edgar C. Duncan, Fredonia, Kan.; Clarence B. Francisco, Kansas City, Mo.; Sidney J. Wolfermann, Fort Smith, Ark., and Samuel E. Mitchell, Muskogee, Okla., vice presidents, and Dr. Edward H. Skinner, Kansas City, secretary-treasurer.——At the annual meeting of the National Association of Police and Fire Surgeons, Grand Rapids, Mich., October 7, Dr. Harry M. Archer, New York, was reelected president; Dr. Daniel J. Donovan, New York, vice president, reelected, and Dr. John J. White, New York, secretary, reelected; Dr. Joseph A. Kene, New York, was elected treasurer. The 1926 meeting will be in Philadelphia and the 1927 meeting in Los Angeles.

Campaign to Endow a Home for Physicians.—The directors of The Physicians' Home, Inc., announce the opening of a campaign to endow a national home for aged and incapacitated physicians. Dr. Charles H. Mayo, Rochester, Minn., is head of the Committee of Sponsors, who will be in charge of the campaign, and the American Medical Association has endorsed the project. The general plan, as outlined by the president of the Physicians' Home, Inc., Dr. Robert T. Morris, formerly president of the American Association of Obstetricians and Gynecologists and professor of surgery emeritus, New York Post-Graduate Medical College, is to care for at least 1,000 physicians at the national home and a very much smaller number in units to be established in other parts of the country. The total amount sought in the campaign for the home will probably be several millions of dollars so as to guarantee the upkeep of the main institution and the smaller units. The Physicians' Home, Inc., is not an experiment. One unit was established four years ago at Caneadea, N. Y., through the generosity of Dr. Stephen V. Mountain of Olean. He donated a twenty-eight room building on a 186 acre farm on the Genesee River in central western New York. This has been successful and it becomes the duty of the directors to enlarge the enterprise. There is a large waiting list for admission which cannot be accommodated at the Caneadea unit. This is the first movement of its kind in this country to sustain an institution which will care for members of the medical profession who through illness, age, generosity or devotion to science are unable in their declining years to provide for themselves and their dependents. The campaign will be a dignified effort on the part of the profession to take care of its own needy ones, and the appeal for funds will be made to the public. Funds will be secured through the organization of groups in various localities. The campaign will be in charge of Mr. Charles Capehart and Mr. James F. McGrath, and the national headquarters are on the twenty-second floor of the Times Building, Forty-Second Street and Broadway, New York, where inquiries should be sent. Checks should be drawn to the order of "The Physicians' Home, Inc.," and forwarded to Dr. Albert G. Weed, national secretary, at the address given above.

LATIN AMERICA

Personal.—On the retirement of Prof. Azevedo Sodré from the chair of clinical medicine at Rio de Janeiro, after forty-one years' incumbency, a commemorative tablet was unveiled with much ceremony and many tributes in the Misericordia hospital. He is director and editor of the *Brazil-Medico.*——The Argentine Academy of Medicine recently elected to honorary membership Profs. P. Duval and L. Bernard, of Paris, and Prof. Rio del Hortega, Madrid, as corresponding member. The three have been lecturing in the eastern Atlantic states of South America.

University Exchanges Between Argentina and Austria.—The *Münchener medizinische Wochenschrift* quotes the details of the recent arrangement between Rosario and Vienna providing for interchange of professors. Each is to remain a year or longer but is not entitled to practice. Each Vienna professor is to be given traveling expenses, a home in the Centenario Hospital and 300 pesos. The Rosario professor gets the equivalent of this except the traveling expenses. It is stipulated that the Vienna professors must be able to speak Spanish, Italian or French and the Rosario professors German or French. Interchange of students is also contemplated later.

FOREIGN

New Medical Journal.—The first number of *The Post-Graduate Medical Journal,* the official organ of the Fellowship of Medicine, contains, among other things, an article by Sir Humphry Rolleston on "The Medical Aspects of Gallstones," and a supplement giving the program for 1925-1926 of postgraduate instruction in London. It is published in London and communications should be addressed to 1 Bedford Street, W. C., 2.

The Fight Against Malaria in Italy.—An exhibition was held recently at Naples showing the work accomplished in redeeming the marshes in Italy. Nearly four million acres have been drained—about two thirds of this since the war. Six pavilions housed the exhibition showing conditions before and after the draining operations. Count Camillo Valle is chief of the Federazione Nacionale delle Bonifiche, which centralizes the forces of private, communal and national efforts in this line.

Personal.—Dr. Esther Gimson-Bare, superintendent of the Clara Swain Hospital, Bareilly, India, a medical missionary from the Methodist Church since 1904, has been awarded by King George the Kaisar-I-Hind Medal for conspicuous service to the British Empire.——Sir Humphry Rolleston, president, Royal College of Physicians of London, and Regius professor of physic, Cambridge, gave the introductory address at the opening of the winter session of the University of Durham College of Medicine, Newcastle-upon-Tyne, October 6, on "Physic and Poetry."——Dr. William Hill, London, gave the opening address of the winter session at the Central London Throat, Nose and Ear Hospital, October 6, on "Practice at the Central in the Late Eighties."

Director of Obstetric Research.—The Council of the University of Melbourne, Australia, has announced that it will appoint a director of obstetric research for two years at a salary of £2,500 per annum with funds donated by the Edward Wilson "Argus" Trustees. The successful candidate for the position will be required, says the *British Medical Journal,* to devote his whole time to obstetric research, to make a survey of obstetric work in Victoria, to investigate the causes of maternal mortality and morbidity in the state of Victoria, and to promote methods for their prevention and treatment. He will also investigate methods of teaching obstetrics, the condition of obstetric practice in hospitals and rural districts and the condition of postgraduate study and prenatal work. The university has appointed a special committee representing the faculty and the Victorian Branch of the British Medical Association which will cooperate with and assist the director.

Course in Ophthalmology in the Chinese Language.—An epochal event occurred early this year in the history of medicine in China with the giving of the first postgraduate course in ophthalmology in the Chinese language at the Peking Union Medical College, Peking. Dr. Harvey J. Howard, head of the ophthalmology department, writes in the *American Journal of Ophthalmology* that the course was carried on under the direction of Associated Professor Tsing-Meu Li, assisted by four junior members of the staff. The course was in the northern mandarin dialect. All teaching at the college has been carried on in English, but there was such a demand for instruction in Chinese that this course was undertaken as an experiment. Nineteen physicians took the course and there were far more applications than could be accepted. Nine of the eighteen provinces in China were represented in the class. The plan now is to alternate the customary Chinese New Year's course by giving it one year in English and the next in Chinese.

Medical Congresses of the Northland.—The fourth congress of tuberculosis specialists of the Scandinavian countries was held at Stockholm in August. One afternoon was devoted to a discussion of "Sanocrysin," and the *Norsk Magazin for Lægevidenskaben* says that the general impression was a disappointment. The indications for "Sanocrysin" have been restricted more and more.——The fourteenth internal medicine congress was held at Stockholm at the same time. The subject appointed for discussion was "Jaundice and Functional Liver Tests." Prof. I. Holmgren presided and emphasized anew in his address that internal medicine is the "mother science" of all medicine. Scheel said he had studied extensively the various liver tests, and such conflicting results had been obtained with certain ones that he regards them as useless for tests of liver functioning. He specified in this group "the carbohydrate test, amino-acid overloading test, the Hay reaction and the latest American stain tests." He was unable to confirm the French statements in regard to "dissociated icterus"; that is, the isolated appearance of bilirubin in the urine. Marcus related that the blood sugar curve after injection of epinephrin could be modified by hypnotic suggestion. E. Kylin stated that he had been able to influence the action of epinephrin and insulin with electrolytes (calcium and potassium). Lundsgaard reported that his research has demonstrated that insulin in the test tube acts on sugar only when muscle cells are added to the insulin-sugar mixture. Also that insulin's action on sugar is in the line of a transposition of the atoms of the sugar molecule, making it easier to assimilate. The next congress will be held in Copenhagen in 1927. The subject suggested for the main topic was "Anaphylaxis."

Deaths in Other Countries

Dr. **Alfredo Ellis**, senator from the state of São Paulo, Brazil, aged 75. He studied medicine at the University of Pennsylvania.——Dr. **A. Richaud**, professor of pharmacology, Paris, aged 60.——Dr. **Otto Mugdan**, Berlin, long a member of the reichstag and leader in measures for the public health and for the organization and advancement of the profession, aged 63.

CORRECTION

Use of Gentian Violet in Thrush.—In the communication of Drs. Faber and Dickey (The Journal, October 10, p. 1154), the quotation from Churchman should have read "strokes of stained gram-positive organisms" instead of "gram-negative."

Government Services

General Allen Given Honorary M.D.

Major Gen. Henry T. Allen, U. S. Army, retired, commander of the American forces in the Rhineland, has been given an honorary medical degree by the medical faculty of the University of Frankfurt as a token of appreciation of the work done by Americans for the children of Germany.

Dr. Grubbs Detailed Assistant Surgeon General

Orders issued September 28 by the U. S. Public Health Service detailed Dr. Samuel B. Grubbs as assistant surgeon general in charge of the Division of Foreign and Insular Quarantine and Immigration of the Public Health Service.——Surg. John S. Boggess has been directed to proceed from Detroit to New York to accompany the immigration inspector taking leper aliens to that city for deportation, and to return by way of Washington for a conference.

Army Personals

Major William A. Foertmeyer, Letterman General Hospital, San Francisco, has been ordered to his home to await retirement.——Major Edmund W. Bayley has been relieved from the army transport service, Fort Mason, Calif., and ordered to the Presidio of Monterey, Calif., for duty.——Capts. Emory H. Gist and Hugh M. Bullard will sail about Jan. 6, 1926, from New York to Hawaii for duty.——Capt. Wesley C. Cox is excepted from the provisions of the National Defense Act which require duty with troops of one or more of the combatant arms.——Col. Henry A. Webber, Atlanta, has been ordered to the Army and Navy General Hospital, Hot Springs, Ark., for treatment.——Major Charles P. Martin has been ordered to sail from China on the first transport to the Letterman General Hospital, San Francisco, for duty.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Oct. 3, 1925.

Outbreak of Paratyphoid Fever Due to a Carrier

In the Borough Hospital of Croydon (a district of London) eighteen persons are under treatment for paratyphoid fever which has been traced to a pastrycook. The patients include two children and comprise both sexes up to the age of 40. They ate confectionery or meat pies which, though purchased in different shops, were all made in the establishment where the pastrycook was employed. He appears to have had a mild attack of paratyphoid in August and continued to work while suffering from the disease. None of the cases proved fatal, though there were some sharp attacks. In the pastrycook's blood was found the paratyphoid bacillus. Since he ceased his employment, no further cases have occurred.

A Band of Blood Donors

A branch of Red Cross work almost unknown to the public is the London Blood Transfusion Service, which was organized in 1920 by the Camberwell division of the Red Cross Society. The first application for a donor was made by King's College Hospital, and four volunteers came forward. In June, 1922, a request was received from Guy's Hospital, and four out of eight volunteers were selected and each underwent transfusion at fortnightly intervals. In the meantime other hospitals heard of the scheme and fresh applications came in, with the result that by the end of the year twelve transfusions had been carried out. During 1923 ten cases were served; in 1924, sixty-two; and up to date, 247. A year ago it became apparent that the Red Cross members could not cope with the demands, and an appeal was made for more volunteers. Among the replies was one from a rover scout (a scout who has reached a certain age). He interested his headquarters in the work, with the result that it was taken up as a regular branch. More than 150 members of this organization are now on the roll, which is more than half the total. So numerous have the calls become for donors that a special appeal has been issued and it is expected that soon there will be 1,000 donors on the roll. Calls come at all hours of the day or night, and there is never more than an hour's delay between the receipt of the call and the donor's arrival at the hospital.

Infectious Diseases in London

The annual report of the Metropolitan Asylums Board (which controls the service for infectious diseases in London) directs attention to an increase of diphtheria in the last fifteen years. The probability of a child under 10 contracting diphtheria is now twice as great as it was prior to 1911. The board considers this a strong argument for some form of immunization, such as has proved successful in New York. Every new nurse on joining is now submitted to the Shick test. One of the board's officers, Dr. F. H. Thomson, medical superintendent of the North Eastern Hospital, has urged the revision of the methods of bacteriologic culture before discharging diphtheria convalescents. He has found that, by a more intensive system, in which six consecutive negative cultures from the throat and nose spread over a period of three weeks, were required, a certain number of carriers who continued to show virulent diphtheria bacilli were found. The year 1924 was marked by a heavy incidence of epidemic (lethargic) encephalitis. The cases numbered 611, almost thrice those of the highest previous record (233 in 1921). The need for providing institutional treatment for juvenile cases is realized. With a view to diminishing the number of cases of otorrhea in fever hospitals, the board some years ago appointed an otologist, Mr. T. B. Layton, to investigate the problem. As a result of an extensive study he has made the following recommendations for the treatment of ear disease in scarlet fever: 1. Incision of the drum-head in every case in which it can be found bulged before it ruptures. 2. When otorrhea has occurred, instillation of antiseptic hygroscopic drops (glycerite of phenol, 1 part; rectified spirit, 1 part, and glycerin, 2 parts, are used by Mr. Layton). 3. Considering the question of operating on adenoids when there has been an ear discharge for twenty-one days in simple scarlet fever, or longer in septic scarlet fever or mixed infections. 4. Performing Wilde's incision as soon as a retro-auricular swelling or edema appears when this is not due to cervical adenitis. 5. Opening the mastoid in such acute conditions of the bone as do not seem amenable to Wilde's incision. 6. Operating on the mastoid when the ear discharge threatens to become chronic and evidence of changes in the bone is found by roentgenography or otherwise. 7. Heliotherapy for patients that tend to develop chronic otorrhea, whether these have had operative treatment or not, and whether they have suffered from simple scarlet fever, septic scarlet fever or mixed infection. These recommendations were carefully considered by a committee of medical superintendents of the board's hospitals. With one exception they met with unanimous approval. In regard, however, to the advisability of incising the drum-head in every case of bulging, the committee felt considerable doubt, contending that the opportunity of performing anticipatory puncture is often precluded because a discharge is often the first evidence that the ear is affected, and that the procedure is practicable only in a small minority of cases.

A Hindu Community Threatened with Extinction

The Hindu community of Kashmir, according to Dr. Kathleen Vaughan, who has returned to England from that country, is threatened with extinction, though it is one of the oldest and most intellectual races in the world and is the ruling race in that country. Though 95 per cent. of the people are Mohammedans, they are ruled by Hindus. The causes of the decay of this fine race, which is decreasing at a rate of 1,000 per annum, are, according to Dr. Vaughan, never heard. She finds four great causes, which, if unchecked, will lead to the extinction in a few decades. These are venereal disease, tuberculosis, osteomalacia among the women, and infanticide. Tuberculosis and osteomalacia appear to be increasing rapidly among the richer classes, who deprive themselves, and especially their wives, of sunlight and fresh air. Many infants, both boys and girls, are deliberately sacrificed at birth. They are thrown into the river or strangled if they are not wanted. In the case of a girl, the parents may not desire the expense of providing a dowry, or the child may be born at an unlucky hour. An astrologer is always consulted, and if the horoscope is not auspicious the infant is not allowed to live. Another reason is that the child is diseased or will not take the breast. The mother has no voice in the decision; it is the husband's mother who decides and sometimes even smothers the child herself.

The Health of Merchant Seamen

Official reports on the health of the navy, as on that of the army and the air force, are issued annually, but there is no report on the 235,000 men who form our merchant marine, though port health officers mention the subject occasionally as it comes before them in the course of their work. However, the board of trade publishes annually a return of the deaths that occur on British ships. It is somewhat late in appearing, as that for 1923 has only just been published.

It shows that there were 724 deaths from injury and 659 from disease. Of the latter, 379 occurred in British, forty in foreign and 240 in lascar seamen. The death rate of British seamen was 5.12 per thousand—a considerable improvement on that of twenty years ago, which was 11.25. Pneumonia kills a few less now than then, tuberculosis and malaria only two thirds as many, typhoid a half, alcohol a quarter, and smallpox a fifth. Yet, as pointed out by Fleet Surgeon W. E. Home in the *Times,* the strong, healthy men of the merchant marine have twenty times the death rate from typhoid that their brethren, the strong with the weak at the same ages, have ashore in England and Wales, and just as much pneumonia.

The Antiquity of Man

Dr. Ales Hrdlicka, curator of the division of physical anthropology, U. S. National Museum, Smithsonian Institution, Washington, has arrived in this country from South Africa, the last country visited in a long anthropologic tour. To a representative of the *Times* he stated that, March 19, he started on a mission from the U. S. National Museum to India, Ceylon, Java, Australia and South Africa for the purpose of tracing and seeing everything bearing on the antiquity of man and the higher apes. He found that in all these countries, with the possible exception of Australia, there is a great deal to be done and much to be expected from researches in this subject. Most of the recent discoveries have been made in the countries of the British empire. India alone has given the remains of five or six varieties of extinct anthropoid apes. In Java, which has given us the most precious of the prehuman forms so far known, *Pithecanthropus erectus,* much remains to be done. The banks of the river that yielded these unique relics are full of fossil bones. The most promising recent finds have been in South Africa—the Rhodesian man and the Taungs great fossil ape These forms were never expected in those localities and the sites are not yet exhausted. As to the biologic position of the Taungs remains, Dr. Hrdlicka considers that they are, as pointed out by Sir Arthur Keith, those of a hitherto unknown manlike ape, possibly somewhat superior even to the chimpanzee. But the last word cannot be said on the subject until an adult specimen of the species has been discovered. The present find is that of a child ape, at the beginning of the second dentition.

The Antisyphilis Dispensary at Creil

The Ligue nationale française contre le péril vénérien, which comprises practically all the syphilologists in the country, is putting forth every effort to suppress syphilis. If all right-minded persons will give aid, the league hopes to free France from syphilis within ten years. Up to the present time a good organization has been lacking. Dispensaries well equipped and directed constitute the centers of the crusade. The league recently opened at Creil a dispensary, which is the first of a series that it hopes speedily to complete. The league demands from the central government only a percentage of the funds it needs. It secures the remainder from the municipalities, the administrations, certain groups and from generous private individuals. For example, at Creil, Baron and Baroness R. de Rothschild have offered a wing of an ancient castle for the dispensary and have had a fine laboratory erected as an annex. They have even agreed to furnish light, water and a nurse and housekeeper. The manufacturers of the region have consented to pay, toward an annual subvention fund of 15,000 francs, 2 francs for each workman in their employ. This fund will pay the operating expenses of the dispensary, which is to serve this industrial center. With the aid received from many private sources, the league has equipped and opened the dispensary at Creil without requesting funds from the central government, the department of Oise or the city. With its admirable equipment and modern laboratory, it is a very inviting place. The patients go there without apprehension and take pleasure in returning. It adjoins a dispensary for respiratory diseases and, consequently, patients who come to the consultation room awaken no unpleasant suspicions in the minds of acquaintances who may see them. In the same building there is a consultation center on infant care, which furnishes many cases of heredosyphilis. The physician in charge of the dispensary, the head of the laboratory and the assistants, appointed after competitive examination, are of unquestionable skill, and receive adequate compensation.

There will be amicable cooperation between the dispensary personnel and the physicians of the region round about. The only patients received at the dispensaries of the league are either indigent or are referred by their physicians. The dispensary is widely used by practitioners for the establishment of diagnoses, for laboratory examinations and as a source of therapeutic information. It is not a center of treatment other than for the indigent.

With such an organization, dispensaries such as the one at Creil are destined to render great service.

Death of Professor Richaud

The University of Paris Faculty of Medicine has lost by death its professor of pharmacology, A. Richaud. Richaud had been pharmacist to the hospitals and, since 1901, agrégé professor at the Faculté de médecine, succeeding Professor Pouchet on his retirement because of age. He did important work on inulin and inulase, on the pharmacodynamics of ouabain and strophanthin, on the coagulation of blood and on the relation of calcium to cardiac muscle. Richaud condensed his lectures into a compendium, which has passed through several editions. For many years he had served actively on the Conseil supérieur d'hygiène.

A Medical Degree for Dentists

At a recent meeting of the Société de stomatologie, M. Paul Boudina questioned whether dentists who do not hold an M.D. degree should be allowed to practice vaccinotherapy, and whether or not the degree of dental surgeon *(chirurgien-dentiste)* should be abolished and an M.D. degree be demanded of all practitioners of dentistry.

Since the present law allows a physician to practice dentistry in all its branches and have recourse to all the resources of therapeutics, a simple dentist's range of action should be limited and he should not be authorized to administer special forms of medication, including the use of vaccines, serums and toxic substances. The ministerial decree of July, 1917, which limits the use of toxic substances by *chirurgiens-dentistes,* established this principle very plainly.

Since a dentist may treat cases requiring vaccines or toxic drugs (which he has not the authority to administer), it would seem desirable that his field be extended. This cannot be legally accomplished except by the acquisition of the M.D. degree.

So-Called Conjugal Tuberculosis and Tuberculous Contagion in Adults

Thinking that a good series of statistics of cases of conjugal tuberculosis would be excellent material to determine the importance of exogenous superinfection in an organism already infected in childhood, E. Arnould in the *Revue de la Tuberculose* has collected statistics of 53,069 homes in which tuberculosis was manifest and in which in 4,472 cases it affected both husband and wife. After a critical sifting, he gives the proportion of conjugal tuberculosis as about 10 per cent. Since the average tuberculosis morbidity among the urban population in the 20-50 age group may be placed at 5 per cent., we have a basis for comparison. The frequency of conjugal tuberculosis is, therefore, not very high and is disproportionate to the opportunities offered for contamination. This finding lessens the importance of exogenous reinfection in the adult, although contagion remains the origin of primary tuberculosis in childhood and adolescence. These considerations show it is not against contagion that the principal effort in tuberculosis prophylaxis must be directed, as far as adults are concerned.

RIO DE JANEIRO

(From Our Regular Correspondent)

Sept. 15, 1925.

Bacterial Structure and Reproduction

Dr. A. Fontes, chief of one of the services in the Oswaldo Cruz Institute, has just published a note on structure and reproduction of bacteria. Microbiologists are rather divided in their conceptions of the bacterial cell: some accept its having a differentiated nucleus, and others favor a diffuse core. When in 1910 Dr. Fontes studied the structure of the tubercle bacillus, he found existing granulations giving rise to other granulations, which in turn had the power of reproduction, through a process of division similar to budding. Fontes concluded that the granulation of the tubercle bacillus was the infecting agent.

He verified his conclusions by filtering caseous pus through a Nordmeyer-Berkefeld apparatus. Guinea-pigs inoculated with this filtrate, and killed after a year, failed to show any tuberculous signs, but showed the presence of embryonic cells having gram-positive granulations. Animals inoculated with material from the organs of these first guinea-pigs, showed tubercle bacilli in gland and lung sections. This proves that infected animals may remain apparently healthy, although harboring latent virus. Fontes' work was confirmed abroad, among others by Kirschenstein, in Riga, in 1922.

In studying the structure of other bacteria, Fontes tends to accept the hypothetic existence of a diffuse nucleus which in certain conditions may develop into a more or less differentiated one. From his point of view, the chromophilic granulations, once liberated by any cause not impairing their vitality, are the starting points of new live elements, which renew the bacterial species.

Coexistence of Normal and Ectopic Pregnancies with Full Term Viable Fetuses

Dr. L. de Araujo has reported to the National Academy of Medicine the case of a patient recently operated on by him at the Santa Casa Maternity. A primipara, aged 29, suffered blood losses up to the third month. The increasing pains in the lower part of the abdomen almost entirely prevented her resting. On reaching the maternity, she was already in labor and had passed water and blood. On palpation, a head was felt, but examination was incomplete because of the pain it caused. The cervix was not dilated. On the morning of the third day another examination was made; the lower uterine segment was distended and thinned, and through its walls fetal sutures and fontanels could be felt. Abdominal inspection showed an ampule-like uterus and at the level of the right iliac fossa, a tumor, which was the cause of the dystocia and suggested a fetal head.

As the cervix remained unrelaxed and the fetus seemed viable, a laparotomy was deemed advisable. A pregnant uterus was found, and behind, another mass, which at first sight looked like a fibroid adherent to the neighboring structures. An attempt at freeing the adhesions was made, but the mass burst open on one side, and an abundance of blood escaped. The uterus was then drawn out and a live but moribund fetus was found. While the operator was trying again to destroy the adhesions a new fetus appeared. This was located in the right tube and was delivered alive and in good condition. The operation was completed by a supravaginal amputation of the uterus and resection of the right tube and ovary. While the patient did well at first, death ensued suddenly on the fifteenth day. The uterine fetus died in convulsions, twenty-four hours after delivery, but the extra-uterine fetus is still alive and doing well. The consensus of opinion was that the case was very uncommon and perhaps unique in medical literature.

First Case of Human Coccidiosis

Drs. C. Pinto and G. Pacheco of the Oswaldo Cruz Institute have just reported the first case of human coccidiosis verified in Brazil. The etiologic agent, *Isospora belli,* described in 1923 by Wenyon, was identified in the patient, a child, aged 4 years. The disease had begun nine months before, with colic, mucous and bloody feces, fever and prostration. The fecal examination showed *Trichuris trichiura* eggs, cysts and rare vegetative forms of *Giardia intestinalis,* vegetative forms of *Trichomonas hominis, Chilomastix mesnili, Endameba histolytica,* and oocysts of *Isospora belli.* In view of this multiple infection, it is hard to determine the pathogenic rôle of *Isospora belli.*

Total Removal of Larynx

Dr. Souza Mendes has exhibited to the Rio de Janeiro Medical and Surgical Society a patient on whom he made a total laryngectomy for cancer. This is the second of these operations performed by him this year, with complete success. The patient was 26 years old, and he was operated on in one sitting and without a previous tracheotomy.

Visit of French Scientists

The Brazilian medical profession feels grateful for the kindness of so many celebrated French medical men in visiting here. Drs. Marchoux of the Pasteur Institute, L. Bernard, Babinski, Vaquez of the Paris Medical School, and G. Dumas of the Sorbonne have lectured at the academy, and the medical school. August 20, Profs. L. Bernard, Babinski and Vaquez were made honorary members of the academy. After their Rio visit, the French physicians will proceed to São Paulo, and thence to Montevideo and Buenos Aires.

NETHERLANDS

(From Our Regular Correspondent)

Sept. 16, 1925.

An International Service of Venereal Prophylaxis

At the Netherlands Congress of Public Health, Dr. De Jong referred to the organization of an international service of venereal prophylaxis for seamen, which was the result of a request from Belgium directed to the International Bureau of Public Health in Paris. The Netherlands have not as yet entered into the compact. Dr. De Jong expressed the desire that, until the Netherlands take part officially in this work, seamen residing temporarily in the ports of Holland might be furnished treatment. At Amsterdam there is already a policlinic that gives gratuitous treatment to sailors. At Rotterdam very little agitation would secure similar service. The speaker expressed the hope that the authorities would soon make the necessary appropriations.

Special Diploma for Doctors of Public Health

In a recent letter, I wrote that the central commission of public health was considering the creation of a special diploma in hygienic medicine for physicians who are planning to take administrative positions that would require a knowledge of social hygiene and public health problems. The special courses would include studies in bacteriology, immunology, epidemiology and prophylaxis, and the hygiene of dwellings. Two three-month periods are proposed, followed by assignment to a post where the candidate would gain practical experience. The bill does not specify details for the organization of such courses, but it would seem that only the medical faculties would be in a position to give the instruction.

The Technic of Nephrectomy

As a means of preventing the fistulas following nephrectomy in renal tuberculosis, Dr. Hustinx recommends complete removal of the kidney and of the ureter up to the point where it enters the bladder. He makes an incision from the pubis to the umbilicus, then curving toward the ninth costal cartilage of the side on which one desires to operate. The peritoneum is detached progressively from the deep aponeurosis of the muscles until the ureter is uncovered. The ureter is followed as far as the renal vein, which is easily accomplished with the patient in the Trendelenburg position. The patient then is placed in the usual position, and the ureter is isolated as far as the kidney, which is easily loosened by this incision. This technic has been employed by the author in other cases of renal or pararenal tumors and in cases of lithiasis, and he has found this approach very favorable.

The Serologic Institute

The new state serologic institute at Utrecht was recently dedicated. During the ceremonies, Professor Aldershoff gave an account of the activities of the institute, which consist in inducing antidiphtheritic immunization by the use of the toxin-antitoxin mixture; immunization against scarlet fever (Dick method) which promises some success; the crusade against asthma, in which Dr. Pondman is engaged, by means of a polyvalent autovaccine; the preparation and study of pertussis vaccines, and the new findings of Calmette and Guérin concerning vaccination against tuberculosis with BCG.

Following the dedicatory address, Minister Aalberse gave the history of the institute, which was founded originally as a private enterprise of Dr. Spronck, before it became the annex, that it now is, to the central laboratory and to the University of Utrecht.

Visit of South American Physicians in the Netherlands

In a study tour organized by the League of Nations, about ten physicians from South America recently visited the public health organizations and institutes in the Netherlands. Dr. Josephus Jitta received them officially and explained the laws governing the organization of public health. He pointed out that the public health services would soon be centralized in a single organization. Dr. Terburgh gave an account of the antismallpox campaign. In spite of opponents of vaccination (who are not very numerous but include a number of agitators and are therefore a social danger), there were only 756 children per million of school age that were not vaccinated. Revaccination, however, is little practiced. It is not compulsory even in the army. In general, Terburgh holds that the antismallpox crusade has failed of its full purpose, for 70 per cent. of the adult population possess only partial immunity.

In the Dutch East Indies, where smallpox was formerly a scourge, vaccination is working wonders. The author explained the system, according to which a European physician trains natives to perform the work of vaccination among the people in their districts. Since the introduction of this method, prophylaxis has extended much more rapidly and the whole population will be revaccinated every ten years. He warned that we must not relax our vigilance because of partial success, for England's recent increased incidence is suggestive of what the result would be.

In Amsterdam, the vistors were interested in the care of emigrants; more particularly, the Lloyd Hotel, an immense establishment organized by the Royal Dutch Lloyd to accommodate the emigrants from central and eastern Europe while they are being examined before embarkation. The emigrants are separated in sections according to the races to which they belong.

The Retirement of Professor Winkler

Prof. Dr. Winkler, professor of neurology and psychiatry at the University of Utrecht, has reached the age limit and has resigned. On the occasion of his retirement, Professor Winkler emphasized that the progress of psychiatry depends on its anatomic and biochemical bases, joined with experimental psychology.

ITALY

(From Our Regular Correspondent)

Sept. 23, 1925.

An Institute of the History of Science

The new institute of the history of science, in Florence, was opened, a few days ago, under the direction of Prof. A. Corsini, a noted fosterer of the history of medicine and secretary of the Società italiana di storia delle scienze. The institute is located in the buildings of the Faculty of Medicine and is under the sponsorship of the rector of the University of Florence, Giulio Chiarugi, professor of normal human anatomy, and of Professor Lustig, dean of the Faculty of Medicine. The object of the new institute is to collect books, pamphlets, objets d'art, armamentarium and whatever else may serve to illustrate the various periods of the history of science, and, more particularly, of medicine, in order that they may be of use to students. There is a reawakened interest in such subjects in Italy. The nucleus of the institute comprises collections of antique surgical instruments; mortars and other instruments of ancient pharmacists; pictures, busts, journals, etc.

Convention on the Abnormal Child

Under the auspices of the Associazione pro infanzia anormale and the Lombardy section of the Lega italiana per l'igiene mentale, a convention was recently held in Milan to promote better assistance for abnormal children. The convention, presided over by Professor Medea, who is the head of these two organizations, was held in the Zaccaria Treves school for abnormal children. The convention recommended that with the aid of suitable organizations the authorities throughout Italy require that the identity of abnormal children be known and that a careful differentiation be made between those who are abnormal and those who are temporarily backward. It advocated likewise special schools for truly abnormal children, with compulsory attendance through the sixteenth year, instead of the fourteenth as at present. The schools should be in charge of teachers who have received modern medicopedagogic training fitting them for such special duties.

Bismuth Salts in the Treatment of Pulmonary Tuberculosis

At a recent session of the Società medico-chirurgica of Pavia, Dr. Bignami reported on his results in the treatment of pulmonary tuberculosis with small doses of bismuth salts administered either hypodermically or by means of inhalations. The author's experiment was impelled by his observation that in certain syphilitic patients with tuberculosis, treatment with bismuth had retarded the tuberculous manifestations. He had noted experimentally also that rabbits treated with bismuth salts show increased resistance to tubercle bacilli. From his observations, which extended over a period of three years, the author, while recognizing that they are insufficient as a basis for decisive conclusions, nevertheless feels that bismuth exerts a favorable action on the course of pulmonary tuberculosis, not only strengthening the resistance of the organism, but also possibly lessening the pathogenic activity of the bacilli.

A Course in Public Health Work to Be Established in Rome

The royal commissioner at Rome, Senator Cremonesi, has arranged with the Instituto italiano di igiene, previdenza e assistenza sociale to establish special courses of instruction in public health work. These courses are intended primarily for employees of the commune of Rome, particularly the instructional corps of the communal schools. By way of experiment, there will be established a course in organization of hygienic-prophylactic services such as exist at present in all progressive countries. To promote interest in the course, the commune has decided to give scholarships and prizes to those who excel in the recitations and written themes of the course.

The First International Congress on Malaria

From October 4 to 6, the first International Congress on Malaria will be held at Rome, at the instance of the Italian government. All the nations of Europe and of North and South America will send delegates; also India, Japan and Turkey. The section on health of the League of Nations will be represented. The topics on the program are: *Anopheles* in relation to malaria; the biology of the parasites; the alkaloids of quinin in relation to malaria therapy; epidemiologic factors and the crusade against malaria; propaganda and statistics.

A Special Course in Colonial Medicine

In the coming November, Bologna will organize a course in colonial medicine open to graduates in medicine and surgery who wish to secure a diploma in that subject. The course will include clinical instruction in colonial diseases, colonial hygiene, protozoology, helminthology, entomology, bacteriology and serology. Theoretical lectures will alternate with laboratory work and demonstrations, the school being supplied with abundant scientific and laboratory material.

VIENNA

(From Our Regular Correspondent)

Sept. 30, 1925.

The Winter Semester in the Medical Department of the University of Vienna

The lectures to be delivered at the University of Vienna, from the middle of October, 1925, up to Easter, 1926, include a number of medical courses. In addition to the regular courses given every year, we note: "The Biologic and Physiologic Aspects of Personality" and "Physiology in Relation to Human Labor," Dr. Allers; "Resuscitation Measures in Apparent Death and Accidents Due to Electricity and Gas," Prof. Dr. Jellinek; "Psychotherapy in Internal Diseases," Dr. Deutsch; "The Bases of the General Medical Theory of Hereditary Transmission," Privatdozent Dr. S. Bondi; "Problems of Child Welfare," Privatdozent Dr. Nobel; "Diagnosis of Constitutional Abnormalities in Children," Dr. Lazar; "Social Aspects in Pediatrics," Dr. Friedjung; "The More Minute Cell Structure of the Cerebral Cortex," Professor Economo; "Psychanalytic Conceptions of Patients," Professor Schilder; "Lectures on Physical Education" and "Reeducation of the Disabled," Professor Spitzy; "Propagation in Relation to the Sexual Life of the Female," Dr. Hofstätter, and "Psychology of Adolescence," Privatdozent Bühler. In the Institute of Criminology, Privatdozent Türkel lectures on "Criminologic Microscopy and Chemistry"; Professor Wasicky on "Forensic Aspects of Toxicology and Examination of the Excrements"; Professor Haberda on "Selected Chapters of Legal Medicine"; Prof. Dr. Oppenheim on "Occupational Injuries of the Skin as Forensic Distinguishing Marks." There are a number of other courses which are more of a technical than a medical nature.

Malpractice and Austrian Law

From time to time, in Austria, suits for alleged malpractice are brought against more or less prominent physicians A strict interpretation of some sections of the antiquated "Constitutio Criminalis Carolina," the law code that was promulgated by Charles V in 1532, might menace the medical profession. The more recent Austrian legislation on the subject deals in three sections with "misdemeanors of physicians" due to "ignorance," "gross negligence" and "violations against the security of life." The provisions, however, are susceptible of so many different interpretations that only popular ignorance of the law prevents physicians from being mulcted more frequently than is now the case. To be sure, it is customary for the courts to impose punishment only for "glaring" ignorance, the penalty being the withdrawal of the right to practice until the physician shall have been reexamined. But in several cases physicians were threatened with suits because operations which they had advised and represented as not being dangerous had resulted fatally, owing to complications. Suits have been brought also for alleged neglect to perform an operation. One physician received a six weeks' jail sentence for having given a midwife a mercuric chlorid tablet, with instructions "to dissolve it in a liter of water," whereupon the midwife allowed the patient to drink the solution that was intended for lavage purposes. Errors of diagnosis, prognosis and judgment do occur, but physicians are human and not omniscient.

In an article signed "Verus," which appeared in a Vienna daily, attention is called to the fact that in 1903 the Austrian minister of justice recommended that opportunity be given during the preliminary examination before the case is brought into open court to discover whether or not a physician is guilty. Even though he is innocent, a physician's reputation is damaged if he is called on to answer a court summons, and often he prefers to "buy his peace" rather than have his name appear in connection with alleged misdemeanors. For these reasons the medical profession demands new legislation which shall explicitly annul the antiquated laws of 1532, 1770 and 1782. A further demand is that, in all actions involving medical problems, physicians shall be accorded decisive influence and authority in determining the guilt or innocence of the accused. This should be effected by the appointment of physicians as temporary judges, in much the same manner as merchants are chosen to function as judges in suits involving technical commercial questions. Furthermore, the law should state explicitly in what kinds of actions expert medical opinion must be sought, for in the past there has been much negligence in this regard. In the *"Aerzteordnung"* (code pertaining to physicians), which is now being drafted, the last mentioned demand has received no consideration, and an attempt is being made to have inserted in the new penal code a section dealing with the matter.

The Seventieth Birthday of Professor Gärtner

Dr. Gustav Gärtner, who, in 1878, was appointed an assistant to Professor Stricker in the newly founded department of experimental pathology, has produced apparatus important in research. The ergostat, the rheostat, the hematocrit, the two-cell bath, the pneumatophore, the tonometer and the methods for the measurement of basal metabolism and nasal respiration are some of the best known of his inventions. Likewise, the treatment of cholera with the infusion of hypertonic sodium chlorid solution was introduced by Gärtner. His reducing method is well known and has brought him great fame. That he was never given a professorial chair was due to his great modesty and unpretentiousness. He still possesses his wonted physical and mental vigor. His seventieth birthday will be celebrated in a festal manner by the various scientific societies and his many personal friends.

The Number of Physicians in Austria

The report of the ministry of public health for 1924 contains statistics on the number of physicians in Austria. In the following enumeration, the first figure represents the number of physicians in the respective towns and cities and the figure in parentheses the number of inhabitants to one physician: Vienna, 4,051 (461); St. Pölten, 27 (1,171); Waidhofen, 5 (1,031); Vienna Neustadt, 43 (859); Amstetten, 37 (2,217); Gauserndorf, 26 (2,374); Mödling, 39 (1,818); Zwettel, 20 (2,318). The rural districts in the vicinity of Vienna had 862 physicians (1,716). Upper Austria had 489 physicians (1,791), with the maximal number of inhabitants (2,565) to one physician in Braunau and the minimal number (762) in Linz. Salzburg had 174 (1,282). The largest number of inhabitants to one physician, in this region, was in Rohrbach, a large district with fifteen physicians (3,346). In Steiermark, a very mountainous region, Graz, a university town, had 461 physicians, or 334 inhabitants to one physician, the smallest number in this section; the largest number was in Weiz, where there were two physicians, or one to 2,842 inhabitants, while the average distribution in this region was one physician to 1,333 inhabitants. In the province of Carinthia, Klagenfurt had sixty-seven physicians, or one to 409 inhabitants; Völkermarkt, sixteen (3,494). The rural districts had 204 physicians (1,817). In Tyrol, Innsbruck (university) with 198 physicians (298) had the largest number of physicians in proportion to the population found anywhere in Austria, but in the whole province there were only 341 physicians (923), for the villages in the mountains are small and do not offer very good prospects for physicians; there being only one physician to from 1,800 to 2,600 inhabitants. The smallest number of physicians proportionately is found in the so-called "New Austria," the rural district that was ceded to Austria by Hungary. Here there is a total of eighty-eight physicians, or one to 3,248 inhabitants. In the whole republic of Austria there were 7,169 practitioners, or one to 912 inhabitants, which is an increase of 150 physicians over last year, which showed one physician to 928 inhabitants.

Marriages

Franklin Howard Pennell, Fostoria, Ohio, to Miss Dorothy Elizabeth McCombs of Bowling Green, September 12.

John Silas Lundy, Rochester, Minn., to Miss Lenore Mittelstadt of Wells, at St. Paul, September 5.

Roland Adcock Slater, Indianapolis, to Miss Mabelle Browning of La Harpe, Ill., September 10.

James J. Morrow, Austin, Minn., to Miss Margaret Alice Till of Davenport, Iowa, September 7.

Theodore Ferdinand Ruther, Effingham, Ill., to Miss Alice Faust of New Orleans, August 18.

James Fulton Percy, Los Angeles, to Mrs. Charles Albert Post of Ventura, Calif., August 28.

Richard F. Sitar, Hopkins, Minn., to Miss Pauline Lewis of Madison, Wis., September 19.

James Alexander Collins to Miss Bessie Rhodes, both of Birmingham, Ala., October 6.

Elmer Lewis Lampe, Bellevue, Iowa, to Miss Agnes Marie Yates of Clinton, August 31.

George Dock, Pasadena, Calif., to Miss Miriam Gould of Boston, October 17.

John J. Burns to Miss Anna McLain, both of Philadelphia, September 8.

Deaths

John Cooke Hirst ⊕ Philadelphia; University of Pennsylvania School of Medicine, 1897; died at his home in Philadelphia, October 4, after a long illness, aged 50 years. He received his earlier education in Lawrenceville and Penn Charter, after which he entered the University of Pennsylvania. Following his graduation in medicine, he studied abroad and then returned to practice, becoming promptly associated with many Philadelphia institutions. He was senior gynecologist and obstetrician in the Philadelphia General Hospital, and associated in similar capacities with St. Agnes, University and Mount Sinai hospitals of Philadelphia. He was also assistant professor of gynecology in the postgraduate medical school of the University of Pennsylvania, and assistant in obstetrics in the medical faculty. He became associated early with the examinations of the National Board of Medical Examiners, and took part frequently in the work of the Section on Obstetrics, Gynecology and Abdominal Surgery of the American Medical Association and of special societies. Dr. Hirst was a frequent contributor to the literature of obstetrics, including two textbooks; recently he gave special attention to research on the use of the corpus luteum. His brother, Dr. Barton Cooke Hirst, is professor of obstetrics in the University of Pennsylvania.

William Lowry Copeland ⊕ Chicago; McGill University Faculty of Medicine, Montreal, Que., Canada, 1872; professor of anatomy, Chicago College of Dental Surgery, 1884-1920, and Chicago College of Medicine and Surgery, 1906-1920; formerly professor and head of the department of anatomy at the College of Physicians and Surgeons; on the staff of the Cook County Hospital, 1892; aged 74; died at the West Side Hospital, September 18, of embolism.

George Tucker Harrison, Mount Kisco, N. Y.; University of Virginia Department of Medicine, Charlottesville, Va., 1856; formerly on the staffs of the Misericordia and St. Elizabeth's hospitals, New York, and the New York Infant Asylum; for many years a practitioner in New York; member of the New York Academy of Medicine, and the American Gynecological Society, and of the Medical Society of Virginia; aged 90; died, October 4.

Michael Joseph Halloran ⊕ Worcester, Mass.; University of Pennsylvania School of Medicine, Philadelphia, 1880; on the original staff of St. Vincent Hospital and after resigning from the staff continued to act as consulting physician; for many years visiting physician at Holy Cross College; aged 71; died at the Maine General Hospital, Portland, Maine, September 22, of cerebral hemorrhage.

George H. Smith ⊕ Hartford City, Ind.; Illinois Medical College, Chicago, 1903; specialized in ophthalmology, otology, laryngology and rhinology; member Indiana Academy of Ophthalmology and Oto-Laryngology; formerly a councilor of the Sixth District Medical Society and a practitioner in Indianapolis; aged 52; died, September 28, at Newcastle, following a long illness.

Larkin H. Callaway, Nevada, Mo.; American Medical College, St. Louis, 1875, and Beaumont Hospital Medical College, St. Louis, 1887; member of the Missouri State Medical Association, and of the American Psychiatric Association; formerly superintendent of State Hospital No. 3; aged 70; died, October 1, of cerebral hemorrhage.

Florence C. Baier, Minneapolis; Medical Department Hamline University, Minneapolis, 1897; member of the Minnesota State Medical Association; on the staff of the North Dakota Hospital for the Insane, 1898-1900; aged 71; died at the home of her daughter in Aurora, Ill., October 3, of cerebral hemorrhage.

Abiram F. Squire, Newport, R. I.; Medical School of Harvard University, Boston, 1867; member of the Rhode Island Medical Society; past president of the Newport County Medical Society; veteran of the Civil War; aged 79; died at the Newport Hospital, October 4, of cerebral hemorrhage.

Philip Henry Sheridan Vaughan, Yarmouthville, Maine; Bowdoin Medical School, Portland, 1889; formerly superintendent of the Eastern Maine Hospital, Bangor; member of the New England Society of Psychiatry; aged 59; died at the Maine General Hospital, Portland, September 21.

Daniel William McDougald, Minneapolis; Medical Department of Hamline University, Minneapolis, 1902; member of the Minnesota State Medical Association; specialized in ophthalmology, otology, rhinology and laryngology; aged 48; died suddenly of heart disease, September 28.

David Alexander Morrison, Buffalo; State University of Iowa College of Medicine, Iowa City, 1882; member of the Medical Society of the State of New York; formerly on the staffs of the Niagara Hospital and of the Deaconess Hospital; aged 67; died, August 17.

Robert Stanton Wood, Washington, Ind.; Medical College of Indiana, Indianapolis, 1905; member of the Indiana State Medical Association; county coroner; aged 52; died at the Daviess County Hospital, September 25, of injuries received in an automobile accident.

Henry A. Calkins ⊕ Leadville, Colo.; Denver College of Medicine, Denver, 1901; president and formerly secretary of the Lake County Medical Society; on the staff of St. Vincent's Hospital; aged 55; died, September 27, of pneumonia.

Henry Dickson Gold, Frazer, Pa.; Temple University Department of Medicine, Philadelphia, 1905; aged 59; died at the Pennsylvania Hospital for Mental and Nervous Diseases, Philadelphia, September 28.

John T. Ullom, Vanderbilt, Pa.; Jefferson Medical College of Philadelphia, 1870; formerly a practitioner in Waynesburg; aged 78; died at the home of his son in Waynesburg, September 24, of general debility.

Frederick W. Seward ⊕ Goshen, N. Y.; University of Vermont College of Medicine, Burlington, 1866; specialized in neurology; proprietor of the Interpines Sanatorium, where he died, October 1, aged 80.

William E. Bell, Terre Haute, Ind.; Medical College of Ohio, Cincinnati, 1890; consulting surgeon Union Hospital; formerly president Terre Haute Board of Health; aged 59; died, October 6.

Joseph A. Shears, New York; New York University Medical College, 1888; for many years connected with the New York City Health Department; aged 61; died, October 1, of heart disease.

James Madison Welch, Wadley, Ala.; Southern Medical College, Atlanta, Ga., 1892; member of the Medical Association of the State of Alabama; aged 71; died suddenly, September 16.

Ada R. Smith Fuller, Des Moines, Iowa; Medical Department of Drake University, Des Moines, 1895; aged 50; died, September 25, at the Iowa Lutheran Hospital, of heart disease.

Guy L. Zimmerman, Lemasters, Pa.; Baltimore Medical College, Baltimore, 1906; a director of the Peoples Bank; aged 51; died, September 26, following a long illness.

George William Miles, Oneida, N. Y.; Columbus Medical College, Columbus, Ohio, 1879; member of the Medical Society of the State of New York; aged 73; died in September.

Sidney Zell Herbert, Evansville, Ind.; University of Michigan Medican School, Ann Arbor, 1902; aged 45; died, October 1, of injuries received in an automobile accident.

George W. Blanton, Brunswick, Ga.; Atlanta Medical College, Atlanta, 1878; formerly on the staff of Brunswick City Hospital, where he died, September 27, aged 67.

Samuel J. Creswell, Mount Calm, Texas; Vanderbilt University School of Medicine, Nashville, Tenn., 1888; aged 63; died in a sanatorium at Waco, September 28.

Tyler DeWitt Jones, Hoboken, Ga.; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1910; aged 43; died at a hospital in Waycross, September 25.

Clifton Lambert Alexander, Elberton, Ga.; Emory University School of Medicine, Atlanta, 1916; died, September 22, following a long illness, aged 32.

John C. Bishop, Wilkesville, Ohio; University of Wooster Medical Department, Cleveland, 1869; aged 85; died, August 21, following a long illness.

Worley DeForest Mercer, Columbus, Ohio; Ohio Medical University, Columbus, 1896; aged 58; died, September 29, of pneumonia.

Robert L. Hood, Atlanta, Ga.; Southern Medical College, Atlanta, 1892; aged 63; died at a local sanatorium, September 30.

Stephen I. Brown, Knox, Ind.; Indiana Medical College, Indianapolis, 1875; aged 77; died at LaPorte, October 5.

George L. Crocker, Maroa, Ill.; Rush Medical College, Chicago, 1897; aged 69; died, October 1, of pneumonia.

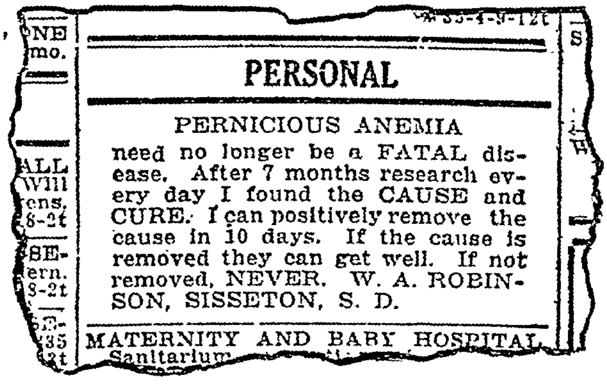
The Propaganda for Reform

In This Department Appear Reports of The Journal's Bureau of Investigation, of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other General Material of an Informative Nature

ROBINSON'S PERNICIOUS ANEMIA CURE

One W. A. Robinson of Sisseton, South Dakota, has been exploiting an alleged cure for pernicious anemia during the past three or four years. Original letters written by Robinson show him to be a man without any general education and his statements regarding the alleged cause and cure of pernicious anemia prove him to be utterly ignorant of medicine.

Robinson's story is to the effect that in 1919 he had what the physicians had diagnosed as pernicious anemia and was told that it was unlikely that he would get well. He then set about it to find a cure for his condition, and this he claims to have done. Robinson's theory of the etiology of pernicious anemia is not new. It is to the effect that the condition is caused by intestinal parasites. He calls these parasites "Anemias" and declares that pernicious anemia "is not a disease at all, any more than 'cooties' is a disease." Robinson claims that he kept up his "research" on the cause and cure of pernicious anemia for nearly seven months (!), and then found both the cause and the cure; that he cured himself and two friends before he began putting the thing on the market. Here is Robinson's conception of the cause of pernicious anemia:



PERSONAL

PERNICIOUS ANEMIA

need no longer be a FATAL disease. After 7 months research every day I found the CAUSE and CURE. I can positively remove the cause in 10 days. If the cause is removed they can get well. If not removed, NEVER. W. A. ROBINSON, SISSETON, S. D.

MATERNITY AND BABY HOSPITAL
Sanitarium

Photographic reproduction of one of Robinson's advertisements.

> "Pernicious Anaemia is a case of slowly starving to death, no difference how much they eat. When the food is digested in the stomach the liquid extract of the food passes into the small intestines where it should be taken into the system through tiny tubes to make blood, flesh and strength; but lying in wait are from 300 to 700 Anaemias, many as large as the first joint of your finger. They absorb the extract of the food—They Get Their's First—and the system gets what is left. . . . Some doctors say it is mal-nutrition. I agree with that, but it is no wonder; the system stands no show when a hungry herd of Anaemias get all the nutriment."

It seems further from Robinson's circulars and printed matter that the "Anaemias" "never let go, till they are destroyed," and that in all of his "seven months research and experimenting" he "never found but one true Anaemia, showing they never let go." Then:

> "When I had gotten the right remedy I found 450 in six days, and several hundred that had been fully destroyed. Then I began to get better and in six weeks gained fifteen pounds and could carry two buckets of water, and I never had a relapse; and now, at the age of 66, have not been as well in twenty years. It is impossible for the Anaemias to remain when my remedy is taken. My remedy is perfectly harmless."

When Robinson and his business were first brought to the attention of The Journal the thing had all the earmarks of an insignificant piece of quackery. The man's obvious illiteracy and ignorance made one feel that the public surely could never be greatly harmed by quackery of this type. As time went by, however, it became evident that sufferers from pernicious anemia were being deluded by Robinson, whose quackery, while crude, is not cheap. He charges $30 for a "treatment," which, he claims, will entirely remove the cause of pernicious anemia in twenty-five days. From letters that came in from physicians, it seemed that the main part of Robinson's "cure" was coarse sand.

In April of this year Dr. W. R. Roberts of Cissna Park, Illinois, sent in a "treatment" which one of his patients, suffering from pernicious anemia, had ordered from Robinson. The patient died, and Dr. Roberts wrote: "The end, in my opinion, was hastened by gastric disturbances induced by this treatment." The treatment in this instance consisted of two parts; one, a substance resembling coarse, sharp sand, and the other a green colored liquid. In some instances Robinson apparently sends in the place of the liquid what he calls "liver pills," but in the present case pills do not seem to have been part of the "treatment." The material was turned over to the A. M. A. Chemical Laboratory, with the suggestion that as the thing was an obvious humbug only cursory tests be made. The laboratory reported as follows:

LABORATORY REPORT

"Two bottles of a treatment for pernicious anemia purported to be exploited by W. A. Robinson of Sisseton, S. D., were subjected to a preliminary examination. One bottle contained a substance resembling coarse sand; this it was found to be; namely, sodium and potassium feldspar.

"The second bottle contained a bitter-tasting, green colored liquid with suspended matter. Tests for arsenic, mercury, iron were negative; the amount of ash was less than 0.1 per cent. Alkaloids were not found. A small amount of a substance yielding an emodin reaction was present. The product is probably an aqueous solution of vegetable material (not identified) containing some chlorophyl."

Since this report came from the Laboratory other inquiries regarding this piece of quackery have been received. The most recent is one from Dr. George Dalton of Malden, Missouri. Dr. Dalton reports that on September 8 he was called to see a patient who was suffering from pernicious anemia and had been taking Robinson's nostrum. The sand which the poor sufferer had been swallowing had caused hemorrhages which resulted in the doctor being called in. The patient died September 14.

As Robinson's dangerous fakery is carried on exclusively through the agency of the United States mails, it is to be hoped that the efficient but overworked department that issues fraud orders will get around to Robinson before the quack gets many more victims.

Correspondence

DIATHERMY IN CALCIFIED SUBDELTOID BURSITIS

To the Editor:—The article on "Action of Diathermy in Calcified Subdeltoid Bursitis," by Dr. Joseph F. Harris (The Journal, October 10, p. 1134), purports to prove from one case that diathermy is a curative agent. If Dr. Harris will take the trouble to review roentgenograms of the shoulder showing calcified subdeltoid bursitis, he will find that in a fairly large proportion the calcium disappears without any treatment whatever.

Arthur L. Fisher, M.D., San Francisco.

DIGESTIVE ENZYMES

To the Editor:—A recent report in The Journal indicates that gastro-enterologists in the United States are now using digestive enzymes but little. I stopped using them entirely about 1905. If there is any one disease in which pepsin would be supposed to be indicated it is achylia gastrica. However, I have two cases of this disease of long duration which attest the uselessness of pepsin. One patient, who began treatment in July, 1903, has gone the last twenty years without a dose of pepsin, and the other, who began treatment in January, 1909, has never to my knowledge had a dose of pepsin. Both of these women were in seriously weakened condition when they began treatment with me, but hydrochloric acid, not enzymes, is the drug that has saved their lives and brought them back to health and strength. They must continue its use as long as they live. These cases are of importance both from the therapeutic and from the physiologic standpoint.

George E. Barnes, M.D., Herkimer, M.D.

PERNICIOUS ANEMIA WITH UNUSUALLY LONG REMISSION

To the Editor:—Since the report of a case of pernicious anemia with unusually long remission appeared (The Journal, September 12, p. 824), I have had a communication from the patient's widow which establishes the period of remission as fourteen years. I make this statement in the interest of accuracy.

Will Howard Swan, M.D., Colorado Springs, Colo.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

SIR RONALD ROSS

To the Editor:—We have had an inquiry for a poem by Sir Ronald Ross on the discovery of the malaria germ, the first line of which is "This day Almighty God has shown to me a wondrous thing." We have tried to locate this through our indexes and have asked the University of Louisville Medical Library. They have not been able to find it but the physician asking for it thought it was published in The Journal.

Edna J. Grauman, Louisville, Ky.

Answer.—The poem by Sir Ronald Ross in which our correspondent is interested was published in The Journal, Sept. 7, 1907. It reads as follows:

This day relenting God
  Hath placed within my hand
A wondrous thing; and God
  Be praised. At his command

Seeking His secret deeds
  With tears and toiling breath
I find thy cunning seeds,
  O million-murdering Death.

I know this little thing
  A myriad men will save.
O Death, where is thy sting,
  Thy victory, O Grave!

Before Thy feet I fall,
  Lord, who made high my fate;
For in the mighty small
  Is shown the mighty great.

The poem also appears in "Memoirs: With a Full Account of the Great Malaria Problem and Its Solution" by Sir Ronald Ross, published by E. P. Dutton & Co., 681 Fifth Avenue, New York, 1923, $9.

VITAMINS — QUININ IN MALARIA

To the Editor:—1. Is there any contraindication to the use of lime juice as a source of the antiscorbutic vitamin for infants when lemon, tomato and orange juice are unavailable, as sometimes happens in the tropics? 2. Why is the juice of cooked tomatoes used for this and not that of raw tomatoes? 3. What form and dosage of quinin are recommended for malaria prophylaxis in infants, and at what age is it begun?

Myrta M. Wilson-Adams, M.D., Monrovia, Liberia, West Africa.

Answer.—1. It has been found that preserved lime juice is not an efficient antiscorbutic remedy. On the other hand, crude or fresh lime juice is said to be less efficacious than lemon juice. Indeed, experimental evidence goes to show that lemon or orange juice is four times as efficient as lime juice in prophylaxis or treatment of infantile scurvy. It has also been found that 5 c.c. of raw lime juice given daily was unable to protect guinea-pigs from scurvy.

2. The raw tomato or its juice is more efficient as an antiscorbutic. The canned tomato, however, may be used particularly under circumstances in which the raw article is not to be obtained, and it must be conceded that the canned product produces a high degree of antiscorbutic power.

Dried orange juice, combined with a malt sugar, is now being sold by one of the American manufacturers, and experience tends to show that dried orange juice is an efficient prophylactic remedy against scurvy.

3. The value of quinin prophylaxis is doubtful. Krauss and Mitchell, in a recent treatise on malaria in children, say that in very malarious regions it is practically impossible to prevent malarial infection, though it may keep symptoms in abeyance. Of a group that had been given 15 grains of quinin three times weekly for five months and 10 grains daily during the remainder of the year, 43.3 per thousand showed active malarial symptoms in spite of the prophylactic use of quinin. Another group of persons who were exposed to malaria were not given quinin and 45.8 per thousand fell ill with the disease. Quinin prophylaxis was also used among 2,000 coolies, with discouraging results. Stitt thinks that the quinin acts as a slow poison without compensating results. Experience also shows that as soon as the quinin is stopped, very often in less than a week, the symptoms of the disease begin to appear.

In contradistinction to these views, Bass believes that the prophylactic use of quinin should be carefully employed. He advises the following doses: children under 1 year, one-half grain (0.3 gm.) daily; 1 year, 1 grain (0.065 gm.); 2 years, 2 grains (0.13 gm.); 3 and 4 years, 3 grains (0.2 gm.); 5, 6 and 7 years, 4 grains (0.23 gm.); 8, 9 and 10 years, 6 grains (0.4 gm.); 11, 12, 13 and 14 years, 8 grains (0.5 gm.) daily. The doses should be taken at night before retiring, as in the treatment for disinfection of carriers. Bass also says that the disease is prevented as long as the treatment is continued.

TETANUS ANTITOXIN — SCHICK TEST

To the Editor:—1. How much danger is attached to reinjection with tetanus antitoxin at long intervals? Should one hesitate to administer it or attempt desensitization when a suspicious wound is being treated from a few months to several years after a previous prophylactic immunization? 2. How long after an immunizing dose of diphtheria antitoxin is the Schick test of value, and how long after may toxin-antitoxin be given? Please omit my name. M.D.

Answer.—1. As tetanus antitoxin is conveyed in horse serum, there is a possible danger that one injection may sensitize the patient to horse proteins, and on that account it probably is best to desensitize before giving a second injection or series of injections in a given case, even if the interval is a long one.

2. The Schick test becomes of value in determining the questions of susceptibility or immunity in about three to four weeks after an immunizing dose of diphtheria antitoxin, because the passive immunity thus conferred does not last much longer than three weeks or so. Toxin-antitoxin may be given about that time, but need not be given until indicated by a positive Schick reaction.

FEDERAL DEPARTMENT OF HEALTH

To the Editor:—What is the history of the Owen bill for creating a federal department of health? Did it ever pass either branch of Congress? What were the principal objections to legislation creating such a department? M.D.

Answer.—In 1910, Senator Robert L. Owen introduced into the Senate a bill establishing a department of health and for other purposes. It was designed to accomplish that end by bringing into the new department all federal health agencies of the government, except those of the army and the navy. The principles of this bill were promptly endorsed by the House of Delegates in 1910. The bill in a somewhat modified form was again endorsed by the House in 1911. With slight modifications it has been before Congress ever since and was pending as S. 3156 when the Sixty-Eighth Congress expired by limitation on March 4 last. Opposition to this bill has come largely from the usual antimedical groups and to a certain extent from officers or employees of the government who feared that their status might be unfavorably altered. Available records do not permit a statement whether this bill ever passed either house of Congress. The Owen bill as it now stands calls for no extension of federal health function and involves no additional expense except such as is necessary to provide for the appointment of a secretary of health, a commissioner of health, and necessary administrative officers, this increase to be offset by decreases in the expenses of the several departments whose functions are transferred in part to the proposed department of health.

INFLUENCE OF ALLERGY ON COURSE OF TUBERCULOSIS

To the Editor:—An article in the *Nederlandsch Tijdschrift voor Geneeskunde* (**1:** 2672 [June 13] 1923) was indexed in The Journal with this heading, August 22, p. 644. What did the writer have in mind?

M. H., Illinois.

Answer.—Korteweg presents evidence to show that the guinea-pig is less susceptible to tuberculosis than we have heretofore assumed and that man is more susceptible. The misconceptions in the past have been due to the fact that the research workers have not been careful enough to discriminate between primary and repeated infection; that is, whether the subject was in a state of allergy or not. He says it is interesting to go over the reports in the older archives and, by the light of the new knowledge as to allergy, clear up the conflicting findings. One worker injected the tubercle bacilli in the ear, for example, and described the blood-borne focus in the lung that had developed at once and directly as an actual primary lesion. Another worker injected the bacilli in the bladder, and then examined the blood-borne focus in the lung after an interval of weeks or months. This focus was not a primary lesion, but had developed after a condition of allergy had been realized. Naturally the two lesions differed widely.

DIATHERMY FOR PROSTATITIS

To the Editor:—In The Journal, October 10, you state that "diathermy furnishes excellent results in cases of chronic prostatitis. It is applied by placing a large indifferent electrode on the abdomen and a prostatic electrode in the rectum."

The technic at the Mount Sinai Hospital advised by Dr. H. Wolf, chief of physiotherapy, is as follows: The patient is seated on a chair. The large indifferent electrode is placed on the abdomen and held in place by means of an elastic bandage. A smaller electrode, triangular and padded with absorbent cotton which has been dipped in salt solution, is placed under the *perineum.*

The advantages of this procedure are that,—there is less danger of burning the patient and the heat of the smaller electrode will penetrate not only the prostate proper but the adjacent structures, as the seminal vesicles, while in the direct method, one cannot be sure of reaching the diseased part and at any rate he cannot treat more than one lobe at the time. That the heat travels up into the rectum is shown by the raised *rectal temperature (from 102 to 103 F.) taken immediately after* treatment.

Benjamin Damsky, M.D., New York.

PAN-SECRETIN — POSTGRADUATE STUDY

To the Editor:—1. Is there any clinical or experimental evidence that *any enzyme or gland product, such as "Pan-Secretin"* of the much advertised Harrower Company, or others, taken by mouth, has any value in replacing or supplementing insulin in the treatment of diabetes? 2. Does the American Medical Association have any organized information available on postgraduate work in medical subjects and clinical opportunities, American and foreign? Please omit my name.

M.D.

Answer.—1. There is no evidence that any preparation taken by mouth has been shown to be an efficient method of obtaining the effects of insulin. A discussion of "Pan-Secretin" appeared in Queries and Minor Notes, The Journal, March 10, 1923, page 717.

2. A folder on this topic is supplied by the Council on Medical Education and Hospitals of the American Medical Association.

CURE OF SYPHILIS

To the Editor:—1. Given a patient with syphilis and a positive Wassermann reaction, is it safe to conclude that this patient is cured, following a course of treatment including from ten to twenty arsphenamin injections and two or three courses of mercury, if a Wassermann negative report is obtained on two or three occasions during the following three or four months? 2. My personal opinion is that a syphilitic patient with a positive Wassermann reaction has not received adequate treatment unless several courses of arsenic, bismuth and mercury have been given covering a two year period and a two year observation period, with Wassermann tests during this last period, and that Wassermann tests taken early are fallacious and only tend to undertreatment if negative. Please answer this under Queries and Minor Notes and please omit name.

M.D., Pennsylvania.

Answer.—1. No.

2. A sound position.

COMING EXAMINATIONS

Arkansas: Little Rock, Nov. 10-11. Sec., Reg. Bd., Dr. J. W. Walker, Fayetteville.

Connecticut: New Haven, Nov. 10. Sec., Reg. Bd., Dr. Robert L. Rowley, 79 Elm St., Hartford; Sec., Homeo. Bd., Dr. Edwin C. M. Hall, 82 Grand Ave., New Haven.

Delaware: Wilmington, Dec. 8-9-10. Pres. Med. Coun., Dr. Henry W. Briggs, 1026 Jackson St., Wilmington.

Maine: Portland, Nov. 10-11. Sec., Dr. Adam P. Leighton, 192 State St., Portland.

Maryland: Baltimore, Dec. 8-11. Sec., Reg. Bd., Dr. Henry M. Fitzhugh, 1211 Cathedral St., Baltimore, Sec., Homeo. Bd., Dr. J. S. Garrison, 517 Old Orchard Rd., Baltimore.

Massachusetts: Boston, Nov. 10-12. Sec., Dr. Frank M. Vaughan, 144 State House, Boston.

Missouri: Kansas City, Oct. 27-30. Sec., Dr. James Stewart, Jefferson City.

Nevada: Carson City, Nov. 2. Sec., Dr. Simeon L. Lee, Carson City.

North Carolina: Raleigh, Nov. 25 (Endorsement of Credentials only). Sec., Dr. Kemp P. B. Bonner, Morehead City.

Ohio: Columbus, Dec. 2-4. Sec, Dr. H. M. Platter, Hartman Hotel Bldg., Columbus.

Philippine Islands: Manila, Nov. 10. Sec., Dr. Jose V. Gloria, 686 Rizal Ave., Manila.

South Carolina: Columbia, Nov. 10. Dr. A. Earle Boozer, 505 Saluda Ave., Columbia.

Texas: Dallas, Nov. 17-19. Sec., Dr. T. J. Crowe, 918-919 Mercantile Bank Bldg., Dallas.

Virginia: Richmond, Dec. 8 11. Sec., Dr. J. W. Preston, 720 Shenandoah Life Bldg., Roanoke.

OPENING OF VANDERBILT UNIVERSITY MEDICAL BUILDINGS

Celebration of Vanderbilt University's fiftieth anniversary was held, October 15-18, and was featured by formal opening of the university's $3,000,000 medical school. Many health officers and physicians from other states were among those inspecting the new school, the hospital and school of nursing.

Drs. Simon Flexner and William H. Welch addressed the medical conference at the semicentennial celebration. G. Canby Robinson, dean of the Vanderbilt Medical School, presided.

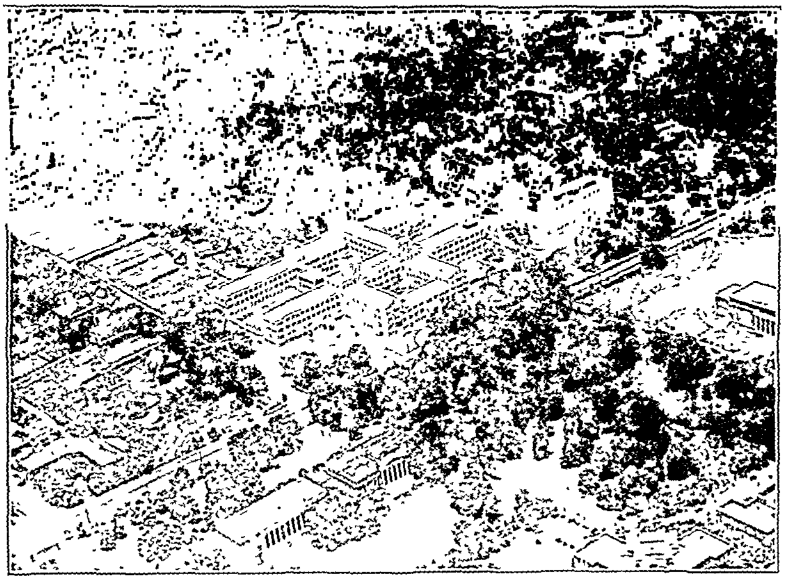

Fig. 1.—Aeroplane view of Vanderbilt University Medical School. To the right above is the nurses' home; below and in the foreground are other university buildings.

Praise of the new school was linked with an appeal that the new facilities be used for the greatest good of the public. Both speakers also urged closer cooperation between public health officers and physicians. Dr. Welch said in part:

"There is nothing more disgusting to me than the antagonism that has sprung up between public health officials and practitioners. For the moment the matter is serious, although it is only a temporary episode and will pass away."

Dr. Flexner asserted that "such a preparation as this to serve science [referring to the new medical plant] is an event of national or even international importance." He compared nineteenth century methods of the medical profession with those of today. In that era, he said, learning of medicine consisted largely in study of texts, whereas modern schools have developed the laboratory method to its fullest extent. He pointed to Vanderbilt's ample facilities for extension of its research.

"With the opening of such schools as this," he continued, "the question is, How can we serve best?"

Mr. George M. Vincent, president of the Rockefeller Foundation, reviewed progress of the medical profession and linked Vanderbilt's school with those of Johns Hopkins, Washington University and the large eastern institutions. He urged that the medical department seek to link its work with that of other schools, and to correlate its service with the needs of the public. "By sympathetic comradeship with the medical profession," said Dr. Vincent, "by social intercourse, by public address, the men and women of this institution may create a sympathetic appreciation of the aims and achievements as well as the baffling difficulties of modern medicine. . . . The times call for a service of this sort from the leaders of scientific medicine. The prevalence of active and well financed campaigns against animal experimentation and vaccination strikes at the foundation of medical research and public health procedure. In certain quarters the very existence of disease is denied. . . . On the leaders of medical science who are not engaged in private practice and on intelligent laymen must fall the burden of informed and courageous support of science and the scientific method as vital factors of individual and social welfare."

Delegates to the semicentennial were entertained at dinner in the medical buildings, and inspected the entire plant.

California June Examination

Dr. Charles B. Pinkham, secretary of the California Board of Medical Examiners, reports the written examination, held at Los Angeles, June 15-18, and San Francisco, July 6-9, 1925. The examination covered 9 subjects and included 90 questions. An average of 75 per cent. was required to pass. Of the 90 candidates examined 80 passed and 10 failed. Ninety-nine candidates were licensed by reciprocity. Fifteen candidates were licensed by endorsement of credentials. The following colleges were represented:

Practical Clinical Psychiatry for Students and Practitioners By Edward A. Strecker, A.M., M D, Medical Director, Pennsylvania Hospital, Department for Mental and Nervous Diseases, and Franklin G Ebaugh, A B, M D, Professor of Psychiatry, University of Colorado Cloth Price, $4 net. Pp 375, with 24 illustrations. Philadelphia: P. Blakiston's Son & Co, 1925

This handbook is prepared to meet the needs of students as an introduction to more extensive works on psychiatry, and of practitioners as a review or incentive to further study of this great group of mentally sick and mentally defective persons The importance of this study is stressed by the authors as epitomized in the statement. "Of 7,000 infants born each day in the United States, about 270, or one in twenty-six, eventually becomes incapacitated by abnormalities of the mind" The discussion of etiology, diagnosis, prognosis and treatment is admirably presented, and the classification of mental diseases follows that in common use in institutions. For the beginner the mastery of this classification will be found a severe task, and yet some such scheme must be used as an introduction to the presentation of the various subjects. The authors have adopted the case method in the presentation of their subjects, a method that appeals particularly to students and is highly interesting to practitioners, and is probably the best of all methods. The case records are clearly set forth, and they are discussed and summarized in an instructive manner. The section on psychoses leaves little to be desired. Perhaps more illustrations would add to the interest of the text. In the discussion of the psychoneuroses, the authors are possibly limited by their institutional training and opportunities, so that the twilight cases and minor cases that bulk so largely in general practice are not adequately presented. While the authors do not follow the Freudian psychanalytic methods, and indeed indicate that in some instances they are distinctly detrimental to the patient, nevertheless they say so much about them that the student is likely to be misled as to their value, both in the understanding of the neuroses and in their attempts at management. The chapter on constitutional psychopathic inferiority is well written and should be in the hands of every practitioner. The mental deficiency classes again seem to be presented from the limited experience of institutional physicians. A well written glossary is of distinct assistance to the beginner, and to some degree makes the book available for the nonmedical reader. The difficult task of compressing a large amount of material within the limits of a small volume is, on the whole, admirably accomplished.

HANDBUCH DER HALS-NASEN OHREN-HEILKUNDE. Mit Einschluss der Grenzgebiete. Herausgegeben von A. Denker und O. Kahler. Erster Band. Die Krankheiten der Luftwege und der Mundhohle I. Erster Teil. Anatomie. Entwicklungsgeschichte Physiologie. Untersuchungsmethoden. Paper. Price, 87 marks. Pp. 1068, with illustrations. Berlin: Julius Springer, 1925.

This large volume is the first of nine that are to cover the subject of the ear, nose and throat, together with subjects on the borderline of otolaryngology and allied topics. Volumes 1 to 5 inclusive will cover the respiratory tract and oral cavity; Volumes 6, 7 and 8, otology, and the final volume will discuss diseases of the esophagus and the neck. The work begins with the anatomy and embryology, together with the comparative anatomy and histology of the nose, pharynx, mouth, larynx and bronchial tree. The next section covers the physiology of those structures with a most complete chapter on olfactometry by Zwaardemaker, and one on the voice and speech by Nadoleczny. The third section on pathology and therapy includes a comprehensive discussion of direct and indirect laryngoscopy by Seiffert. One appendix deals with the radiography of the nose, accessory sinuses, larynx, trachea and bronchi; another gives a short account of immunology. The articles are contributed by distinguished specialists and workers in the various subjects of otolaryngology. The numerous topics are presented in a detailed manner, and most of the chapters are accompanied by a comprehensive bibliography. The subject matter is further elucidated by excellent illustrations and diagrams. Judging from the first volume, this work will be of an encyclopedic character and will no doubt serve as a standard of reference for years to come. It is impossible to discuss in detail the many features; the character of the contributors of the many chapters is a guarantee of the authoritativeness of the statements made, and opinions expressed by the various authors. Not since the publication of Heymann's Handbuch of Laryngology, published in 1898, have we had so complete a system bringing the subjects up to date, as that presented by this work of Denker and Kahler. The publishers have also done their part, as shown in the excellent paper, type and illustrations that they have used.

THE FATS. By J. B. Leathes, M.A., M.B., F.R.S., Professor of Physiology in the University of Sheffield, and H. S. Raper, C.B.E., M.B., D.Sc., Brackenbury Professor of Physiology in the University of Manchester. Second edition. Paper. Price, $4.50. Pp. 242. New York: Longmans, Green & Co., 1925.

This is a new edition of one of the valuable series of Monographs on Biochemistry, issued fifteen years ago by the senior author. It partially parallels the monograph by Maclean on "Lecithin and Allied Substances" in the same series, but it is devoted primarily to a consideration of the simple fats. It covers not only the chemical properties of the fats and fatty acids, the methods of extraction and estimation, and their physical properties, but also their physiology, fully half the book being devoted to the latter topic. The reader will find a brief statement of what is known at present about the fats expressed in readable fashion, especially in respect to the biologic functions of the fats. Of particular interest to the physician is the chapter on the part played by the fats on the life of the cell, for here is pointed out clearly the importance of fats and lipoids for normal function. The newer ideas of the arrangement of molecules in surface films are utilized in explaining the properties of cell membranes. One notes with regret that the author adheres to a nomenclature for the fatty substances which is not in harmony either with the spelling used by Maclean in the same series of monographs or with the usage of the American Chemical Society. It will be a glad day for editors when the biochemists can agree on a nomenclature and spelling of the important group of substances that are so well described in this monograph.

THE CEREBRO-SPINAL FLUID IN CLINICAL DIAGNOSIS. By J. Godwin Greenfield, M.D., B.Sc., M.R.C.P., Pathologist to the National Hospital for the Paralyzed and Epileptic, and E. Arnold Carmichael, M.B., Ch B., Resident Medical Officer, National Hospital for the Paralyzed and Epileptic. Cloth. Price, 12 shillings net. Pp. 272. London: Macmillan & Co, 1925.

This book can be recommended to both laboratory workers and practitioners. It is a clear and concise statement of most of the essentials in the methods of examining spinal fluid. It also has an excellent discussion of the spinal fluid findings in the various diseases in which the central nervous system is involved or lumbar punctures are likely to be performed. The significance of the various spinal fluid findings is well discussed. An excellent table of contents and an index make the book easily usable. An extensive bibliography is given which gives a true index of the scope of the volume, showing that the American literature has been neglected to some extent. For example, important articles on meningitis sympathica and on spinal fluid sugar are neglected. Nevertheless, this book can be recommended for a place in the physician's library.

Medicolegal

No Recovery for Services by Unlicensed Person—Note

(Lyon v. Leet (Iowa), 202 N. W. R. 881)

The Supreme Court of Iowa, in affirming a judgment dismissing the petition in this action on a promissory note which the defendant gave for treatment in 1917 by the plaintiff, says that the plaintiff was then engaged in the practice of chiropractic, maintained an office therefor, and publicly professed to cure or heal diseases. The services were rendered some four years before the enactment of the law regulating the practice of chiropractic in Iowa. The plaintiff, in that he was a person who publicly professed to cure or heal, came within the prohibition of Section 2579 of the code of 1897, which in part provides that any person shall be held as practicing medicine "who shall publicly profess to cure or heal." This court has held that one so publicly professing to cure or heal without a license so to do violates said statute, and is subject to the penalty provided for such violation. It is the general and uniform holding of the courts that one who publicly professes to cure or heal, or hold himself out as a *physician, without a license to practice as such, cannot recover* compensation for his services rendered in such capacity. It is obvious that the plaintiff in this case violated the statute in publicly professing to heal or cure without a license so to do. The contract to compensate him for services so illegally rendered was void. The note in suit having been given as compensation for said services was void in the hands of the plaintiff, the original payee thereof.

Temperamental Eccentricities—"Irrational"—Evidence

(Lee v. State (Okla.), 234 Pac. R. 654)

The Criminal Court of Appeals of Oklahoma, in affirming a judgment of conviction of defendant Lee of murder, says that the only claim of error urged in the defendant's brief was that the trial court excluded and withdrew from the jury testimony offered in some instances and given in others, which testimony tended to show that the defendant at the time of the homicide was insane, but no attempt was made to establish the defendant's insanity by expert witnesses, or those skilled as alienists, or persons trained and competent to diagnose or analyze diseases of the mind. Where testimony tending to establish insanity is offered, the trial judge must determine in the first instance whether the proffered testimony reasonably justifies an inference of insanity. It follows, therefore, that if such evidence has been admitted, and the facts so shown do not justify an inference of insanity, the court may withdraw the testimony from the consideration of the jury. If, however, the evidence in any slight degree tends to support the plea of insanity, it should be admitted. If there is any competent testimony tending to establish insanity, the weight of such testimony is for the jury. Opinion evidence on insanity must be shown to be based on facts submitted as a foundation for that opinion. Mere conclusions of the witness, based on observation, without a showing of fact from which such conclusions may logically be drawn, are insufficient. That being true, it would seem that erroneous conclusions not warranted by the facts, may be excluded.

It has been held that temperamental eccentricities of mind and conduct, alone, are not evidences of insanity. A man may do the most extraordinary things; he may recklessly squander his money; his conduct may be the subject of ridicule; he may be addicted to sudden bursts of passion and of harsh treatment toward those he should treat with tenderness; his deportment on a particular occasion may be an outrage on decency and propriety. All this, if it be the result of eccentricity of character, or of depraved taste, or an unfortunate temper, and does not proceed from a permanent disorganization of the mental faculties, will not support a plea of insanity.

The opinion of a nonexpert witness that a person is irrational, based on observations of this character, is a conclusion merely, not warranted by the facts. Most persons have some temperamental peculiarities of thought and action that to others seem queer. The term "irrational" is an elastic term, one that may convey one idea to one person and an entirely different idea to another. "Irrational" may mean unreasonable, foolish, absurd, and a person in such sense may be irrational, and still not be, in any legal sense, insane. If it could be shown as a defense in every homicide case that the perpetrator at some period of his life acted queer, unreasonable or absurd, that defense could be interposed and relied on in all homicide cases.

To establish a legal defense on the ground of insanity, there must be a showing that at the time of the commission of the deed the person accused was laboring under such a defect of reasoning, from some disease of the mind, as not to know the nature and quality of the act he was doing, or, if he did know, that he did not know that what he was doing was wrong. Idiosyncrasies, peculiarities or unreasonable conduct may be a symptom of insanity when these are due to some disease of the mind and when it is shown that at some period of the man's life he was not possessed of such traits.

Disability "Permanent" Notwithstanding a Recovery

(Penn Mut. Life Ins. Co. v. Milton (Ga.), 127 S. E. R. 140)

The Supreme Court of Georgia, in answering questions certified to it by the court of appeals, says that a policy of insurance provided that if the insured should furnish proof that he "has become wholly disabled by bodily injury or disease, so that he is and thereby will be permanently and continuously unable to engage in any occupation whatever for remuneration or profit, and that such disability has existed continuously for not less than sixty days prior to the furnishing of proof," thereupon the company would grant certain benefits. Did the language "permanently and continuously" mean that the total disability must last forever before the insured would be entitled to the benefits provided in the policy? "Permanent" is the antithesis of "temporary." The word "permanent" does not always mean forever or lasting forever. The meaning of that word is to be construed according to its nature and in its relation to the subject matter of the contract. The words "permanently and continuously," standing alone, would mean that the total disability must be a lasting one; but when these words were taken in connection with other language used in the several provisions of this insurance policy, the fair construction of these words was, not that the total disability should last or exist forever, but that a disability which existed continuously for no less than sixty days prior to the furnishing of proof was, within the meaning of the policy, a "permanent disability."

A provision, following the one stated above, to the effect that in such case the insurance company would waive the payment of the premiums which thereafter might become due under this policy "during the continuance of the said total disability," carried an implication that the insurer contemplated that the disability might terminate, in which event the waiver of the payment of premiums would come to an end. Again, a provision that monthly payments of $50 would be made "during the continuance of said total disability of the insured and prior to the maturity of this policy" clearly indicated that the insurer meant that the total disability, on proof of which it would grant the benefits named, was not one which might last during the entire life of the insured, but one which might end prior to his death.

So the supreme court is of the opinion that under the terms of this policy a total disability which lasted for sixteen months, and from which the insured had recovered, was a "permanent disability" within the meaning of the provisions of the policy.

Evidence from Necropsies Made Without Notice

(Lowe v. People (Colo.), 234 Pac. R. 169)

The Supreme Court of Colorado says that in this homicide case, in which the body of the deceased was taken to Illinois for burial and then exhumed and a necropsy made, the disclosures of the necropsy were evidenced by the testimony of the physician who performed it and that of other witnesses there present, by photographs taken during its progress, and by that portion of the skull of the deceased showing a fracture. All this, counsel for the defendant insisted, should have been excluded, because the defendant was given no notice that such a proceeding was contemplated, and had no legal representative in attendance. Authorities were cited which advised such representation, which said that distinguished writers on medical jurisprudence hold that evidence of such necropsies will be excluded if "taken flagrantly ex parte" (from, or in the interest of, one side only); that all the circumstances surrounding such a transaction should be inquired into; and that under certain circumstances such evidence should be accompanied with cautionary instructions. But none of those authorities supported this assignment of error, and that which cited the opinion of writers on medical jurisprudence disagreed with their conclusion, and added:

> "Not only has the practice been to receive the testimony of experts who have made ex parte investigations, but, in our opinion, it is entirely proper that the testimony should be allowed to go to the jury, whose duty it is to determine the weight to be accorded to it."—Rogers on Expert Testimony (Ed. 2), Sec. 14, p. 35.

The Supreme Court of Colorado believes that this is the correct rule. Once the contrary is established, no logical halting place can be discerned short of declaring that at all important steps in the people's investigation and preparation for trial the defendant shall be represented. Furthermore, this court rejects the suggestion that, if admitted, such evidence should be accompanied by cautionary instructions as being, in ordinary cases, an improper invasion of the province of the jury.

Society Proceedings

COMING MEETINGS

American College of Surgeons, Philadelphia, Oct. 26-30. Dr. Franklin H. Martin, 40 East Erie Street, Chicago, Director-General.
Central States Pediatric Society, Chicago, November 6-7. Dr. H. T. Price, Westinghouse Building, Pittsburgh, Secretary.
District of Columbia, Medical Society of, Washington, D. C., Dec. 2. Dr. C. B. Conklin, 500 Medical Science Bldg., Washington, D. C., Sec'y.
Philippine Islands Medical Association, Manila, Dec. 16-19. Dr. Isabelo Concepcion, College of Medicine and Surgery, Manila, Secretary.
Porto Rico, Medical Association of, Coami, Dec. 14-15. Dr. R. M. Suarez, Box 314, Santurce, Secretary.
Radiological Society of North America, Cleveland, Dec. 7-11. Dr. Robert J. May, St. Luke's Hospital, Cleveland, Secretary.
Southern Medical [illegible] November 9-12. Mr. C. P. Loranz, Empire [illegible] Secretary.
Southern Surgical [illegible] .y., Dec. 15-17. Dr. Hubert A. Royster, 423 [illegible] N. C., Secretary.
Western Surgical Association, Wichita, Kan., Dec. 18-19. Dr. Harry P. Ritchie, Lowry Building, St. Paul, Minn., Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal for a period of three days. No foreign journals are available prior to 1920, nor domestic prior to 1923. Periodicals published by the American Medical Association are not available for lending, but may be supplied on order. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested).

Titles marked with an asterisk (*) are abstracted below.

American Journal of Anatomy, Philadelphia

36: 1-176 (Sept. 15) 1925

Interpretation of Recorded Arterial Anomalies of Human Pelvis and Thigh. H. D. Senior, New York.—p. 1.
Hair in Relation to Homology and Phylogeny. C. H. Danforth, Stanford University, Calif.—p. 47.
Prepubertal and Postpubertal Oogenesis in White Rat, Mus Norvegicus Albinus. M. H. Cowperthwaite, St. Louis.—p. 69.
*Autoplastic and Homoplastic Parathyroid Transplantation. W. W. Swingle and J. S. Nicholas, Pittsburgh.—p. 91.
*Mitochondria. IX. Bacterial Nature. I. E. Wallin, Denver.—p. 131.
Pancreatic Bladder. E. A. Boyden, Boston.—p. 151.

Parathyroid Transplantation.—It is the belief of Swingle and Nicholas, based on experimental findings in cats, that many of the reported cases of successful homoplastic parathyroid transplantation in man, i. e., successful in the sense that the tetany was permanently cured, are due not to permanent survival of the graft, but to a purely temporary effect produced by absorption of the graft and its hormone which tided the individual over a critical period of a few days until the functionally deranged glands of the individual, or accessory parathyroids, could assert their activity.

Bacterial Nature of Mitochondria.—From the results of new experiments the conclusions arrived at by Wallin from previous investigations, namely, that mitochrondria are bacterial organisms symbiotically combined with the cells of all higher organisms, appear to be unconditionally confirmed. Mitochondria are highly sensitive micro-organisms which respond with pleomorphisms to changes in their environment. Symbosis is not a biologic curiosity as such, but represents the expression of a fundamental biologic principle, "symbionticism," which finds its most complete expression in the relationship represented by mitochondria in the cell. The functions and source of mitochondria, as well as their full significance in relation to the organic world, remain for future investigations to determine.

American Journal of Obstetrics and Gynecology, St. Louis

10: 313-460 (Sept.) 1925

Uterine Endoscopy; Endometroscopy with Aid of Uterine Insufflation. I. C. Rubin, New York.—p. 313.
*Improvements in Operative Treatment of Uterine Retrodisplacement. H. S. Crossen, St. Louis.—p. 327.
*Solid Teratomata of Ovary; Two Cases. W. T. Black, Memphis, Tenn.—p. 345.
*Use of Zinc Chlorid in Gynecology. J. C. Masson, Rochester, Minn., and H. O. Foucar, London, Ont.—p. 355.
Some Unusual Vaginal Fistulae. H. R. Spencer, London, Eng.—p. 365.
*Present Status of Intravenous Use of Mercurochrome. E. B. Piper, Philadelphia.—p. 371.
Pelvic Lesions as Contributing Factor in Chronic Cystic Mastitis. C. J. Miller, New Orleans.—p. 375.
Elusive Ulcer of Bladder. F. E. Keene, Philadelphia.—p. 380.
Analysis of One Hundred and Fifty-Two Cases of Ectopic Gestation. W. B. Hendry, Toronto, Ont.—p. 386.
Pus Tube. H. A. Royster, Raleigh, N. C.—p. 392.
*Sedimentation Test in Gynecology. J. L. Baer and R. A. Reis, Chicago.—p. 397.
Occupational Diseases in Women. B. Friedlander, Detroit.—p. 403.

Treatment of Uterine Displacement.—Crossen emphasizes the importance of the study of the pathologic conditions present in each pelvis, and the selection of the operative method best adapted to these conditions. It is such study and selective treatment, he says, that promises most advance in the effective handling of uterine retrodisplacement.

Teratomas of Ovary.—Black urges that a uniform classification be adopted. A satisfactory classification is cystic and solid teratomas. Solid teratomas are rare and unusually malignant. The histogenesis of teratomas is not understood. For embryologic and physiologic reasons the blastomere theory is more comprehensible. Parthenogenetic development has been demonstrated in some of the lower forms of life, but not in the human. There are no pathognomonic symptoms. The prognosis is grave. Conservatism should be observed in the young when the covering membrane is intact, and there is no evidence of malignancy. In older women, if there is a suspicion of malignancy, a radical operation should be performed.

Use of Zinc Chlorid in Gynecology.—The thirty cases in which zinc chlorid was used in the Mayo Clinic were selected from 1,492 cases in which surgery was advised for some pathologic condition of the uterus. In 416 cases, dilatation and curettage were done, in 471 cases, hysterectomies were done, in seventy-five cases myomectomies were done, and in 500 cases radium was used. Experience with the method leads Masson and Foucar to believe that it has a very limited field; *it is probably not applicable in more than 2 per cent.* of uterine cases. However, in cases in which the treatment is especially indicated, satisfactory results are usually obtained. The chief disadvantage is the lack of any very accurate means of dosage. The advantages of the procedure are its simplicity and the fact that the endometrium can be destroyed without injury to the ovaries. A major operation can be avoided in certain borderline cases. Should this treatment prove unsatisfactory, hysterectomy can still be performed.

Intravenous Use of Mercurochrome.—Piper is not an ardent advocate of this treatment because it is not unattended by danger. Its use in puerperal septicemia per se is most discouraging, though there have been some good results. In spite of various investigators who contend that the penetrability of some synthetic preparation will eventually solve this problem, Piper is of the opinion that there is some other, at present unknown, factor, which must first be determined before blood-stream infection may be eradicated successfully. No intravenous medication will avail without common sense surgery.

Sedimentation Test in Gynecology.—Baer and Reis present the results of a study of 192 sedimentation tests carried out in 100 gynecologic cases. The sedimentation test is useful in determining the presence or absence of infection in the body. With pathologic conditions of the pelvis, a negative sedimentation test, i. e., a sedimentation time over two hours, conclusively rules out pelvic infection. The rate of sedimentation is directly proportional to the virulence of the infection. The test is a further aid for determining the safe time for operation. The sedimentation test seems a more delicate prognostic index, good or bad, than either the leukocyte or temperature curve.

American Journal of Pathology, Chicago

1: 445-546 (Sept.) 1925

*Intranuclear Inclusions in Visceral Disease. W. C. Von Glahn and A. M. Pappenheimer, New York.—p. 445.
*Congenital Heart Disease with Partial Situs Inversus, Absence of Inferior Vena Cava, and Other Anomalies. A. J Miller, Boston.—p. 467.
Progressive Alcoholic Cirrhosis; Four Cases. E. M. Hall and W. Ophuls, San Francisco.—p. 477.
Focal Tuberculin Hypersensitiveness in Infected Organ Previous to General Sensitization. F. W. Stewart, Boston.—p. 495.
Gross and Histologic Changes in Edema of Paraphenylenediamine. M. L. Tainter and E. M. Hall, San Francisco.—p. 503
*Mechanical Irritation as Etiologic Factor of Cancer. N M Alter, Denver.—p. 511.
*Neuroblastoma of Intestine. S. A. Ritter, New York. p. 519

Intranuclear Inclusions in Visceral Disease.—The presence of intranuclear bodies with specific tinctorial properties has been widely accepted as indicative of infection with a virus having special affinity for tissues of neural or ectodermal origin. Von Glahn and Pappenheimer present morphologic evidence that similar bodies may be found in lesions of internal organs, and bring forward for consideration the possibility that viruses of this type may localize in tissues other than skin and central nervous system.

Situs Inversus and Heart Anomaly.—The case presented by Miller may be summarized as: congenital heart disease, comprising a patent foramen primum and secundum, patent pars membranacea septi, one atrioventricular valve empting into the left ventricle, misplaced ventricular septum, both aortae arising from the left ventricle, hypertrophy of the left ventricle and right atrium; anomalous vessels comprising absence of inferior vena cava with the renal and common iliac veins emptying into the azygos vein; absence of the transverse portion of the left innominate vein which empties into the coronary sinus; a common stem for the right subclavian and both common carotid arteries; transposition of the aortae, persistent ductus arteriosus, and both coronary arteries arising from a common stem; situs inversus of liver, gallbladder, hilum of liver, esophagus, stomach, duodenum, pancreas and spleen; accessory pancreatic duct and spleens.

Irritation as Cause of Cancer.—The case of carcinoma of the sigmoid reported by Alter appears to present a striking example of mechanical irritation as an etiologic factor in the histogenesis of cancer. The cancer originated where the head of the polyp caused friction of long duration.

Neuroblastoma of Intestine.—Two cases of intestinal neoplasm are reported by Ritter. They are grouped with the neuroblastomas because of their histologic characteristics. In both instances the tumors arose in persons past middle age. Metastases were found only in the adjacent mesenteric lymph nodes. The observations indicate a new and hitherto undescribed site for primary neuroblastomas. So far as can be ascertained, no similar cases have been reported in the literature.

American Journal of Public Health, Albany, N. Y.

15: 757-846 (Sept.) 1925

*Public Health Laboratories. I. V. Hiscock and M. S. Hiscock, New Haven, Conn.—p. 757.
Sun Worshipping in Pennsylvania. J. C. Funk, Harrisburg.—p. 764.
Significance of Tuberculin Test in Pasteurized Milk Supply. J. H. Shrader, Baltimore.—p. 767.
*Automatic Faucet Possible Vector of Infection. I. C. Hall and J. U. Wing, Ithaca, N. Y.—p. 770.
*Use of Hemolyzed Specimens in Kahn Test. P. L. Hendrick and M. K. Lowe, Lansing, Mich.—p. 772.
*Vital Capacity of Children Infested with Hookworm. F. L. Roberts, Trenton, Tenn.—p. 774.
Rupp Method for Detection of Chlorin in Milk. J. Y. Keister, Washington, D. C.—p. 781.
*Cost of Preschool Health Service. J. C. Gebhart, N. Y.—p. 784.

Public Health Laboratories.—The Hiscocks found that public health laboratory service is well developed in the majority of the 100 largest cities of the United States. The scope of laboratory operations is apparently more uniform than the methods of record keeping. The importance of research is generally recognized by laboratory directors, but in nearly 80 per cent. of the laboratories special studies of this character cannot be undertaken because of lack of adequate funds and a sufficient corps of trained workers. The average number of examinations performed in seventy-eight cities was 78 per thousand population, 77 per cent. being of a diagnostic character. A study of the work of several first-class laboratories indicates, however, that from 100 to 125 examinations per thousand population may be expected from such a laboratory, organized on a full-time basis, except in a few cases where extensive-research-problems are under investigation. The cost of laboratory examinations exclusive of research varies considerably, but averages 51 cents. The cost per capita for laboratory services ranges from less than 1 cent to 13 cents, but averages 4 cents. Under present conditions, from 4 to 9 cents per capita are needed in most cities for the maintainence of a first-class public health laboratory, providing for research as well as for a wide range of bacteriologic and chemical examinations. The attitude of local physicians toward the laboratory is reported as favorable or cooperative in most cases.

Automatic Faucet Vector of Infection.—Hall and Wing call attention to a possible danger in a type of automatic faucet or tumbler filler, often used in restaurants and cafeterias. It consists of a rubber covered cross bar against which the lips of the glass are pressed, thereby releasing a flow of water into the glass. The removal of the glass stops the flow of water. If only clean glasses were used there would be no objection. But one often observes a customer swallowing the contents of his or her glass at the fountain and refilling or coming back from the table for more. It is evident that fresh saliva from the lips of a used glass may be conveyed directly to the next one placed in position and the frequency with which such an apparatus may be used even in a small establishment suggests that infectious diseases may be so transmitted.

Use of Hemolyzed Serum in Kahn Test.—Kendrick and Lowe conclude from data presented that the results with hemolyzed specimens in the Kahn precipitation tests are reliable.

Vital Capacity of Hookworm Infested Children.—This research by Roberts shows that hookworm infestation does not materially decrease the vital capacity of the child population between 6 and 18 years of age when this population is considered as a whole.

Cost of Preschool Health Service.—The experience of the Mulberry Health Center of New York City organized and maintained by the Association for Improving the Condition of the Poor, is reported on by Gebhart. The center has developed an economic and efficient community program for reaching the preschool child which will appeal to other communities facing the same problem. The conduct of the preschool drive has demonstrated that the health center, a community health venture, may very readily become the agency to enlist the interest, secure the cooperation and coordinate the efforts of all organizations working in the district for the advancement of the welfare of the preschool child. The per capita cost ($1.75) for the group which had all defects corrected without follow-up is the lowest. The group reporting all defects corrected with the assistance of the field nurses was $3.33, while the per capita cost for the group reporting no defects corrected was nearly as high ($3.16).

American Journal of Roentgenology and Radium Therapy, New York

14: 207-290 (Sept.) 1925

Experimental Study of Markings Seen in Roentgenograms of Lungs of Normal Dogs. W. J. Marquis, Rochester, Minn.—p. 247.
Metastatic Manifestation in Spine of Hodgkin's Granuloma. N. H. Robin, New York.—p. 251.
Treatment of Bone Sarcoma by Toxins, Radiations, Amputation or Resection. J. C. Bloodgood, Baltimore, Md.—p. 253.

Effect of Ultraviolet Radiation on Transplanted Carcinoma.—In vitro experiments made by Sugiura and Benedict indicate that the proliferating capacity of Flexner-Jobling rat carcinoma was stopped by the radiation in comparatively short exposures. This destructive action appears to be due to the selective absorption of the radiation by the cancer cells. The results of irradiation of a malignant mass at a depth in the animal body by ultraviolet radiation applied externally may be summarized as follows: (*a*) The development of small tumors is checked by severe doses; (*b*) there is an increased rate of growth of malignant tumors after inadequate irradiation of small tumors, and (*c*) large tumors are seldom beneficially affected by the irradiation. Radiation from a quartz mecury arc lamp does not confer resistance on rats and mice to transplanted cancer.

Roentgenotherapy of Chronic Cough.—The class of children in which roentgen-ray irradiation seems of distinct therapeutic service in the treatment of cough are summarized by Fisher as follows: The children from 2 to 9 years of age—rarely older—and in only an occasional instance younger: they are usually healthy looking, well nourished and without any distinctive physical signs in the chest. Occasionally, a few râles may be heard, but usually auscultation and percussion yield no information of any detectable intrathoracic pathologic change. Yet in all the cases there is a history of longstanding cough, very often harassing and persisting even during sleep. The cough is in most instances nonproductive. Occasionally some glairy mucus is expelled. Some attacks are paroxysmal in character and may simulate bronchial asthma from which it can usually be differentiated by the lack of dyspnea, the accompanying breast heaving and rapid respiration. The longer duration—some cases may be of several years' duration—will serve to distinguish it from whooping cough. Clinically, these children more closely resemble a nonproductive chronic bronchitis than any other clinical entity. The results from roentgen-ray therapy have proved highly gratifying. Complete cessation of the cough is obtained in practically every instance.

Boston Medical and Surgical Journal

193: 583-616 (Sept. 24) 1925

*Control of Gaseous Metabolism Apparatus. F. G. Benedict, Boston.—p. 583.
*Echinococcus Cyst of Spleen. D. Boyd, Boston.—p. 591.

Control of Metabolism Apparatus.—The extensive use of gaseous metabolism technics makes control of the various forms of apparatus imperative. Benedict says that this is best accomplished by developing in the air current a production of carbon dioxid and an abstraction of oxygen approximately equivalent to that produced by a man at rest. The combustion of known amounts of pure ethyl alcohol in a suitable burner, a combustion chamber, and a ventilating device make such controls possible. With the mechanicochemical device of Carpenter and Fox (a modification of which is described) alcohol can be introduced at any desired rate, the normal respiratory movements of a human subject can be simulated, the efficiency of valves can be tested, and both open — and closed — circuit respiration apparatus, including respiration chambers of any size and the various forms of gas analysis apparatus, can be controlled.

Echinococcus Cyst of Spleen.—In the case described by Boyd the diagnosis remained obscure because the patient had never lived on a farm and denied having ever had any contact with dogs or any animals as pets. The patient was known to have borne the splenic tumor for thirty years, during which time she had surprisingly few symptoms.

California and Western Medicine, San Francisco

23: 1089-1232 (Sept.) 1925

Arteriosclerosis. J. Phillips, Cleveland.—p. 1121.
Recent Advances in Cancer Research. L. A. Emge, San Francisco.—p. 1128.
*Psychoneuroses: Psychasthenia, Neurasthenia and Hysteria; Treatment. T. J. Orbison, Los Angeles.—p. 1132.

Treatment of Chronic Arthritis. L. W. Ely, San Francisco.—p. 1157.
Obstetrics, Stronghold of Medicine Today. G. G. H. McPheeters, Fresno.—p. 1159.
Operative Treatment of Abnormalities of Fifth Lumbar Vertebra. A. E. Gallant, C. B. Bennett, Berkeley, and S. N. Jacobs, San Francisco.—p. 1162.
Functional Tests of Hearing. I. H. Jones, Los Angeles and V. O. Knudsen, San Francisco.—p. 1166.
Intracranial Hypertension and Serous Meningitis. E. W. Twitchell, San Francisco.—p. 1170.
Stricture of Ureter and Dysmenorrhea. R. L. Schulz, Los Angeles.—p. 1173.

Psychoneuroses.—In the 140 cases of psychasthenia analyzed by Orbison an hereditary taint was present in most of them as well as in forty-five hysterias, but not in the 126 neurasthenias. Treatment was partly by the so-called training camp method, and partly by complete rest treatment for six weeks and modified rest with beginning out-of-bed exercises. The results have been: twenty-two cures, two excellent, three improved, one probable cure, one treatment not completed.

*Case of Heterogenitalism. J. McD. McKinney, New York.—p. 229.
Effect of Single Doses of Thyroid on Fowls. M. Zavodovski, Moscow.—p. 232.

Evaluation of Organotherapy.—Rowntree says that in organotherapy human frailty looms large. Unfortunately, it must be admitted that in no other branch of medicine has its retarding and pernicious influence been more apparent than in the treatment of diseases of the glands of internal secretion. But the outlook in organotherapy is most hopeful. Success in its limited and legitimate field has been striking, in fact, little short of miraculous, and so encouraging that the field is now ardently exploited, both legitimately in the search for the elucidation of disease, and criminally by those who squeeze gold out of human heartaches. If we are to protect the public against unseasoned and immature conclusions, we must depend on reliable information only. Information concerning standard drugs can be obtained from the United States Pharmacopeia. New drugs of promise, introduced in an ethical manner, are accepted almost without delay by the Council on Pharmacy and Chemistry of the American Medical Association, and are listed and described in one of its annual publications, "New and Nonofficial Remedies." Old and new ethical drugs, which are useful and reliable, are described in a small book, "Useful Drugs," also published by the Council. The most flagrant offenders are exposed in the columns of The Journal of the American Medical Association under the heading, "Propaganda for Reform," under "The Bureau of Information."

Effect of Ovarian Extract on Ovariectomized Rats.—In an experiment made by Durant with eight doubly ovariectomized and seven litter control white rats, the daily feeding of glycerin extract of whole pig ovary for a period of three weeks had no effect on the voluntary activity of the ovariectomized animals. Thrice daily feeding of large doses was likewise ineffective. In view of the proved adequacy of the method used to detect the influence of ovarian hormone, Durrant feels that these experiments cast further doubt on the efficacy of ovarian preparations administered by mouth.

Heterogenitalism.—The case of a boy, aged 16, is described by McKinney showing mental and behavioristic retardation associated with a feminine contour and breast development of the adolescent female type. The penis was well developed and the testes descended, though soft. No abnormality could be discerned in the formation of the generative system, with the exception of the soft testes. Rectal examination revealed nothing abnormal.

Migraine with Pronounced Abdominal Crisis. W. A. Brams, Chicago.—p. 244.
Three Months' Amnesia Following Moonshine Whiskey Debauch. B. Lemchen, Chicago.—p. 246.

Roentgen-Ray Treatment of Pertussis.—In Hess' opinion, excessive exposure of young children to the roentgen ray is dangerous. Therefore, the neighboring organs should be protected and only the minimum number of exposures necessary for relief are to be given. The results, both immediate and remote, of roentgen-ray treatment in whooping cough should be given further study before the method is recommended for general use.

Encysted Surgical Sponge.—In the course of a necropsy on an adult female a tumor was seen in the left iliac fossa firmly adherent to the omentum above and by a tag of omentum to the peritoneum below. The growth was the size of a golf ball and the capsule was smooth, except at the places of adherence. On opening the capsule, which was 5 mm. in thickness, the content of the cyst was seen to be a surgical gauze sponge firmly compressed and encysted by the omentum. In the clinical history which accompanied the body an operation was mentioned, but the time was not given. Whether or not symptoms ever occurred as a result of the condition, Foley says, could not be determined from the history.

Study of Chromosomes.—Parmenter presents cytologic observations on Loeb's parthenogenetic frog material, with considerations on the mechanism by which the diploid number and both sexes may be produced. Both sexes of adults and tadpoles are present. The chromosome number is diploid and probably twenty-six in both sexes. Sex chromosomes cannot be distinguished. The chromosome numbers observed by other authors in parthenogenetic frog material are haploid, diploid, and variable. Their significance is considered. The mechanism producing the diploid number, based on European observations, appears to be a doubling of the haploid number at some time after the second polar body is given off. Overripeness may be a factor in producing both sexes of parthenogenetic frogs and tadpoles. Genetic data indicate that the normal male is digametic and that there are differences of potency between male and female factors for sex which vary in frogs of the two races and in strains within the race. These differences have been interpreted by Witschi as forming a series of multiple allelomorphs.

yield no information of any detectable intrathoracic pathologic change. Yet in all the cases there is a history of longstanding cough, very often harassing and persisting even during sleep. The cough is in most instances nonproductive. Occasionally some glairy mucus is expelled. Some attacks are paroxysmal in character and may simulate bronchial asthma from which it can usually be differentiated by the lack of dyspnea, the accompanying breast heaving and rapid respiration. The longer duration—some cases may be of several years' duration—will serve to distinguish it from whooping cough. Clinically, these children more closely resemble a nonproductive chronic bronchitis than any other clinical entity. The results from roentgen-ray therapy have proved highly gratifying. Complete cessation of the cough is obtained in practically every instance.

*Control of Gaseous Metabolism Apparatus. F. G. Benedict, Boston.—p. 583.
*Echinococcus Cyst of Spleen. D. Boyd, Boston.—p. 591.

Control of Metabolism Apparatus.—The extensive use of gaseous metabolism technics makes control of the various forms of apparatus imperative. Benedict says that this is best accomplished by developing in the air current a production of carbon dioxid and an abstraction of oxygen approximately equivalent to that produced by a man at rest. The combustion of known amounts of pure ethyl alcohol in a suitable burner, a combustion chamber, and a ventilating device make such controls possible. With the mechanicochemical device of Carpenter and Fox (a modification of which is described) alcohol can be introduced at any desired rate, the normal respiratory movements of a human subject can be simulated, the efficiency of valves can be tested, and both open — and closed — circuit respiration apparatus, including respiration chambers of any size and the various forms of gas analysis apparatus, can be controlled.

Echinococcus Cyst of Spleen.—In the case described by Boyd the diagnosis remained obscure because the patient had never lived on a farm and denied having ever had any contact with dogs or any animals as pets. The patient was known to have borne the splenic tumor for thirty years, during which time she had surprisingly few symptoms.

Effect of Single Doses of Thyroid on Fowls. M. Zavodovski, Moscow. —p. 232.

Evaluation of Organotherapy.—Rowntree says that in organotherapy human frailty looms large. Unfortunately, it must be admitted that in no other branch of medicine has its retarding and pernicious influence been more apparent than in the treatment of diseases of the glands of internal secretion. But the outlook in organotherapy is most hopeful. Success in its limited and legitimate field has been striking, in fact, little short of miraculous, and so encouraging that the field is now ardently exploited, both legitimately in the search for the elucidation of disease, and criminally by those who squeeze gold out of human heartaches. If we are to protect the public against unseasoned and immature conclusions, we must depend on reliable information only. Information concerning standard drugs can be obtained from the United States Pharmacopeia. New drugs of promise, introduced in an ethical manner, are accepted almost without delay by the Council on Pharmacy and Chemistry of the American Medical Association, and are listed and described in one of its annual publications, "New and Nonofficial Remedies." Old and new ethical drugs, which are useful and reliable, are described in a small book, "Useful Drugs," also published by the Council The most flagrant offenders are exposed in the columns of THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION under the heading, "Propaganda for Reform," under "The Bureau of Information"

Effect of Ovarian Extract on Ovariectomized Rats.—In an experiment made by Durant with eight doubly ovariectomized and seven litter control white rats, the daily feeding of glycerin extract of whole pig ovary for a period of three weeks had no effect on the voluntary activity of the ovariectomized animals. Thrice daily feeding of large doses was likewise ineffective In view of the proved adequacy of the method used to detect the influence of ovarian hormone, Durrant feels that these experiments cast further doubt on the efficacy of ovarian preparations administered by mouth.

Heterogenitalism.—The case of a boy, aged 16, is described by McKinney showing mental and behavioristic retardation associated with a feminine contour and breast development of the adolescent female type. The penis was well developed and the testes descended, though soft No abnormality could be discerned in the formation of the generative system, with the exception of the soft testes. Rectal examination revealed nothing abnormal.

Roentgen-Ray Treatment of Pertussis.—In Hess' opinion, excessive exposure of young children to the roentgen ray is dangerous. Therefore, the neighboring organs should be protected and only the minimum number of exposures necessary for relief are to be given. The results, both immediate and remote, of roentgen-ray treatment in whooping cough should be given further study before the method is recommended for general use.

Encysted Surgical Sponge.—In the course of a necropsy on an adult female a tumor was seen in the left iliac fossa firmly adherent to the omentum above and by a tag of omentum to the peritoneum below. The growth was the size of a golf ball and the capsule was smooth, except at the places of adherence. On opening the capsule, which was 5 mm. in thickness, the content of the cyst was seen to be a surgical gauze sponge firmly compressed and encysted by the omentum. In the clinical history which accompanied the body an operation was mentioned, but the time was not given. Whether or not symptoms ever occurred as a result of the condition, Foley says, could not be determined from the history.

Measles Diplococcus Cultures Cause Skin Reaction.—Tunnicliff concludes: Anaerobic dextrose broth cultures of the green-producing diplococcus found in measles, killed by 0.5 per cent. phenol, appear to produce a skin reaction in persons who have not had measles, but not in measles patients after the appearance of the eruption, or in 96 per cent. of persons who give a history of measles. The measles antigen is neutralized in persons who have not had measles, by convalescent human measles serum, but not by the serum of a person with a negative history of measles. Reaction occurs also in normal rabbits, while rabbits immunized against measles fail to react. The measles antigens are neutralized in rabbits by convalescent human measles serum and by the serum of goats recovering from the reaction produced by measles diplococci, but not by normal goat serum. Green-producing cocci from other sources generally give no reactions in rabbits, but the strains that do produce similar reactions in both immune and in nonimmune rabbits and are not neutralized by convalescent human measles serum. Normal rabbit serum neutralizes measles antigen partly; immune rabbit serum completely neutralizes it. These results indicate that the gram-positive, green-producing diplococcus found in measles is of etiologic significance.

Experimental Tuberculosis.—Austin states that the inoculation of simple extracts, not incubated, of certain fresh normal organs of the rabbit appears to influence the development of experimental tuberculosis in rabbits. The extracts of different kinds of organs vary considerably as to the amount of influence displayed. Extracts of suprarenal and lung frequently would seem to retard the development of the disease, those of heart and liver produce less effect, as a rule, while extracts of spleen and kidney exert little or no influence. The freshness of the organs used, the short time utilized in preparing the extracts, the avoidance of incubation and the preservation of the extracts, between inoculations, at icebox temperature make it seem possible that the more or less protective substances present in some of the organ extracts exist in the organs before removal from the animal.

Use of Novasurol as Diuretic. H. Oerting, St. Paul.—p. 593.

Dick Test for Scarlet Fever.—Of fifty-seven children tested by Colby in private practice, forty-nine, or 86 per cent., gave positive reactions. Of 304 children tested in institutions, 153, or 50 per cent., gave positive reactions. Of 100 nurses tested, thirty-two, or 32 per cent., gave positive reactions. The reaction was found positive during the first two or three days of the rash and negative in convalescence.

Causes of Death in Fetus and New-Born.—During the years 1914 to 1924, inclusive, there was in Minneapolis a total of nearly 98,000 living births, of which over 50,000, or 51 per cent., were delivered in the hospital, and about 48,000, or 49 per cent., in the home. Of these deliveries approximately 36,000, or 36 per cent., were done by physicians in the home, making a total of over 87 per cent. delivered by physicians. During this period, about 12,000, or 12 per cent., of the deliveries were done by midwives. The percentage of home deliveries has decreased from 75 per cent. to 30 per cent. The percentage of deliveries by midwives has decreased during this same period of time from 20 to 6 per cent. During these same years there was a total of about 3,700 stillbirths with an average percentage of living births of 3.7, which percentage has remained practically stationary during this entire period of years. In this time over 2,200, or 60 per cent., of the stillbirths occurred in the hospitals of the city. The percentage of stillbirths occurring in the hospitals has increased from 35 to 75 per cent. During this time approximately 1,400 stillbirths occurred in the homes, an average of 2.9. There have been 1,850 neonatal deaths in the hospitals, this being 54 per cent. of the total number. Something over 1,500 neonatal deaths occurred in the home, an average percentage of 45. The total number of later infant deaths during this period was over 2,800. The total infant deaths during this period of time were over 6,000, the rate dropping from 82 in 1914 to 54 in 1923, with an average rate of 68.

*Specific Precipitating Substance from Tubercle Bacilli. P. P. Laidlaw and H. W. Dudley.—p. 197.
*Useful Preservative for Whole Blood. A. H. Baker.—p. 201.

Influence of Site of Inoculation on Infectivity of Anthrax Bacilli.—Panton and Benians summarize their observations as follows: Death following transcutaneous inoculation of anthrax in rabbits does not appear to depend solely on the soiling of the skin by the needle in passage. The receptivities of the skin and the subcutaneous tissues of the rabbit for anthrax infection are different. A dose fatal in the skin can be tolerated under the skin. Subcutaneous inoculation is followed by immunity both to dermal and to transcutaneous inoculation in a small proportion of animals. This immunity is again lost subsequent to dermal inoculation. The white mouse is insusceptible to pneumococcal infection of the skin, highly susceptible to transcutaneous inoculation, and relatively insusceptible to purely subcutaneous infection. Some degree of immunity appears to follow both dermal and subcutaneous inoculation. The rabbit shows marked individual susceptibility to pneumococcal infection of the skin. The susceptible animal develops an acute inflammation of the skin, and no dermal immunity follows. These experiments suggest the possibility that in the experimental production of anthrax infection in rabbits and of pneumococcal infection in mice by transcutaneous inoculation a double factor is involved, both skin and subcutaneous tissues playing a distinct part.

Sex Glands and Metabolism.—The effects on nitrogen metabolism, on the one hand of castration and on the other of injections of testis or of ovaries (without corpora lutea) observed in most animals, Korenchevsky says, indicate that the sex glands probably contain hormones, which increase nitrogen metabolism. The varying effects on the nitrogen metabolism obtained after injections of emulsions of testis or of ovaries may possibly be explained by (1) the presence in them of specific (e. g., corpora lutea in ovaries) or of nonspecific (e. g., insulin-like substances) principles; (2) by the varying degree of functional efficiency and, therefore, the varying reaction of the synergetic and antagonistic female animals by the different stages of development of the corpora lutea or of the remaining ovarian tissue in their own ovaries. Experiments on thyroidectomized animals show that, in spite of the close interrelationship between sexual and thyroid glands, changes in nitrogen increased stimulation of the thyroid gland.

Blood and Urine Diastase During Meals.—It has been demonstrated by Cohen that the output of diastase into the urine varies greatly. During the day, the rate of diastase output rises and falls without apparently any definite cycle of change. Meals seem to produce an immediate increase in output, which is more marked in some individuals than in others. After the meal effect there is no definite indication whether the output will rise or fall. Readings made during starvation periods have also been found to be irregular. The blood diastase remains at a constantly low level throughout the observation periods, despite the marked changes in the urinary diastase content. It would appear, therefore, that diastase is irregularly absorbed from the bowel, and then is excreted as completely as possible from the blood. In the light of these observations, examination of isolated specimens of urine for clinical purposes would seem to yield very unreliable information. On the other hand, however, the relative constancy of the blood diastase content renders the necessity for any special precautions with regard to meals unnecessary.

Specific Precipitating Substance from Tubercle Bacilli.—Glycogen has been isolated by Laidlaw and Dudley from tubercle bacilli, likewise a carbohydrate complex of the nature of a gum. This gum gives specific precipitation with immune serum. The gum is not a true antigen, since it fails to induce the formation of antibodies. The significance of these findings is discussed.

Useful Preservative for Whole Blood.—Baker has found that fowl blood will travel safely for several days through the post, and permit a satisfactory agglutination test on its arrival if the boric acid content of the tube be between 1:100 and 1:500.

Dick Test in Scarlet Fever.—Brown regards the Dick intracutaneous test as a reliable index of susceptibility and immunity to scarlet fever. The test is a valuable aid to diagnosis, and a strongly positive skin reaction in the first forty-eight hours of a scarlatiniform eruption would lead one to hesitate before making a diagnosis of scarlet fever. When a patient who has recently shown a positive Dick reaction develops a scarlatiniform attack, the reappearance of the red area at the site of original inoculation is confirmatory of a diagnosis of scarlet fever. The results of the test demonstrate that age susceptibility is highest at a period before the children commence to attend school, whereas age incidence is greatest during the first few years of school life. This shows that immunization, if adopted as a prophylactic measure in "state medicine," should be carried out in the first few years of life. The well recognized fact that an attack of diphtheria increases the patient's susceptibility to scarlet fever is confirmed by the test.

Cerebral Degeneration in Infant.—One case is recorded by Schuster, with necropsy findings. The location of the disease to the basal ganglions, he thinks, suggests the possibility of its being associated with the hepatolenticular degeneration described by Wilson. It is a malady of youth, and is also a symmetrical bilateral degeneration of the lenticular nucleus, especially the putamen, and the question arises as to whether this can be the result of a similar toxemia in a stage previous to hepatic involvement, or, perhaps, a rapid form peculiar to infants, omitting the liver degeneration altogether, though Wilson considers the liver as the primary focus of the disease in his cases. There are many points of similarity between the two diseases, but Schuster prefers, for the present, at least, to regard them as separate clinical entities.

Multiple Neuritis.—Stewart holds that it is no longer possible to limit the conception of multiple neuritis to one in which the peripheral nerves alone are affected. One must think in terms of neurons, not of nerves, and study cases clinically from the point of view of functional disturbance or, more correctly, interference with function. It is illogical to separate a nerve cell from its fibers; they are essentially one from the point of view of function, and interference with either must, and does, affect both. In all cases of toxic affection of the nervous system, the element of selectivity is present in greater or less degree, and the greater the degree the more specialized will be the functional disturbance. Further, the selective action is not necessarily directly due to a primary action on the nerve elements proper; it may be to its affinity for the chemical elements of the tissues in which they lie. The other factor is the path of infection and its influence in determining the clinical function.

Gastric Secretion. R. K. S. Lim.—p. 505.

Compound Pregnancy.—In Ewer's case a tumor was attached to the lower end of the uterus with a pedicle about 5 cm. in diameter. It was decided to remove both the tumor and uterus, as it seemed impossible to divide them. On being opened, the larger of the tumors contained a perfectly developed fetus. No fluid was present. There was evidence of maceration or lithopedion formation. The fetus seemed to be completely mummified. On manipulating the uterus, another fetus popped out. No liquor or blood appeared. It measured 18 cm. in length and weighed 270 gm. No maceration or destruction was apparent.

Rare Obstacle in Labor.—James' patient was six months pregnant, and asked to have her pregnancy terminated at once because she could not give birth to a full-grown child in the ordinary way. On examination James found that for the upper third her thighs were bound closely together by a very dense, gristly cicatrix, continuous anteriorly with the skin of the abdominal wall. The deformity was the result of a burn suffered at least ten years previously. Evidently she had lain for months with the adjacent burned surfaces of her thighs in contact, while the healing process slowly proceeded. Anteriorly, there was not even a pin-point aperture between the cicatrix and the abdominal wall, which was pulled tensely down by the retraction of the scar tissue. Posteriorly, the trouble had not extended to the buttocks and perineum, nor had it involved the posterior portion of the labia. The thighs could not be separated sufficiently, however, to permit the passage of even a moderate-sized infant. Hence, the vaginal route was quite obviously out of the question for the delivery of a viable fetus, even several weeks before term. The woman was advised to wait and return at term for a cesarean section. She accepted the advice, and in due time James performed the cesarean section and delivered a healthy looking male infant.

Result of Operation for Asthma.—Analysis of 202 cases of asthma previously subjected to operation made by Tod shows that where the airway is blocked or there is an obvious focus of infection, operation often relieves the symptoms of asthma very much and in young people may even result in a cure, while if the nose is apparently normal the cautery may be of great service. So far no specific cure for every case of asthma has been found, hence every positive method of relieving the symptoms of this most distressing disease should be given a fair trial.

De Minimis.—Edmunds describes a number of practical devices which he has found useful in his surgical work, such as the easy and ready removal of nonabsorbable intradermic sutures; keeping a bandage in position for wounds of the neck; a nutrient beef tea; keeping Thiersch grafts in position; insertion of drainage tubes; removing finger nails and toe nails, etc. He asks that all surgeons place on record these minor or lesser details of technic which usually can only be learned by a visit to clinics and yet mean so much in the successful outcome of a case.

Renal Element in Diabetic Coma.—Eleven cases of diabetic coma are reported by Payne and Poulton and certain cases are reviewed from current literature. A definite renal element, as shown by oliguria, albuminuria and urea retention and failure to excrete ketone bodies, and occasional sugar, is present. In some cases this renal failure is so decided as to cause a marked resemblance to uremic coma. The cause of the renal failure has been discussed. The treatment is carried out by means of large injections of insulin, and by the administration of much fluid, containing dextrose, by the mouth.

Tuberculosis and Cancer.—The steady decline in the number of deaths from tuberculosis and the equally steady advance of cancer is discussed by Cherry, and vital statistics bearing on the subject are reviewed for the purpose of finding a reason for this apparent relationship. The question to be answered is, whether heightened resistance to tuberculosis has any effect on the greater incidence of cancer.

Lactic Acid in Blood Vessels of Liver and Muscles.—Collazo's experimental research on dogs demonstrated that the liver transforms carbohydrates into lactic acid. Blood from the liver and muscles as well as that of the general venous circulation contains more lactic acid and less glucose than the arterial blood.

Action of Scoparius on Veins.—Research on dogs showed Busquet and Vischniac that broom induces not only constriction of the artery, but also of the vein. The action is due partially to direct excitation of the venous wall, and partially to a mechanism in which the nerve center and the venoconstrictor efferent fibers are involved.

Fate of Oils in Subcutaneous Tissue.—Binet and Verne injected guinea-pigs, rabbits and dogs with oils. Under a leukocyte reaction, the substances changed and their resorption was very slow. The resorption of animal fats (horse oil) proceeded more rapidly than that of vegetable oils (olive oil).

Vaccination of Animals Against Botulinus Poisoning.—Weinberg and Goy vaccinated rabbits and guinea-pigs by twelve subcutaneous injections of botulinus anatoxin, given once daily in a dose of 1 c.c. The results seemed to be more pronounced in animals previously sensitized by injection of a small dose of anatoxin. The same effect was manifest with a single injection of 3 c.c. of the botulinus toxin treated with formaldehyd. The authors emphasize that vaccination was also effectual with anatoxin given by mouth.

Method for Cultivation of the Enterococcus.—Muller describes a method for obtaining cultures of the enterococcus, which may prove valuable in preparation of enterovaccines.

Apparatus for Cultivation of Anaerobes.—Muller illustrates a special tube for cultures of anaerobic bacteria. The technic is based on absorption of oxygen by hydrogen in presence of a heated catalyzer, without the use of the electric current.

Enhancing the Action of Cations on the Auricle.—Deloyers noted that the action of calcium and potassium ions on the isolated right auricle of a rabbit became more intense under electrolytic concentration of these ions near the Keith node. The action of cations on the heart was instantaneous.

Tar Cancer Not Due Merely to Local Irritation.—Maisin and Masse conclude from their experiments on mice that cancer from tar may be ascribed not only to local irritation, but also to the toxic action of the tar on the whole organism.

Degeneration of Thymus from Alcohol.—Injections of ethyl alcohol into the peritoneal cavity of white rats induced pyknotic degeneration of the thymus cells. The lesions were considerably developed by the fifteenth to the eighteenth hour after the injection, and were followed by sloughing by the twenty-fourth hour. The same phenomenon occurred with injections of sodium chlorid solution with a little hydrochloric acid. Thus lesions identical to those from the roentgen rays may be produced by substances not exerting a direct action on the acid-base balance of the blood. Jolly believes that an indirect action from the hydrogen ion concentration may possibly be responsible for the degeneration of the thymus.

Resistance of Galleria to Danysz' Bacterium.—Chigasaki's experiments demonstrated that the resistance of *Galleria mellonella* to Danysz' bacterium was most manifest in the caterpillar, less in the perfect moth, and still less in the chrysalis. The resistance was materially reduced during the stage of transformation from larva to pupa.

Action of Vapors of Mercury and Arsenic on Syphilis and Trypanosomiasis.—Research on 160 mice or rats and twelve rabbits convinced Poincloux that vapors of mercury and arsenic are easily absorbed by the lungs. Inhalation of mercury exerted a beneficial action on syphilis and nagana. Inhalation of arsenic anhydrid cured definitely nagana in mice.

Infection from Tuberculous Filtrates.—Summarized in Paris Letter, October 10, page 1149.

Enhancing the Potency of Diphtheria Antitoxin.—Ramon has noted for several years that diphtheria antitoxin from horses with an abscess in the area of antigen injection (toxin or anatoxin) contains about twice as much antitoxin as serum from horses without the complication. After different experiments, he finally obtained a considerably more potent diphtheria antitoxin by using for the injections diphtheria anatoxin mixed with pulverized tapioca. This was due apparently to the induced local reaction, with edema, leukocyte afflux and retarded resorption of the antigen. The antitoxic potency of the serum from twelve horses, injected with 290 c.c. of anatoxin, was 200 units. Subsequent inoculation of these horses with 450 c.c. of the anatoxin-tapioca mixture, increased the antitoxic power of their serum to 800 units by the eighth day after the last injection. A total of forty horses were inoculated with 640 c.c. of the mixture. The average amount of antitoxin in the serum was about 700 units per cubic centimeter at the end of the hyperimmunization. The range was from 800 to 2,500 units. The antitoxin content of serum from horses immunized by the old technic with 1,200 or 1,500 c.c. of toxin was only 400 units.

Enhancing the Potency of Tetanus Antitoxin.—Ramon and Descombey observed that while 1 c.c. of serum from five horses injected with 220 c.c. of tetanus anatoxin neutralized 200 times the lethal dose, the serum from five horses injected with the same dose of anatoxin, plus pulverized tapioca, neutralized 10,000 times the lethal dose. Twenty-eight, previously inoculated with anatoxin and then toxin, were further given injections of toxin; fourteen were injected with the toxin-tapioca mixture. The serum from the first group of horses contained only 1,500 units, while the serum from the second group showed over 3,000 units.

The Bacteriophage a Living Organism.—On the basis of his personal experiments and those of others, d'Herelle reiterates anew that the bacteriophage is a living corpuscular element, independent of the lysed bacteria, which displays vital properties of assimilation and adaptation. He disagrees with Carrel who regards the bacteriophage as analogous with Twort's agent. The latter, he says, may originate from bacteria, since transmission of action is not exclusively restricted to living bodies. This has been demonstrated by the activation of pancreatic juice and by the disease of tin.

The Calcium in the Blood in Asphyxia.—Binet and Blanchetière's research on dogs, under chloral, indicated that the venous blood contains more free calcium than the arterial blood. Asphyxia is accompanied by hypercalcemia, sometimes preceded by transient hypocalcemia.

Action of Tropin on Secretion of Salivary Glands.—Hazard and Mercier conclude that tropin—a base derived from atropin—exerts a paralyzing action not only on the vagus but also on the secretory nerve terminals in the submaxillary gland. The secretion of saliva progressively decreases with each dose of tropin. The gland recuperates very slowly even under strong excitation.

Iodized Autovaccine in Treatment of Enteritis.—Monziols' treatment in thirty cases of chronic enteritis was with from fifteen to twenty intramuscular injections of an iodized autogenous vaccine (Weinberg's tilotherapy) given daily or at two or three days intervals. The vaccine is made from the stools. The results were favorable in twenty-eight patients. Improvement of stools and of the general condition was manifest after a few injections. The method, he says, is simple, easily applied and absolutely harmless.

Influence of Electrolytes and of Hydrogen Ion Concentration on the Bacteriophage.—Arloing and Chavanne assert that the presence of an electrolyte is necessary, but not sufficient alone to produce the bacterial lysis. The lysis is not a chemical phenomenon, since changes of hydrogen ion concentration can occur without arresting the lysis. The bacteriophage may exert its lytic action also in an acid medium.

Rôle of Perichondrium in Formation of Bone and Cartilage.—Policard and Boucharlat found exclusively connective cells in explant cultures of periosteum and perichondrium from mammals. Evidently the formation of bone and cartilage is due not only to the periosteum and perichondrium, but it involves also certain humoral actions, which are lacking in test tube cultures.

Inertia of the Gallbladder: Symptoms and Treatment.—Chiray and his co-workers call attention to cases of distended gallbladder in which stagnation of the bile is not from gallstones nor from inflammatory adhesions, but from insufficiency of the contracting power of the gallbladder. With duodenal intubation or intraduodenal injection of magnesium sulphate, an abnormal amount of dark colored bile is obtained. The inertia of the gallbladder may be revealed by its tenderness in the recumbent position, dyspeptic phenomena, and also by migraine with bilious vomiting. It appears to be chiefly induced by changes of the vegetative nervous system. The treatment consists in repeated medical drainage of the bile, thus training the gallbladder to better functioning. Pilocarpin or eserin, by the mouth or in subcutaneous injections, as well as pituitary extract, exert a positive action in these cases.

Value of the Diazo Reaction in Diagnosis of Bilirubinemia.—Piotrowski analyzes the different methods for quantitative estimation of the bilirubin in the blood. He concludes that van den Bergh's reaction, as modified by Thannhauser and Andersen, is the most dependable procedure. Retention of bilirubin in the blood may be detected by the diazo reaction even in the absence of clinical manifestations.

The Meinicke Turbidity Test in Syphilis. L. Beretvàs.—p 460.
*The Cerebrospinal Fluid in Malaria. R. Monteleone —p. 470.

Chronic Meningomyelitis.—The man was 35 years old when a clinical picture insidiously developed with pains in the lumbar region, weakness of the legs and disturbances in urination. The asthenia and bladder disturbances progressed and the reflexes were gradually abolished, suggesting a glioma in the lower spine. A grave attack of malaria speeded up the chronic affection, with terminal sepsis from retention of urine, four years after the onset. Necropsy disclosed chronic proliferative processes in the spinal meninges and cord and in their vessels, with lesions of degeneration, essentially destructive, in the vessels. There was no evidence of tuberculosis or syphilis. The Wassermann test and tentative treatment for syphilis were negative. Sabatucci has been able to find only one similar case on record. By exclusion he is inclined to attribute the whole clinical picture to malaria—the man lived in a malarial zone—and warns that malaria should be suspected in every case of meningomyelitis in which other obvious causes can be excluded.

The Cerebrospinal Fluid in Malaria.—Monteleone found the lumbar puncture fluid normal in the old chronic cases. In fifty persons with malaria parasites in their blood, the pressure rose with the temperature, but sometimes kept above normal even during the intervals between the febrile attacks. The sugar content was high in the acute cases and, in certain instances of pernicious malaria, the albumin content was high, with lymphocytosis. The findings thus suggest congestion, not a malaria meningitis, but merely a meningeal syndrome connected with the fever.

*Hemorrhagic Pancreatitis. T. Lanfranco.—p. 442.
*Oncogenetic Importance of Trauma. G. Villata.—p. 451.

Hemorrhagic Pancreatitis.—Lanfranco remarks that hemorrhagic pancreatitis seems to be becoming more frequent, but this is merely because many cases in the past have not been diagnosed correctly. He describes two typical cases, with necropsy in one, and emphasizes as differential points the absence of jaundice in what seemed to be an unusually severe recurrence of gallstone colic without jaundice. There was slight fever in one and none in the other case; the pulse was small and rapid. The patients were well nourished, and the facies did not suggest peritonitis. The tenderness and stiffening of the abdominal walls were most pronounced above the umbilicus. The meteorism was epigastric and there were signs of fluid in the peritoneum, and considerable dyspnea and restlessness.

Importance of Trauma as a Factor in Cancer.—Villata reviews what has been published on this subject, and relates that a single severe trauma had preceded the malignancy in 6.8 per cent. of his forty-five personally observed cases of sarcoma in bone, and in 6.6 per cent. of thirty cases of sarcoma in muscle, and in 3 per cent. of thirty-one in internal organs. Excluding the dubious cases, 8 per cent. of the total 127 sarcoma cases. With carcinoma, the corresponding total percentage was 5.19 per cent. Summarizing the whole, gives 2.23 per cent. of 762 cases of cancer. The interval before the cancer became manifest ranged from a few weeks to eleven years. He accepts that trauma undoubtedly favors production of cancer in the injured tissues, but is never directly responsible for the malignancy.

Riforma Medica, Naples

41: 745-768 (Aug. 10) 1925

*Substance That Activates Carbohydrate Metabolism. Condorelli.—p. 745.

Hydatid Cyst in Liver or Gallbladder Disease? Cantelli.—p. 750.
*Vegetative Disturbances After Encephalitis. Calligaris.—p. 754.

Vegetable Substance Activating Metabolism of Carbohydrates.—Condorelli calls attention anew to the substance he has obtained by alcohol extraction from leaves of grains, which rapidly reduces the sugar content of the blood, and usually of the urine, in pancreatectomized dogs and in diabetic patients. The tolerance for carbohydrates is augmented for some time after administration of the fitochinina, as he calls this substance. There is no precipitation with picric acid, thus differing essentially from insulin and glycophytin. The most striking difference, however, is that the fitochinina does not manifest any appreciable action in the normal; it resembles vitamins in this respect. Only in certain pathologic conditions does it display its special effect. It seems to be harmless; normal rabbits showed no disturbance after intravenous injection of 20 c.c. The fitochinina is not precipitated by the usual reagents that act on albumin.

Gastric and Nervous Sequelae of Epidemic Encephalitis.—Calligaris refers to cases in which the tongue is chronically coated, and gastritis is assumed when in reality the leukoplakia of the tongue is a manifestation of the derangement of the vegetative nervous system, as are also the numerous nervous symptoms. The list of possible nervous manifestations is so long and varied that one can almost speak of a functional blocking of the extrapyramidal vegetative system. A special feature of these postencephalitis nervous manifestations is that they are often limited to one small portion of the body, a hand, a finger, half of the face, etc. The paresthesias are peculiarly strange and multiform, such as a sensation of the loss of part of the body, of internal tremor, sensation as of flying, or of a cold blast. An abnormally exaggerated appetite or thirst has been noted after epidemic encephalitis, and Calligaris has been impressed by the way in which these signs of derangement in the vegetative nervous systems may remain latent most of the time and flare up only after meals, or previous symptoms then become much exaggerated.

*Hydatid Cysts in the Liver. H. García Lagos.—p. 395.
Roentgenographic Study of the Duodenum. J. Cunha.—p. 409.
*Serohemoflocculation. A. Prunell.—p. 427.

Hydatid Cysts in Liver Opening into the Biliary Tract.—García Lagos adds four more to the list compiled by Prat recently, and warns that the cyst in the liver may be overlooked when the symptoms from the gallbladder or bile ducts dominate the clinical picture. In one of his cases an operation on a second cyst in another lobe of the kidney was deferred for two months. In two cases the cysts had never caused symptoms until the perforation into the common bile duct when pains, diarrhea and fever with jaundice called for an emergency operation. The patients recovered under drainage of the cyst alone. In other cases the clinical picture was that of chronic gallbladder disease. A cyst in the liver should be suspected in every case of liver colic and of jaundice from retention.

Serohemoflocculation.—This is Prunell's term for his flocculation test for syphilis. It is based on the parallelism between any reduction in the degree of dispersion of the globulin and the biologic activity of the blood serum. The balance of colloids depends on the balance between the ions.

Archivos Lat.-Amer. de Pediatría, Buenos Aires

19: 797-842 (May) 1925

*The Aorta in Children. E. A. and J. J. Beretervide.—p. 797.
*Natural Autoplacenta Galactagogue. E. M. Pueyrredón.—p. 802.
*Unilateral Parkinsonism. M. A. Jáureguy.—p. 815.
Invagination in an Infant—Meckel's Diverticulum. N. Leone Bloise.—p. 821.

Aortitis in Children.—The Beretervides state that in child cadavers a bistoury inserted to graze the left margin of the sternum, in the second and third interspaces, enters the aorta. In children, therefore, auscultation of the aorta should be applied to the left of the sternum. The diameter of the ascending aorta is 1 cm. to the age of 8, and 1.3 cm. from 9 to 14. When the diameter exceeded this, congenital syphilis was beyond question in their 476 cases.

Placenta Extract as Galactagogue.—Pueyrredón comments on the fact that herbivora become carnivorous only at one time, namely, after the birth of the offspring, when they eat their own placentas. His experience with tablets of human placenta substance corroborates the assumption that ingestion of the placenta promotes the production of milk. He summarizes six clinical cases which seem to establish the galactagogue action of the tablets.

Hemiparkinsonism.—Jáureguy's patient, a boy of 15, developed a condition of hemiparkinsonism two years after an attack of epidemic encephalitis. The extrapyramidal contracture is exclusively on the right side. Under intravenous treatment with sodium cacodylate he materially improved in the course of four months. He was given a total of 59 gm. of the cacodylate, in nine weeks, in a 50 per cent. solution.

*The Mikulicz Syndrome. F. Bazán and R. Maggi.—p. 843.
Dementia Praecox in Boy Aged 7. Beretervide and Pozzo.—p. 854.
*Acute Leukemia. Alice Armand Ugón.—p. 860.
Syphilitic Meningitis in Infant. M. A. Jáureguy.—p. 864.
*Post-Measles Encephalitis. J. Bonaba.—p. 868.
Vincent's Angina with Hemorrhagic Septicemia. Portú Pereyra.—p. 874.
*Extreme Edema of Infant's Legs. M. A. Jáureguy.—p. 877.

The Mikulicz Syndrome.—Congenital syphilis was evidently responsible for the chronic bilateral enlargement of the salivary glands in the boy, aged 8, as also for the hypothyroidism and defective development of the genital organs. The lacrimal glands were not affected. The condition has persisted unmodified by any treatment.

Acute Leukemia.—Armand Ugón reports the seventeenth case under observation in Morquio's service. The boy, aged 7, died two months after the acute lymphoid leukemia had been recognized, after six weeks of the insidious onset. The family and child were otherwise healthy. Roentgen irradiation was borne well but did not induce improvement.

Encephalitis Consecutive to Measles.—Bonaba's patient was a girl, aged 13, whose fever kept up after apparent recovery from measles. The twentieth day convulsions developed, soon becoming restricted to the right side and yielding to right hemiplegia of the adult type, with pronounced aphasia. This clinical picture is now gradually subsiding. Bonaba urges more intensive study of the posteruptive stage in acute infectious diseases as it is a period fraught with many dangers from secondary infection and from the pathologically altered fluids and secretions.

Extreme Edema from Deficiency Diet.—A thin vegetable soup had been ordered by the physician to correct the diarrhea of the young infant, but the mother kept it up for months, boiling the decoction of carrots, garlic, etc., down to one half. The edema of the legs resembled elephantiasis while the trunk was underdeveloped and atrophied. On a suitable diet the edema disappeared in about a week. There had evidently been retention of chlorids.

*Diagnostic Puncture of the Pouch of Douglas. J. Roura Rosés.—p. 13

Puncture in the Pouch of Douglas.—Roura Rosés has found puncture useful in the diagnosis of inflammation in the pelvis in twenty-three cases. If the blood obtained is dark and thick, it is due to hemorrhage. If it is limpid and flows readily, casual puncture of some vessel or a traumatic hemorrhage is probable. Pus confirms the presence of adnexitis or pelviperitonitis. A viscous fluid indicates a mucoid cyst in the ovary while, if the fluid is limpid, the cyst is para-ovarian or a hydatid cyst. A frankly serous fluid is a sign of serous peritonitis, and in this case the puncture is therapeutically useful, the fluid aspirated with the syringe.

Clínica, Montevideo

3: 71-91 (May) 1925

*General Paralysis in a Child. A. Sicco and N. Leone Bloise.—p. 71.
*Retrobulbar Neuritis. R. Botey.—p. 79.

Infantile General Paralysis.—A woman with two healthy children contracted syphilis from an infant given her to nurse. A series of abortions followed and finally a boy was born who developed general paralysis at the age of 12. A change of character, the child becoming morose and irritable, was the first manifestation of the general paralysis; the boy had previously been apparently normal except for two attacks of febrile rheumatism which had entailed a mitral defect.

Retrobulbar Neuritis and the Posterior Sinuses.—Botey says that the enthusiasm in regard to treatment of retrobulbar neuritis by operations on the sinuses is a little exaggerated. Even with the apparently best established diagnosis, the operation may fail to relieve. He advises the endonasal, transseptal route, and describes several cases. In one, the vision did not improve after the operation until the man gave up smoking entirely, although he had never smoked much. The retrobulbar neuritis in this case was bilateral, and Botey warns that this suggests some general cause rather than a local sinusitis. The sinusitis cases are generally unilateral.

19: 97-120 (Aug. 1) 1925

*The Nephritis Mask of Thyroid Insufficiency. J. C. Mussio Fournier.—p. 97.
Dyes in Therapeutics. M. Aceña.—p. 98. Cont'n.

The Nephritis Mask of Thyroid Insufficiency.—Mussio Fournier states that he has encountered cases of apparent chronic nephritis, and treated as such for months or years without benefit, but the symptoms all disappeared under thyroid treatment. The main symptoms are slight anemia, a tendency to somnolency, slight albuminuria with casts and headache, dizziness and numbness of the fingers. There may be slight puffiness of the eyelids in the morning and, in women at the menopause, the arterial tension may be high. Restriction of salt and protein in the diet gives no results. The endocrine disturbances may affect the metabolism of water. The diagnostic criterion is the success of thyroid treatment.

10: 985-1090 (June) 1925

*False Roentgenologic Aortitis. R. A. Bullrich.—p. 985.
*Gerodermia and Eunuchoidism. R. A. Izzo.—p. 988.
*Amebic Dysentery in Argentina. S. E. Parodi.—p. 1005.
*Surgery of the Skull in Ancient Peru. E. Bello.—p. 1010.
*Meningococcus Meningitis in Chile. M. A. Sepúlveda R.—p. 1047.

Blunders in Diagnosis of Aortitis.—Bullrich protests against the assumption of aortitis based on the roentgen findings alone. They are liable to be misleading.

Eunuchoidism and Gerodermia in Women.—Izzo describes with illustration a case of eunuchoidism with dystrophy of the skin and genitals in a woman, aged 38, who seemed to be over 60, and presented symptoms suggesting thyroid insufficiency and perverted pituitary function, with curvature of the spine and genu valgum. In another case the man, aged 66, presented gerodermia of the genital dystrophia type with the same clinical picture as the woman. The two cases confirm the gerodermia variety of eunuchoidism, and its practical identity in men and women, although in the latter it should be called ovarodystrophic gerodermia.

Intestinal Parasites in Argentina.—Parodi states that in 1,071 cases in which the stools were examined, the ameba was found in 204 during the four years of the examinations, that is, in 19 per cent.; and 11.3 per cent. were carriers without symptoms of dysentery at the time. Trichomonas was found in 5.98 per cent., the blastocystis in 5.79 per cent., and giardia in fifty-seven of the 1,071 cases.

Surgery of the Skull in Ancient Peru.—Bello gives an illustrated description and diagrams of the holes made in the Inca skulls in ancient Peru, with the present conceptions of their origin and the tools with which they were made. He thinks there can be no doubt that they represent therapeutic trephining openings made on the living skull. The instruments were stone at first, but later metal instruments were used. This therapeutic trephining dates from the period before the Inca dominion. One of the skulls shown has three of these openings. This article was presented at the recent Pan-American Scientific Congress at Lima.

Epidemic Meningitis in Chile.—Sepúlveda states that until October, 1923, meningococcus meningitis was unknown in Chile. That month the first two cases were encountered at Santiago, and in the same month a year later two others. The disease was probably imported by carriers. Serotherapy was applied early, but three of the patients died.

*Strongyloidosis in Yucatan. S. Figueroa.—p. 33.
Hookworm in Yucatan. V. Rodríguez A.—p. 38.
*Mal del Pinto in Yucatan. R. Romero.—p. 46.

Creeping Disease.—The larva of strongyloides was found in the lesions in the leg of a boy, aged 5.

Pinto in Mexico.—Romero says that in Yucatan the mal del pinto is endemic and it occurs in three forms: white or pinkish patches of depigmentation of the skin, which begins in the hands or the genital organs but may affect in time any part of the body; white, with a preceding excessive pigmentation; this form occurs mostly in the hands. The third form is white patches which begin in the face. Numerous photomicrographs show the different aspects of these forms and the spores of the three varieties. The disease is prevalent in several states in Mexico, Tabasco, Chiapas, Veracruz, Pueblo, Guerrero and the federal district.

Direct Vision of Circulation in One's Own Eye.—Fortin here describes the application of this autoretinoscopy to the study of arteriosclerosis, aortic insufficiency, glaucoma and capillary derangement.

Orthostatic Albuminuria.—Martini and Comas report the case of a girl, aged 13, who for five years had presented albuminuria which had been assumed to be of the orthostatic type. Roentgenologic examination finally revealed atony and defective motor functioning of the stomach, with general splanchnoptosis. After correction of the ptosis by dieting and an abdominal bandage, the albuminuria disappeared. It had previously resisted all treatment.

The Frequency of Venereal Diseases. Neumann.—p. 1491.

Poisoning with Volatile Arsenic Compounds.—The recent German literature brought several reports of an acute disease observed exclusively in fishermen of a bay in the Baltic Sea, the so-called Haff. This "Haff disease" was considered to be caused by a poisoning with volatile arsenic compounds. Joachimoglu and Spinner exposed guinea-pigs and mice for from fifty to fifty-two days to the arsenic compounds which are liberated by cultures of *Penicillium brevicaule*. No symptoms or anatomic evidences for arsenic poisoning were observed in these animals. The authors conclude on this ground that the Haff disease has very probably some other etiology.

Contagiousness of Measles.—Rohr reports some epidemiologic data which emphasize anew the clinical observation that measles is very much more contagious in the usually not recognized initial stage than in the stage of eruption.

A Virulence Test for Smallpox Vaccine.—The disease caused by the introduction of vaccine into the cornea of a guinea-pig has a strictly regular and uniform course. Gins advocates, on the ground of these observations, the use of the intracorneal injection into guinea-pigs as a method for standardization.

Periarterial Sympathectomy.—After three years of experience with this operation, Brüning believes that the divergent results after it must be explained by a difference in the functional state of the sympathetic nerve system. If the tonicity of the system is pathologically increased, the result of the operation is definite and lasting; if the operation is done on a normal sympathetic nerve, the desired result will be only temporary.

Sedimentation of Erythrocytes After Vaccination.—The sedimentation rate is increased following vaccination. The increase parallels the temperature curve and the leukocytosis. Connerth found that the sedimentation rate is only quantitatively different after cutaneous, intracutaneous, and subcutaneous vaccination.

Paralysis and Neuropathic Constitution. M. Flesch.—p. 1733.
The Treatment of Exophthalmic Goiter. F. Klewitz.—p. 1734.

Immunobiologic Studies in Measles.—The serum from convalescent measles patients is most efficient seven to nine days after the drop of the temperature; before this time it has no immunizing effect. Keller and Moro believe that this is due to the fact that there are two different antibodies effective in measles: one is a lysin, which according to Pirquet liberates the toxic substances from the virus, and a second one, which works like an antitoxin against these toxins. Consequently, this antitoxic antibody appears only a considerable time after the virus has been subjected to the lytic action of the first. This theory received experimental support through the fact that convalescent serum injected subcutaneously before the eruption prevents the measles exanthem (a product of the virus toxin), at the site of the injection.

Experimental Studies on Fat Embolism.—Rabbits which are repeatedly injected intravenously with sublethal amounts of fat show an enormous rise of the nonprotein nitrogen and a considerable drop of the blood sugar. Histologically, all the capillaries contain fat droplets, especially in the renal glomeruli; the liver is free of glycogen, and shows severe degenerative changes. Paul and Windholz undertook their experiments after the death of a woman under the picture of uremia following a fracture of the femur. Necropsy revealed a generalized capillary fat embolism.

Are Stained Bacilli Killed?—Schmidt found that various pathogenic bacilli are still viable after the usual heat fixation and staining with alcoholic or aqueous solutions of anilin dyes. In the gram process, however, the micro-organisms are killed, very likely by the action of the iodin.

Simultaneous Therapy.—Strasser emphasizes the importance of treating a disease simultaneously with various therapeutic agents. Quoting as examples bronchial asthma and mucous colitis, he explains in the first instance the synergistic action of induced perspiration, internal administration of potassium iodid, and the intravenous injection of calcium chlorid, and in the second instance of coarse food, atropin and papaverin, and hot applications.

Bock's Demonstration of Hormones in the Blood.—Bock found that in the juice of endocrine glands double refractive bodies can be found which rotate polarized light in a strictly specific degree. The same bodies can be found in the blood. Peritz reinvestigated these findings, and arrived at the same conclusions. He believes that the clinical application of Bock's method will prove very valuable.

The Colloid of the Thyroid Gland in Childhood.—Frank found that the colloid of the thyroid gland from children gives different microchemical reaction from the colloid in adults. The line of demarcation appears to be around the age of 8.

*Resistance of Human Hemoglobin. H. Bischoff.—p. 1394.
Recent Works on Intestinal Tract. W. Wolff.—p. 1398.

Encephalitis Following Vaccination.—Lucksch observed several children who died under the picture of an epidemic encephalitis which began about ten days after vaccination. Necropsy revealed slight reddening and edema of the brain and the meninges and perivascular round cell infiltrations in the mesencephalon and in the medulla. Rabbits which were injected in the cornea with the vaccine used in the diseased children, developed in 50 per cent. of the cases, a typical encephalitis. It cannot be decided as yet whether the vaccine virus may be identical with an encephalitis virus, or whether the vaccination aroused in these cases a latent encephalitis infection. Similar observations have recently been published in Switzerland and in Holland.

The Resistance of Human Hemoglobin.—Bischoff found that the hemoglobin of adult men is slightly more resistant to the action of sodium hydroxid and acetic acid than that of adult women. In pregnant women shortly before delivery the resistance against sodium hydroxid increases. The hemoglobin of the cord blood is 130 times more resistant than the maternal hemoglobin.

Localized Sympathicotonia and Epilepsy.—Muck observed in fifty-six of 100 patients suffering from epilepsy the sign he described in sympathicotonic migraine: When the mucous membrane of the nose is slightly sprayed with epinephrin and irritated by touching with a sound, white lines appear, which persist even after the epinephrin ischemia disappears. The sign is not constant.

Acute Leukopenia After Intradermal Injections.—F. W. Müller's experiments on the leukopenia following intracutaneous injections, and especially the control counts without injections, suggest that great caution is necessary before accepting the conclusions of E. F. Müller.

Valsalva's Experiment Causing Attacks of Tachycardia. Galli.—p. 120.

Sedimentation Rate of Erythrocytes.—Groedel and Hubert applied this test to 304 patients, and found that in almost any internal disease and in normal persons the sedimentation rate may be normal or increased. In cases with a normal number of erythrocytes and with a high hemoglobin content, the rate is usually normal or only slightly accelerated. There is no parallelism between the speed of sedimentation and the viscosity of the blood.

Rumpel-Leede Phenomenon in Hypertension and Endocarditis Lenta.—The application of pressure around the arm produces minute petechial hemorrhages below the area of the compression in patients with scarlet fever. This Rumpel-Leede phenomenon is never observed in normal persons with the exception of women during the menstrual period. Weissmann reiterates the theory that the phenomenon is caused by pathologic changes in the capillary endothelium. He found it to be positive in most patients with endocarditis lenta and with essential hypertension.

Cholesteremia in Arteriosclerosis.—Mjassnikow found a considerable increase of the blood cholesterol regularly only in cases with arteriosclerosis, in an advanced stage, in the aorta and the coronary arteries. In patients with milder forms of arteriosclerosis, the blood cholesterol was increased only in 50 per cent. of the cases. In subjects in whom the process was localized in the kidneys and in the peripheral arteries, and in those with hypertension, normal amounts were found. These studies are based on the examination of seventy patients.

Blood Pressure at High Altitudes.—The rise in blood pressure at high altitudes can be counteracted in many persons by increasing the oxygen tension. Grossmann concludes from his observation that the rise must be due to a deficiency in oxygen. The point attacked is the tissue of the vasomotor center; the arterial blood may show a normal oxygen tension, and acidosis may not be demonstrable.

Gastroscopy.—Sternberg describes a gastroscopic method which makes direct observation of the pyloric function possible.

*Test for Urinary Infection. O. Weltmann and K. Haslinger.—p. 73.
*Ganglion Cells in Pelvis and Ureter. Hryntschak.—p. 86.

Nephrectomy.—Weiser reports the results of 149 nephrectomies performed at Hochenegg's clinic. Of thirty-eight patients who were operated on for malignancies, ten died; out of 111 nephrectomies performed on various other indications, eight died. The importance of thorough preliminary examinations and of functional tests is emphasized.

The Nitrite Reaction in the Urine as Indicator of Infection.—Most of the organisms which are found in urinary infections produce nitrites. Weltmann and Haslinger discuss in detail how a simple reaction for nitrites will greatly help the diagnosis of urinary infections.

Ganglion Cells in the Urinary Tract.—Hryntschak examined a large number of serial sections of the renal pelvis, ureter, and of the intramural part of the ureter, in man, pigs, dogs and cats, with a special staining method for ganglion cells. He concludes that the mucosa and the muscular parts of the organs mentioned above do not contain any ganglion cells.

*Spermatogenesis in Disease of the Epididymis. N. I. Kukudshanow.—p. 205.
*Actinomycosis of the Bladder. A. Weiser.—p. 211.

Renal Excretion of Acids and Alkalis.—The urine which is excreted by the glomeruli is neutral. The tubuli resorb some of the excreted alkali; the result is the normally acid urine. Irritation or disease of the glomeruli results in an increased excretion of acids. If the tubular apparatus of the kidney is diseased, or injured by pressure due to pyelitis, renal stones, tumors, or hydronephrosis, the tubuli are not able to resorb alkali; the result is a neutral urine. Von Pannewitz believes that the examination of the p_H value of the urine affords very significant data in the functional diagnosis.

Spermatogenesis in Diseases of the Epididymis.—Kukudshanow found that occlusion of the spermatic duct leads to regeneration rather than degeneration of spermatogenesis. He emphasizes on this ground the importance of conservative operative procedures.

Actinomycosis of the Bladder.—The actinomycotic infection of the bladder leads frequently to the formation of a group of fistulas of the bladder wall. Before perforation takes place. a bullous edema is observed, which does not allow of a specific diagnosis. Weiser believes that only the cystoscopic findings of fistulas as described above and the microscopic and cultural examination suffice to make the definite diagnosis.

Operative Treatment of Double Vagina. G. T. Zomakion.—p. 2021.
"Obstetric Examination by the Rectum." T. Johannsen.—p. 2026.

Treatment of Postpartum Hemorrhage.—Von Büben comments on the conflicting views as to the causes of inertia of the uterus after delivery and whether active or expectant treatment should be the rule. In the last twenty years in the Budapest Maternity there were 163 cases of grave hemorrhage among 35,878 term deliveries, that is, 0.45 per cent., and thirty of the women died, thus, 0.08 per cent. of the entire number. If the placenta has been expelled, pituitary extract is given by the vein, and its transient action is reenforced by ergot intramuscularly. The extended legs are crossed, and the fundus of the uterus is held firm. The vagina is rinsed out with hot permanganate solution (0.1 per cent. at 50 C.) to stimulate the cervical ganglion. If this fails, the uterus is rinsed out with a weaker solution of the same, but the douche can is held low to refrain from dislodging the thrombus by the force of the jet. Ice water would be more of a stimulus but would chill too much. Bimanual compression of the vagina and abdominal wall help to arrest the supply of blood to the uterus, or the hand in the vagina kinks the uterus near the internal os. The Dührssen tamponade is of course the most effectual measure, but he never packs the vagina alone; he always includes the uterus but never packs it tight enough to interfere with its contractions. He never applies mechanical pressure directly to the aorta, fearing injury of intestines or ureter and heart disturbance from blocking the circulation. Even if the supply of arterial blood is cut off by the Momburg belt or other device, the hemorrhage would only increase as the venous blood is prevented from returning to the heart.

Syphilitic Nephritis.—When in the course of syphilis a nephritis is observed, it is hardly possible to prove that the latter is caused by the syphilitic infection. Burgerhout believes that in cases in which the syphilitic infection undoubtedly preceded the nephritis, and which are characterized by high albumin content, reduced secretion of urine, normal and low blood pressure, and the absence of red cells in the urine indicating a tubular affection (nephrosis), we are justified in diagnosing the disease as syphilitic nephritis. Specific treatment may or may not be successful.

Bacteriophages and Filtrable Viruses. N. Gamaley.—p. 28.
*Vaccine Treatment of Dysentery. K. Gluhoff.—p. 31.

The Extinction Phenomenon in Scarlet Fever.—The aim of Zlatogoroff and Derkach's experiments was to establish the nature of the antigen substances in the serum responsible for the Schultz-Charlton blanching phenomenon in scarlet fever. Rabbits and monkeys were infected with emulsions and filtrates of substances from scarlet fever patients. The extinction-inducing property was most pronounced in serums from convalescent animals, on the eighth or tenth week after infection. The extinction phenomenon was never obtained with monkey serum. With serum from rabbits injected with emulsions, the phenomenon was positive in 80 per cent. and always negative with serums of those injected with filtrates. A pronounced blanching phenomenon could be induced with serum from animals immunized by streptococcus toxin or living cultures of the bacillus. The production and accumulation of the Schultz-Charlton substances was slower than that of ordinary amboceptors. A high agglutination titer for the scarlet fever streptococcus always paralleled a pronounced extinction phenomenon from serum. No relation was evident between the appearance of the Schultz-Charlton substances and the antigen property of the filtrable scarlet fever virus. The blanching of the scarlet fever eruption by human and animal serums thus seems to be a specific local immune reaction to the streptococcic toxin.

Serum and Vaccine Treatment in Dysentery.—Gluhoff reports that specific serotherapy, used in the beginning of an epidemic of bacillary dysentery in 1924, proved ineffectual, while administration of a dysentery vaccine was followed by the recovery of the eight patients. The results of the treatment were demonstrated by Kravkoff's method based on the reaction of vessels in the isolated ear of rabbits to the serum from dysentery patients. Since the suprarenals are affected in dysentery, the patient's serum, poor in epinephrin, induces only a slow contraction of the vessels. As recovery progresses the contraction occurs more rapidly and strongly. A single oral dose of 200 or 300 thousand millions of dysentery bacilli was well tolerated, and induced notable improvement within twenty-four hours. Recurrence was prevented by continuing the vaccine treatment for a time after the stools were normal. A liquid vaccine, treated with alcohol, was used, which has not the disagreeable taste of the vaccine tablets.

*Postoperative Acetonuria. M. Rabinovitch.—p. 431.

Injections of Brain Emulsion in Epilepsy. — Horoshko applied this treatment in twenty cases of epilepsy of long standing with frequent seizures, refractory to the usual treatment. He used a 10 per cent. emulsion of brain from rabbits or antirabies vaccine. From fifteen to thirty daily subcutaneous injections, each at a dose of 1 c.c. were given. The treatment was repeated after from one to four weeks. Good results were obtained in certain cases by ninety or 100 injections, given daily with short intervals. After a few injections seizures became less frequent; the effect was marked on petit mal which often completely disappeared. The psychic condition had been greatly improved. Aggravation of the disease was noted only in one case of post typhus epilepsy with grave lesions of the brain. The author considers the brain emulsion as a specific protein therapy. He emphasizes that in 50 per cent. of all his epileptic patients the blood coagulation time was short before the seizures; afterward, in about 33 per cent. the coagulation time became longer.

Simplified Method for Weigert's Staining of Nerve Fibers.—The advantage of their technic, Maikoff and Shargorodsky say, is that the staining procedure is simpler and more rapid. Besides the myelin, also the chromatophil masses of cells are visible in the same slide, without additional staining. The slides are treated with the chromate as usual and then stained with picrofuchsin, not with hematoxylin.

Factors of Postoperative Acetonuria.—Rabinovitch believes that the severe diet as well as emotional shock preceding the operation play an important part in the occurrence of postoperative acetonuria. The latter does not depend on the amount of blood lost, the kind of anesthetic, nor on the duration of the operation. Young persons and women seem more predisposed to postsurgical acetonuria. This complication is not grave.

Nederlandsch Tijdschrift v. Geneeskunde, Amsterdam

Sensitivity to Insulin on Different Foods Grevenstuk et al.—p. 1038.
*Two Cases of Weil's Disease W Schuffner and Ruys.—p. 1020.
Case of Toxic Lymphangitis D G Cohen Tervaert—p. 1026

Connection Between Psychic and Physical Processes.—Weinberg attacks this problem from the level of the consciousness. Study of thirty normal subjects confirmed that, when this level is high, the excitability of the sympathetic nervous system is high, and when it is low, the parasympathetic system predominates On account of this psychic-physiologic parallelism, psychopathies require improved psychiatric technic, but they also require physical and chemical measures, including organotherapy, to correct the abnormal conditions in the vegetative system. The third element to be considered in treatment is the primary anomaly in the endocrine system, as in myxedema or eunuchoidism, mainly responsible for the psychopathy in the first place. Chronic emotional conditions are liable to entail changes in the vegetative system which, in case of a congenital or acquired substandard condition of any part of this system, may bring on diabetes, gout, hypertension or other grave disease. A combination of psychotherapy and organotherapy may prove useful here also.

Weil's Disease.—In the three cases recently observed at Amsterdam, the disease developed nine or eleven days after submersion in or working on a foul ditch. Wild rats, that were spirochete carriers when caught, were kept by Schüffner and Ruys for up to twenty-one months, without losing the spirochetes from their urine. Jaundice was intense in the three cases, and two terminated fatally. In the recent swimming pool epidemic at Burg, only 34 per cent. of the seventy-six affected developed jaundice, and none died.

Tests for Mixing of Milks. E. Hekma.—p. 310.
*Cod Liver Oil Does Not Dissolve Tubercle Bacilli. M. D. Horst.—p. 320.

The Globulin in Serologic Tests.—Schuiringa and Kapsenberg assert that the globulin of a serum giving a positive Sachs-Georgi reaction will give the reaction alone, without the other elements of the serum. The albumin alone has no such power

The Significance of the p_H for Bacteriology.—Kolthoff argues that the p_H at the end of the growth of certain bacteria might be accepted as a constant if all research workers would use the same culture medium and buffer index. Otherwise not.

Alleged Dissolving of Tubercle Bacilli by Cod Liver Oil.—Horst was unable to confirm Lansberg's statements in this line. Tubercle bacilli were not found easily soluble in cod liver oil. The changes in the oil are due to the air and the heating, not to dissolving of the bacilli, even in a year.

*Ileus from Meckel's Diverticulum. K. Lehmann.—p. 649. C'cn.
*Experimental Nephritis. J. Jessen.—p 656.
*Extrapyramidal Syndromes. VI. A. Wimmer.—p. 666. C'cn., p. 673.

Ileus for which Meckel's Diverticulum is Responsible.—Lehmann compares a personally observed case with those on record, and emphasizes the importance of differentiating between ileus from strangulation and ileus from obstruction by a constricting mechanism. With the latter, enterostomy might relieve the pressing symptoms and allow the bowel to recuperate before resection. In Ekehorn's statistics of sixty-seven cases, the mortality of this form of ileus was 76 per cent. while it was 91 per cent. in the strangulation cases.

Experimental Nephritis.—Jessen asserts that the contradictory results obtained by various research workers in this line is due to the differences in technic. He has obtained identical results in his own work, injecting rabbits subcutaneously with uranyl acetate by the drip method for three months. In every animal the convoluted tubules showed typical changes in certain special regions. The rabbits developed connective tissue and lymphocyte infiltration in the altered parts of the convoluted tubules, and these in another three months shriveled completely.

Extrapyramidal Syndromes.—Wimmer describes the case of a girl of 14 who for six years had had attacks of brief tonic spasms suggesting epilepsy. The last year there had been for the first time certain athetotic movements in the intervals, with difficulty in swallowing, and tremor, with torsion spasm, the manifestations sometimes resembling the positions in decerebrate rigidity. He queries whether this case should be classed as striatal epilepsy, or as an autointoxication affecting a congenitally substandard portion of the brain, or as defective development of the subcortical grey masses or as an idiopathic torsion spasm.

68: 673-696 (July 23) 1925

*Diastase in Serum and Urine. E. Polack.—p. 681.

Diastase Content of Serum and Urine.—Polack states that the figures he obtained in examination of 100 patients with various diseases and controls were lower than those reported by others elsewhere. He used for the tests a 1 per cent. solution of sodium chlorid; a 0.1 per cent. solution of starch, and a one fiftieth normal solution of iodin, left in contact for one hour at 37 C. The normal index range is from 4 to 16.

68: 697-720 (July 30) 1925

*Etiology of Myopia. E. Holm.—p. 697.
*Iodometric Titration of Small Amounts of Acids. Holbøll.—p. 710.
*Neutrality Regulation in Epileptics. Jensen.—p. 715.

Etiology of Myopia.—Holm presents evidence to show that myopia, although practically always due to an inherited special form of the eye, yet can be classed in two main groups, those in which the myopia becomes manifest without any special strain on the eyes, and those in which it develops only after near reading, acute infectious diseases, or in anemia or congenital syphilis. The excessive forms of myopia belong in the first group, which is a dominant. In the second group, the myopia requires heredity from both parents for it to develop. Myopia from hydrophthalmos or glaucoma forms perhaps a third group.

Iodometric Test for Titration of Acids.—Holbøll warns that the solution of thiosulphate should not be poured on the acid fluid when the amount of acid is small. He adds it to the potassium iodid, as in Hagedorn and Jensen's sugar test, and states that when the time and the amount are constant, the acid response is constant, and is more evident when amounts up to 15 c.c. are used.

Neutrality Regulation in Epileptics.—Jensen reports three cases of genuine epilepsy in which neutrality regulation proceeded normally.

Vol. 85, No. 18 Chicago, Illinois October 31, 1925

RECONSTRUCTION AND PLASTIC OPERATIONS ON THE HIP *

FRED H. ALBEE, M.D., Sc.D.
NEW YORK

No other joint offers so great an opportunity for the bone surgeon to indulge his ingenuity as does the hip. Yet there is probably no large joint in which less surgery was undertaken, until the last decade. In fact, although arthrodesis of the knee joint for tuberculosis and other conditions had been frequently undertaken by a large number of surgeons for many years, no one had attempted to devise an operation to arthrodese the hip joint until I brought forward this operation[1] for advanced arthritis deformans (ostearthritis) in 1908.

THE MODERN ARMAMENTARIUM

Four influences—the technically facile fracture orthopedic table, the bone mill, the Smith-Petersen approach to the joint, and the possibility of bone grafting—have led to the development of the extensive amount of plastic operations on the hip now possible, the limits of which to a large degree depend on the ingenuity and experience of the operating surgeon.

The anatomy of the hip is exceptional. It is a ball and socket joint, which makes it possible to move it in every direction; the most powerful muscles of the whole body play on it, so that in the event of fractures near it, displacement by muscle traction, either voluntary or involuntary, may be great, and means other than manual effort and the ordinary hip rest are imperative, both in closed and in open surgery. Moreover, the hip is more deep-seated, and therefore more inaccessible than any other joint. For these combined reasons, it is not only imperative that a fracture orthopedic operating table be available, but also that it be so constructed that the various limb postures required may be quickly obtained and readily maintained with the desired amount of traction, during the course of operation, and postoperatively, during the application of plaster-of-Paris casts. It is exactly these requirements that the Albee table meets.

The modern approach to the joint by the Smith-Petersen incision has widened the field, and has made it possible to do plastic operations that were previously considered impossible of accomplishment.

The bone mill has also contributed to the increased ease of operation, owing to the rapidity of cutting that it renders possible.

Also, the ability to transfer bone from one part of the anatomy to another has had a very great influence in bringing about the success of operations on the hip, as well as in extending the operative possibilities. Bone may be obtained locally, or elsewhere, as from the tibia. The bone graft is of extreme value in selected cases, in operations that aim for mobility, and in those that aim for arthrodesis.

TYPES OF OPERATION

Because of the variety of conditions for which reconstruction and plastic operations on the hip are undertaken, it seems best to discuss them in two general groups, based on the aim of the operation: Group 1, cases in which the operation aims to obtain, retain or improve mobility; and Group 2, those in which arthrodesis of the joint is desired.

OPERATIONS IN WHICH MOBILITY IS DESIRED

Under the head of operations in which mobility is desired fall cases of ununited fracture of the neck of the femur; old arthroplasties with dislocation, congenital dislocation of the hip and acquired dislocations.

UNUNITED FRACTURES OF THE NECK OF THE FEMUR

It still remains true that the bone graft peg operation for ununited fractures of the neck of the femur, for the purpose of restoring the hip as nearly as possible to its original anatomy, offers in selected cases the most favorable results. Its field, however, in my hands, has become much more limited than formerly, especially since the introduction of my reconstruction operation, which consists of removing the head of the femur, performing a plastic on the stump of the neck, and forming a physiologic bone-muscle lever to restore abduction (Figs. 1 and 2).

The reconstruction operation is indicated in all cases in which the nonunion has been of long duration, with considerable erosion of the neck of the femur, on both the capital and distal fragments; especially, if it is associated with a considerable amount of laxity between the fragments, or if there is much shortening. (The latter would necessitate pulling down the distal fragment by means of the orthopedic table, thus bringing a great deal of lateral pressure on the bone graft peg, if that type of operation was used.) The reconstruction operation is also desirable in all cases in which, for any reason, a short convalescence is essential, particularly in older subjects. It affords a very satisfactory amount of motion, in some cases as much as 90 per cent. In cases in which erosion has been extensive, with consequent loss of a considerable portion of the neck of the femur, even though the bone graft operation may be successful, the anatomy of the parts has

---

* Read before the Section on Orthopedic Surgery at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

[1] Albee, F. H.: Arthritis Deformans of Hip: Report of a New Operation, abstr., J. A. M. A. 50: 1553 (May 9) 1908.

suffered, and the range of motion at the hip is necessarily impaired. Moreover, the erosion of the neck and the shortening of the head, sometimes to the degree that it becomes a mere shell, diminish the efficacy of the bone graft in securing motion, and bring about conditions unfavorable to the reception of the bone graft peg. Because of these influences, I now resort to the bone graft operation in not more than 10 per cent. of the ununited fractures that come to me.

TECHNIC OF THE RECONSTRUCTION OPERATION

The head of the femur is removed. The stump of the neck on the distal fragment is rounded, so as to be received with a minimum amount of irritation in the acetabulum. A lever about 4 inches long, including almost the entire trochanter and about one sixth of the diameter of the shaft of the femur, is separated and pried outward, producing a greenstick fracture at the lower end. The mere abduction of the limb, when the patient is held by the Albee table, throws the neck of the femur into the acetabulum.

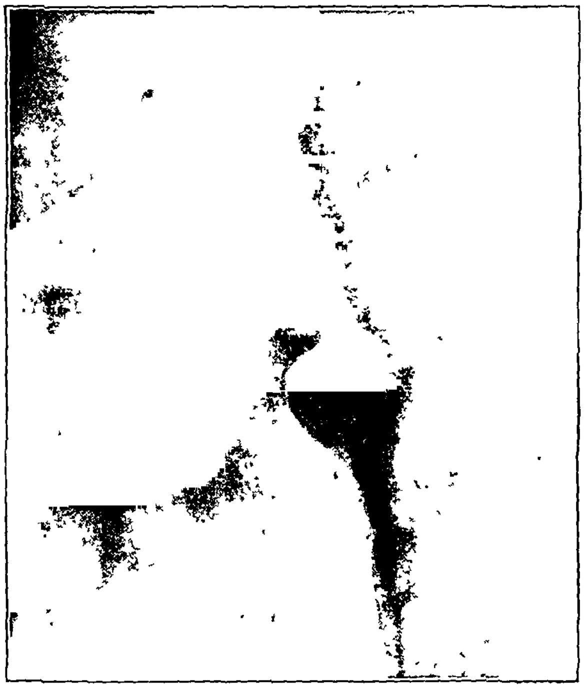

Fig. 1.—Typical case of ununited fracture of the neck of the femur, with loss of most of the neck.

The approach is that devised by Smith-Petersen, and is very similar to the Sprengel approach. The skin incision consists of two parts: (1) from the anterior superior spine directly downward, and (2) from this point over the anterior superior spine directly backward along the crest of the ilium for a distance of 3 or 4 inches. With a scalpel, the fascia lata is severed parallel with the crest of the ilium and sufficiently below it to leave a fascia flap to receive sutures in the approximation of the severed fascia lata at the close of the operation. Then, with the Albee osteotome, used for splitting the spinous processes in the Pott's disease operation, the muscles are stripped down from the side of the ilium by subperiosteal separation, and are separated from one another directly downward from the anterior superior spine The capsule of the hip joint is completely exposed. The joint is entered by a T incision with the stem running directly downward along the neck of the femur. The head of the T is made about three-fourths inch from the rim of the acetabulum, for the purpose of furnishing a cuff of capsule to act as a lining of the outer portion of the joint, and for the neck to rest against when the head has been reconstructed. Care should be taken to make the incision into the capsule sufficiently spacious so that the difficulty of getting the head out of the acetabulum will be minimized. The crucial ligament is then severed by means of a half inch osteotome, and any adhesions of the capsule to the periphery of the head are carefully separated with a scalpel.

The limb is then strongly everted by adjusting the fracture table, so as to make room for the delivery of the head. With two long half-inch chisels or osteotomes, the head is pried out of the acetabulum, with a motion much like that used in eating with chop-sticks: one osteotome is thrust into the inner, and one into the outer substance of the head, and the two are used as levers against the soft parts to pry the head out of place. As soon as the head is delivered, the foot should be inverted by adjustment of the table, so that it points directly upward. Then, with the scalpel, the soft parts are severed in a straight line down on the anterior surface of the trochanter and the outer portion of the shaft of the femur to admit the osteotome that is to split off the lever as indicated in Figure 3 *A*. With the broad Albee spinal osteotome, the bone is severed (Fig. 3 *A*) and pried outward (Fig. 3 *B*). The stump of the neck is then rounded so as to produce a minimum amount of irritation on the acetabulum. The assistant is directed to adjust the table so that the limb is brought to the limit of physiologic abduction at the hip, and at the same time the upper end of the femur is lifted forward and guided into the acetabulum (Fig. 3 *B*). Thus the bone lever is automatically held by the posture in the position shown in Figure 3 *B*.

In the angle between the shaft and the lower end of the graft, small bone grafts obtained from the upper portion of the shaft of the femur may or may not be inserted, to supply additional foci of osteogenesis and to hasten union. The muscles and soft parts should not be separated at all from the bone lever or from the great trochanter. The bone lever is pulled anteriorly. The wound is now ready for closure, with two interrupted sutures of medium kangaroo tendon in the muscles and fascia attached to the bone lever and in the anterior portion of the wound. All dead spaces are overcome by means of continuous suture of No. 1 chromic catgut. The skin is closed by continuous suture of 0 plain catgut. The line of incision and the suture holes are puddled with tincture of iodin, 3.5 per cent. The leg is put up in a long spica, extending from the tips of the toes to well above the costal margin, with the abducted position undisturbed. The plaster is molded so as to hold the upper end of the femur anteriorly, and is kept on for a period of six weeks. The leg is then allowed gradually to resume the normal position, and the bone-muscle lever assumes the relationship shown in Figure 3 *C*. The patient is persuaded to begin walking immediately. Daily massage and manipulation, at both the hip and the knee, are at once instituted, to bring about motion.

ILLUSTRATIVE CASE

The mechanism of my reconstruction operation for ununited fracture of the neck of the femur could not be more beautifully illustrated than by the following case:

Miss H. H, aged 32 years, came to me, July 11, 1924, referred by Dr. G. W. Crile. She had suffered from ankylosis of both hips, apparently the result of suppurative arthritis. In 1917 an arthroplasty had been performed on the left hip, and in 1919, on the right hip, by Dr. Carl Hoy of Columbus Excellent motion was obtained in both hips, and the operator is to be congratulated on the exceptional result *in the left hip* The right hip, however, was a serious disappointment to the patient; so much so that she felt she would much *prefer* the stiff hip that she had had prior to operation, because *there* was constant danger of dislocation whenever the limb came to or beyond the midline. Moreover, the function of abduction had been lost

This case presented two features: (1) a constantly recurring dislocation of the hip whenever the limb swung to the midline or beyond, and (2) loss of the function of abduction These are the very conditions which my bone-muscle lever was designed to overcome or prevent. The operation, July 14

1924, was therefore approached with a great deal of interest by myself and my associates. The roentgenograms in this case are interesting (Figs. 4 and 5). The newly formed joint resulting from the previous arthroplasty was found to be an excellent false joint, with a well formed acetabulum, containing clear fluid, quite closely resembling synovia. The femoral portion of the hip, however, was merely the stump of the neck. The hip was most lax, and could be readily dislocated. The bone lever was erected from the outer and upper end of the femur, precisely as described and illustrated previously. Figure 5 illustrates the bone lever firmly united in its oblique position to the shaft of the femur. In May, 1925, the patient wrote that the hip had not dislocated, and that she considered the result excellent.

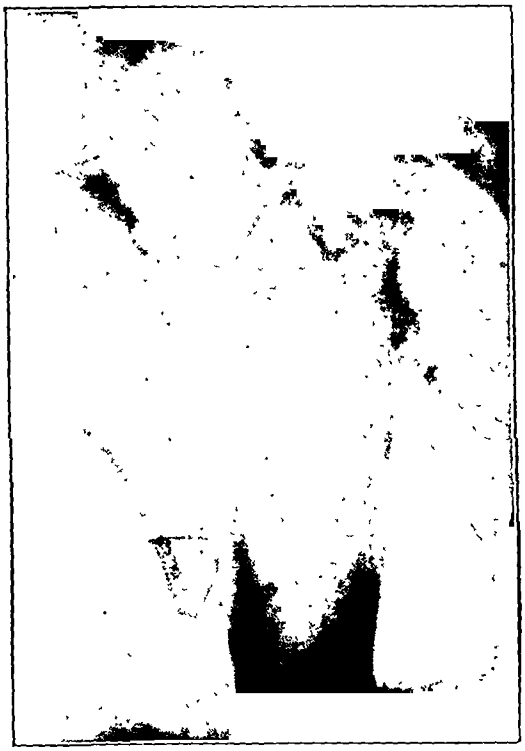

Fig. 2.—Result after bone-muscle lever has united in place; illustrating the wide distance between the great trochanter and the side of the pelvis in proximity to the rim of the acetabulum, thus allowing for generous abduction.

MECHANICAL ACTION OF BONE-MUSCLE LEVER

The mechanics of this operation, which have already been discussed, may be further elucidated by a description of the mechanical action of the bone-muscle lever in this case. The insertions of the short trochanteric or abductor muscles were carefully left intact on the trochanter or proximal end of the lever. As the approach to the hip did not interfere with the innervation or force of these muscles, the ability to abduct, lost with the leverage action of the neck of the femur, was restored at the same time that dislocation, when the leg came to the midline or beyond, was prevented by the outward excursion of the proximal end of the lever and the resultant tension not only on the trochanteric muscles, but on the soft parts surrounding them. This caused the newly formed femoral head to be jammed firmly into the acetabulum, thus preventing dislocation (as indicated by direction of the arrow in Figure 3 *C*).

Attention should be called to a misleading statement by Whitman[2] who, in discussing my operation says: "The trochanter, being ill adjusted to the acetabulum, is liable to displacement if motion is permitted, and in both instances there is complete loss of leverage for the abductors, therefore lessened muscular control and a consequent tendency toward flexion and adduction of the limb." This is quite untrue, and indicates a misconception of my technic, as does the illustration in which he attempts to illustrate my reconstruction operation. The latter entirely misrepresents the mechanics of the operation, in that the lever is about one fifth the length I have always made it, and is not oblique to the shaft of the femur, as it should be. The operation, properly performed, does not interfere with abduction, and a review of forty-eight cases shows that muscle control was definitely conserved in all. An inspection of my diagram in this paper (Fig. 3) will show that this operation produces the most efficient leverage action of any operation so far reported.

CONGENITAL DISLOCATION

Because of the extensive scope of this paper, I shall not refer to the various reconstruction operations for congenital and acquired dislocations of the hip, but shall limit my discussion to cases in which the acetabulum is so shallow, or the head so faulty in shape, that the latter will not remain in place after reduction; and those in which the limb has been so shortened and the hip so far elevated that it is impossible to deliver the head into the acetabulum. In such instances, it is necessary to construct an acetabulum higher up on the ilium. Here, again, the surgeon's mechanical ingenuity should be drawn on to meet the exact mechanical conditions found. The methods that I have resorted to in such cases have already been described.[3] One method with which I am particularly pleased is one in which the bone graft material is wholly obtained from the outer table of the side of the ilium itself. The work, in brief, consists of either deepening the acetabulum by means of bone graft wedges, or extending the roof of the acetabulum by means of turning down a graft from the outer table of the ilium over the head of the femur, situated in the shallow acetabulum (Figs. 6, 7 and 8). Or an acetabulum may be formed higher up on the ilium.

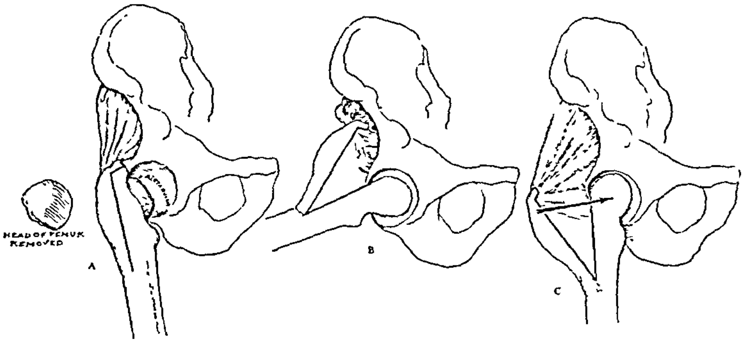

Fig. 3.—Albee's method of treating ununited fractures of the neck of the femur by removing head of femur and producing greenstick fracture, the trochanter being swung outward on the periosteal hinge. The remains of the neck of the femur and upper end of the great trochanter are to articulate with the acetabulum, the inverted portion of the capsular ligament contributing to the formation of the new articulation.

I wish to emphasize the wisdom of adopting this last procedure in all cases in which it is necessary to employ such great force in securing reduction that undue trauma to the acetabulum or the head of the femur results. Formerly, and unfortunately in certain instances even today, surgeons regarded reduction as the prime indication of satisfactory treatment, regardless of the trauma entailed. Further study of such cases, however, reveals the fact that so much limitation of motion resulted from the trauma at the time of reduction that the late results must be classed as most unsatisfactory. Had the surgeon been less heroic and more ingenious in his methods, constructing an acetabulum higher up on the side of the ilium, the late results would have been a slight amount of shortening, with a satisfactory functional hip and a large range of motion.

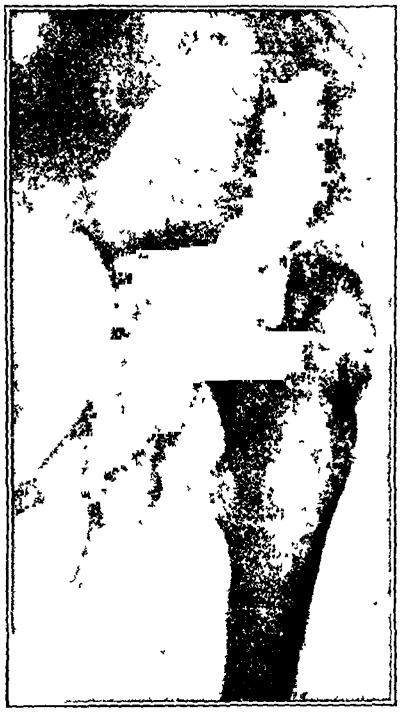

Fig 4—The result of a previous arthroplasty, with the head and part of the neck of the femur removed Because of the close proximity of the tip of the trochanter to the outside rim of the acetabulum and side of the pelvis, the femur is transformed into a lever with its fulcrum point at the tip of the trochanter Consequently, abduction of the femur draws the reconstructed articular portion (on its neck) out of the acetabulum, and dislocation results.

Numerous other types of bone plastic operations have been practiced in these cases, and will be described at a later date.

CASES IN WHICH ARTHRODESIS IS DESIRED

No joint in the body is better adapted to arthrodesis, or offers a better functional result following it, than does the hip. Although I have been performing such operations for more than fifteen years, I am still surprised and gratified beyond expectation by the late results in certain patients who come back to me to express their satisfaction. I have no other group of cases in which operation affords so high a percentage of thoroughly satisfied patients. A patient who is told that the hip is to be stiffened to relieve pain naturally expects increased limitation of motion in that quadrant of his body. He is most agreeably surprised to find that, in his own judgment, the motion has been increased after the hip has been ankylosed. This happens in a large percentage of cases. When the hip becomes entirely ankylosed, and all anxiety regarding pain has ceased, the muscle spasm induced by nature's attempt to guard the hip joint is relieved, and the compensatory motion in the lumbar spine or knee joint is so great that the patient believes motion has been increased, in certain cases even in the hip itself. This is accounted for by the unusual anatomic condition: the psoas magnus controls motion not only at the lumbar spine but also at the hip. Other muscles control motion at both the knee and the hip, namely, the biceps femoris, semimembranosus, semitendinosus, rectus femoris, sartorius and adductor gracilis. Consequently, involuntary muscle spasm, which takes place in muscles controlling motion at the hip, not only causes pain at the hip, but has a marked inhibitory influence over motion in the lumbar spine and in the knee joint.

The first medical body before which I demonstrated the operation for arthrodesis of the hip was the International Congress of Surgery at Budapest in 1909; at that time I reported five cases, all of arthritis deformans. Since that time I have somewhat modified the technic, and have applied the operation to a large variety of hip conditions, such as tuberculosis in the adult, infectious arthritis, comminuted fractures and dangle hip from paralysis.

MODIFIED TECHNIC

The approach is through the Smith-Petersen incision. The technic originally designed consisted merely of removing all cartilage from the superior surface of both the head and the acetabulum, so that cancellous bone of the head comes in contact with cancellous bone of the acetabulum. Because of a certain percentage of delayed unions, and a few failures to unite, I have supplemented this procedure by sliding a graft (approximately 1½ inches wide, and extending from just above the rim of the acetabulum to just below the crest of the ilium) downward toward the outer table of the ilium into the split substance of the trochanter, having first denuded and widened the neck of the femur, so as to secure as much raw surface of bone for contact with the under surface of the graft as possible. In certain instances it has been possible to swing the graft on a pedicle of muscle instead of sliding it. In obtaining the graft, care should be taken to leave the rim of the acetabulum intact, in order to furnish the maximum surface of acetabulum to fuse with the head of the femur. Care should also be taken that about one half of the graft is contacted with the pelvis, and one half

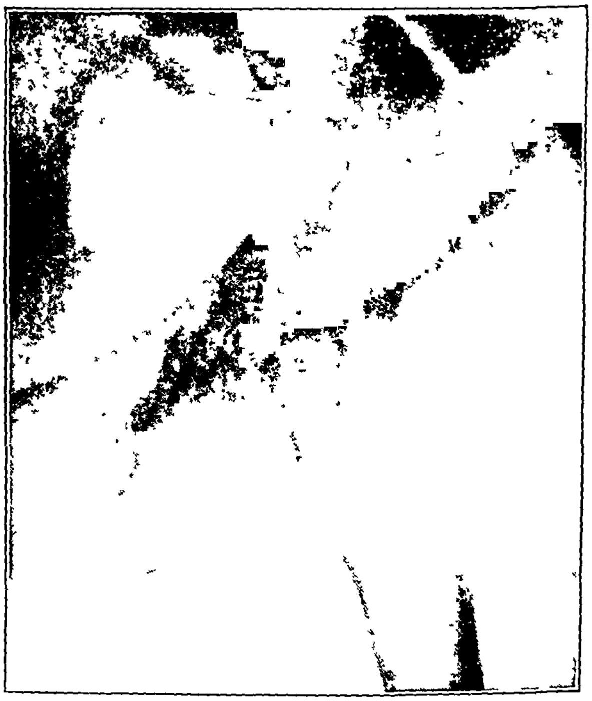

Fig 5—Mechanical effect of the Albee reconstruction operation in displacing outward the fulcrum point of the trochanter, thus taking away the leverage or dislocating action from abduction of the femur. It further illustrates the mechanical advantages of this operation as set forth in the text

with the femur; this produces an osteogenic or vascular conducting bridge, spanning across the hiatus, to be arthrodesed. Caution is necessary in attempts to arthrodese any joint, as nature is most efficient in restoring motion and interfering with arthrodesis following operative procedures—one reason for fortifying the result by adding another element of safety, the bone graft.

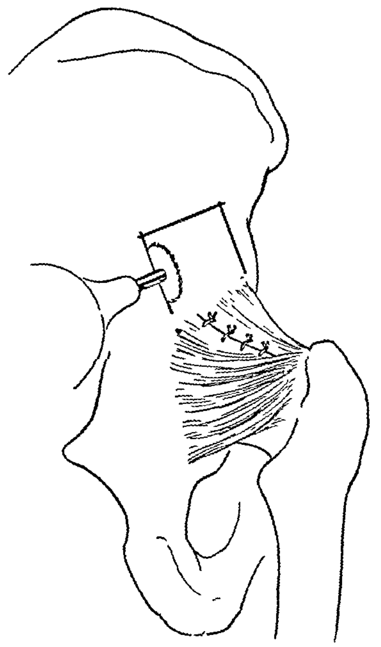

Fig. 6.—Closed incision in the capsule that was made to inspect the depth of the acetabulum, etc. The motor saw cuts for the turning down of the outer table of the ilium over the femoral head and overlying capsule, as illustrated in Figure 7, may be noted.

The technic, when applied to any lesion whatever, varies only in accordance with the mechanical confirmation found.

It has recently been stated[4] that arthrodesis offers "an uncertain outcome because abduction of the limb, the attitude of election, separates the upper surface of the head from the acetabular roof to which it should be apposed in order to secure union, and in a large proportion of cases, although sufficient restriction of motion may be assured after prolonged fixation to relieve pain, there is recurrence of a certain degree of flexion and adduction deformity after the support is removed." I can only recommend that such untoward results can be entirely avoided by the use of the proper technic, and it is for this very reason that I have in late years employed the bone graft as a safeguard, and as an added element in hastening and insuring solid bony ankylosis.

It is desirable to employ the immobilizing influence of union of the femur to the pelvis in cases of acute or subacute joint disease, especially tuberculosis, in which for various reasons it is not desirable to enter the infected area. This is principally because of the danger of causing metastatic infection, immediate or remote, by traumatizing an acute tuberculous area or lesion. Moreover, since the tubercle bacillus inhibits osteogenesis, any tuberculous joint is an unfavorable site in which to attempt to secure ankylosis. In such instances, I have employed a technic, which I first described in my Bone and Graft Surgery (1915 edition).

Two large strong tibial grafts are employed. The approach is by a curved incision over the gluteal muscles lying between the ilium, just posterior to the anterior-superior spine and the tip of the great trochanter. A straight incision through the fascia and the entire muscle is made from a point just inferior and posterior to the anterior-superior spine of the ilium to the anterior surface of the great trochanter; another straight incision is made from a point approximately from 1½ to 2 inches posterior to the upper end of the first incision, to the posterior surface of the great trochanter; the two converge to a common point at the inferior portion of the outer surface of the trochanter. Then, with the motor saw, bone incisions are made in the trochanter, converging below and in a line with the incisions just made in the muscles, thus leaving a triangular area of the trochanter between the converging sawcuts (Fig. 9). The bone on the anterior portion of the trochanter is turned anteriorly with an osteotome, the soft parts being used as a hinge. The same precedure is carried out on the bone posterior to the second motor-saw cut, except that the trap door of bone is turned posteriorly. The shaft of a long osteotome or chisel is then laid in this gutter, and its cutting edge placed on the side of the ilium; then, at the upper end of the anterior incisions in the muscle, the outer table of the ilium is severed by gentle taps of the mallet. The hole is enlarged to receive the end of a tibial graft, which is later to be driven in. The bone at the upper end of the posterior incision in the gluteus muscle is treated similarly. The tibia, preferably on the same side, is laid bare from the tubercle to about 2 inches above the ankle joint. With the Albee bone saw, a graft is obtained from the center of the tibia. This should be sufficiently long so that, when divided in halves, it will furnish two grafts adequate to span the space from the trochanter to the holes already made in the ilium. The ends of the graft are made wedge shaped, so that they can be driven into the holes in the ilium, by placing the graft in the trochanteric gutter and gently rapping it into place with a bone-driving instrument, which simulates a nail set used for a similar purpose by the carpenter. The trap doors of bone are swung back over the distal ends of the graft and held by means of interrupted sutures of medium kangaroo tendon, thus keeping the graft in position. The wound is then closed by the usual method.

Figure 10 shows the condition in a case of tuberculous hip disease, which had been treated for three years by adequate braces before the patient (a woman, aged 43) came to me. I continued the mechanical treatment for an additional period of two years by means of the Phelps brace with crutches, but at the end of this time (1915), the hip was more acutely painful than at any previous period. Because of the discouragement of both the patient and myself, I resorted to the operation just described. The roentgenogram presented in Figure 10 is a most interesting demonstration of the influence of mechanical stress on a graft, in that the graft increases in strength and diameter in proportion to the amount of mechanical stress brought to bear on a particular portion. It may be noted that these grafts are much larger in diameter at the point near the trochanter where more mechanical stress comes on them than at the end where they are united to the ilium, which is the end of the lever distal to the fulcrum point.

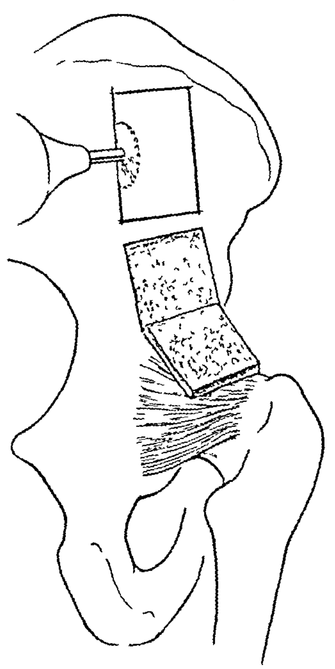

Fig. 7.—Bone from the outer table of the ilium turned down with periosseous structures, the bone itself acting as a hinge. With the motor saw removed, the bone from the upper portion of the ilium serves for a brace, as indicated in the next illustration.

This patient was sent to the Burke Foundation Convalescent Hospital at White Plains, where she made such an uneventful and satisfactory recovery that she was engaged as an employee in the hospital, and has continued there ever since with absolute relief of all symptoms. She is in perfect health at the time of writing.

---

[4] Ann. Surg. 80: 781 (Nov.) 1924.

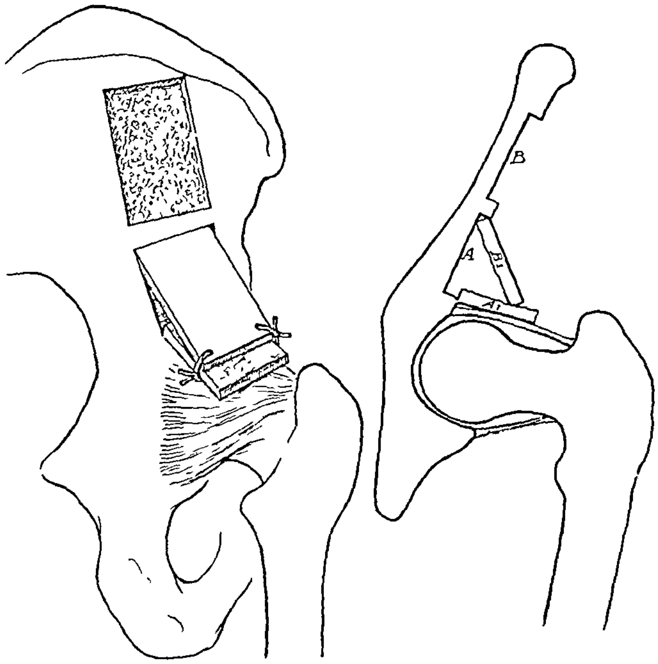

Fig 8.—The completed bone work, with interrupted kangaroo sutures in place. These kangaroo tendon sutures are inserted into the capsule and into the drill holes in the bone graft, in order to hold them firmly in place

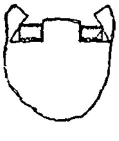
Since this patient was operated on, twelve other cases have come to operation. These will be the subject of an independent paper to be published later. Three of the patients were suffering from acute symptoms and had been treated elsewhere, by stretching and manipulation, for a pronounced adduction and flexion deformity. In each instance, the deformity had recurred, with an increase of pain. One of the patients had received manipulative treatment three times, with a recurrence of the deformity each time. In all three cases, the adduction and flexion deformity was easily corrected at my operation by the influence of the orthopedic table, the patient being fully etherized. The bone grafts have afforded arthrodesis, immobilization and the avoidance of braces.

INDICATIONS



This operation for tuberculous hips is especially indicated in cases of long standing in which there has been an extensive destruction and absorption of the head and even the proximal end of the neck of the femur, and occasionally of the acetabulum; that is, in cases in which the bony material that might be utilized to secure fusion by the ordinary type of arthrodesis is absent. By the use of the bone graft, entrance into the tuberculous joint is avoided, and the active osteogenic bone of the grafts is contacted with the healthy active bone of the femur on one side and of the pelvis on the other. The full effect of the arthrodesis is thus afforded by means of bone graft bridges in the soft parts extra-articularly.

40 East Forty-First Street.

ABSTRACT OF DISCUSSION

Dr. W. C. Campbell, Memphis: Dr. Albee has brought to our attention a most interesting and important subject. There are four different types in which reconstruction is necessary in hip joints. They are those in which the weight of the body is thrown on the muscle and the soft structures, from which many suffer considerable hip strain, referred pain and various symptoms. The four conditions that I mention are, first and of most importance, an old fracture of the neck of the femur. This condition is considered absolutely hopeless by the profession in general. In old fractures of the neck of the femur we now have methods such as Dr. Albee and others have demonstrated, in which relief can be given to a large percentage and we can not only relieve the constant pain but also place the patient on his feet. Of course he has a persistent limp, but crutches are discarded. The second type of case that I might mention is the paralytic dislocations, such as dislocation of the hip joint following poliomyelitis, in which there is considerable mechanical disability. A third class is the old congenital dislocations. The fourth class is the result of tuberculosis. In paralytic dislocation of the hip I employ a technic which consists of cutting loose the upper portion of the flat acetabulum, and displacing outward, so as to extend and deepen the socket. Multiple flaps of bone are turned downward from the crest of the ilium to reinforce the extended acetabulum. In congenital dislocations, we do just as Dr. Albee has demonstrated: make the acetabulum above the seat of the normal joint. In some cases, Dr. Albee changes the fulcrum of the trochanter and gives a direct muscle pull in exactly the right direction. That is a great advantage. I do not see why it could not be used in conjunction with the Brackett operation. I am not quite sure that it is necessary to remove the head in all these cases. It takes a little more time, and I think that if this is well reamed out we may obtain pretty fair fibrous union, even bony union. I think that extending the acetabulum, as mentioned above, is an advantage. As to arthrodesis of the hip, I have had no experience with that method. It is very difficult to accomplish fusion in the hip joint by removing all the cartilage even to raw bony surfaces. At least, I have had a great deal of difficulty in producing solid bony fusion in this way, and the method that Dr. Albee has shown I think gives a better chance.

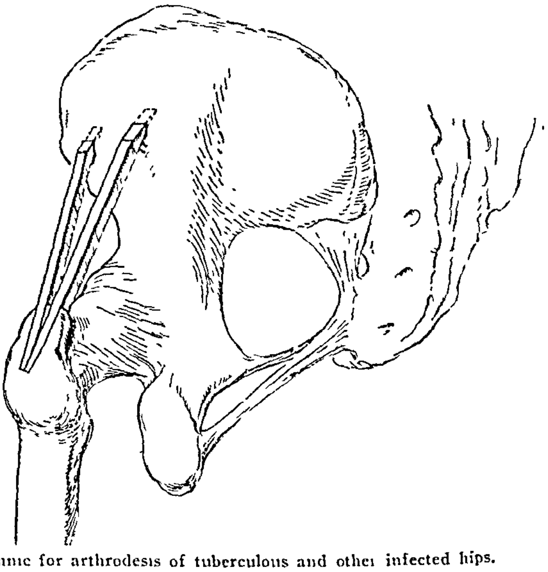


Fig 9.—Technic for arthrodesis of tuberculous and other infected hips.

Dr. M. N. Smith-Petersen, Boston: For some time we have used the Whitman operation in ununited fractures of the neck, and it is a technically easier operation than the operation described by Dr. Albee. Dr. Albee's operation requires thorough familiarity with his equipment, not only on the part of the surgeon but also on the part of the assistants.

In performing the Whitman operation I myself prefer to transplant the trochanteric muscular attachment with the shell of bone rather than the entire trochanter. Earlier union and earlier function are thereby secured. In regard to extra-articular arthrodesis, we have come to the conclusion that we do not get consistently good results. In the intra-articular arthrodesis, dislocating the hip, cleaning out the acetabulum and denuding the head, we use in addition extra-articular osteoperiosteal grafts to hasten bony union. In popping the head of the femur out of the socket, the capsule should first be widely opened. Incomplete exposure invariably means unnecessary trauma. May I say a word about the Lorenz operation? I feel so strongly against that operation that I want to take the opportunity to say that it is mechanically unsound; it does not consider anatomic or physiologic laws. At the present time it is our duty in every possible way to prevent surgeons from undertaking an operation which cannot help but produce ill effects later. Temporarily, it may give a functionally good result: but, as years go by, the results are bound to be disastrous.

Dr. M. S. Henderson, Rochester, Minn.: I should like to ask Dr. Albee about the advisability of removing the head of the femur in these cases. I know that there are certain cases in which, no doubt, the head is so atrophied and devitalized that it should be removed. Dr. Campbell called attention to Dr. Brackett's operation, and, in several cases, I have had excellent results by employing this operation, which consists of freshening the head of the bone, reshaping the upper head of the femur and placing them in apposition and maintaining that position until they unite. In one case in which there seemed to be no life in the head, so far as I could see, and it looked as though it was atrophic, the head went on to good function, securing its nutrition from the lower fragment. The Brackett operation is particularly applicable in younger people when the neck is completely absorbed. So many factors enter into the selection of operation for this type of reconstruction work that, in a brief discussion of this kind, it is difficult to do justice to the subject; but I should like to know Dr. Albee's candid opinion as to the necessity of the removal of the head of the femur and how often he thinks it should be done, comparatively speaking. Dr. Albee stated that in only 10 per cent. of the cases that come to him now was he doing the bone grafting operation. That is very interesting and would indicate that the bone graft in the reconstruction work in the neck of the femur has not lived up to what we had expected. Nevertheless, when there is a fair amount of neck left to the femur, and the patient is reasonably young and in good condition, it seems to me that the bone graft reconstruction operation is the one of choice.

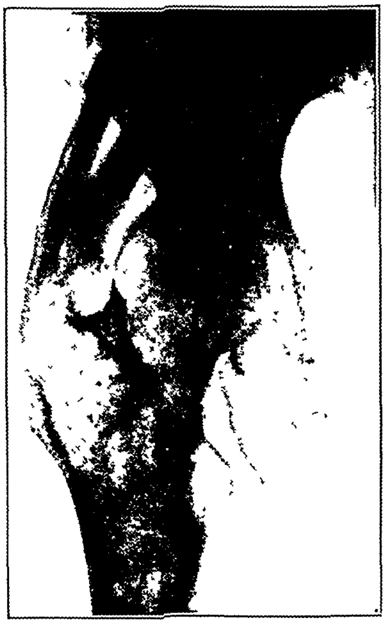

Fig. 10.—Postoperative result eight years after operation. The influence of mechanical stress on the grafts may be noted. The joint has become completely bony ankylosed.

Dr. W. G. Stern, Cleveland: The Whitman modification of Brackett's operation, which Whitman also calls the "reconstruction operation" of the hip joint, does not depend on bony union for its success, and it is fairly easily done. Still, the shock of such an operation in old persons is a danger that should not be passed over lightly, and that leads me to speak in favor of the Lorenz "bifurcation operation" that Dr. Smith-Petersen condemns. There is something to be said in favor of the anatomic arrangement of affairs in the Lorenz operation. In an ununited fracture of the neck of the femur, one leaves the head in place, and the capsule of the hip itself is not disturbed. The operation is merely a subtrochanteric or intratrochanteric osteotomy of the shaft of the femur, and the upper part of the lower fragment is so placed by abduction that it either impinges below the fractured head of the femur, or in congenital luxation of the hip so impinges on the acetabulum that the original capsule of the joint is between the upper end of the distal fragment and the acetabulum itself. Therefore, having the original capsule between the bony fragment and the articular surface, I do not see how this is more unscientific and more unsound than the usual arthroplasty operation at the neck of the femur, in which a fascia graft is taken from somewhere else and placed between the two raw surfaces. The bifurcation operation can be done very easily, and takes only ten or fifteen minutes. There is practically no hemorrhage, and no sutures are used. All one needs do is to abduct the limb in such a way (about 30 degrees) that the upper end of the distal fragment is either in the acetabulum or impinges beneath the head of the bone in ununited fracture. The upper fragment, whatever it may be, so rotates inward that one has a real bony hand or buttress projecting up against the acetabulum, and one has the original, undisturbed capsule of the joint in between the operative field and the acetabulum. The thing for us to do is to test out the operation by choosing our cases wisely, treating them properly and then studying our results. Be that as it may, I believe with Dr. Albee that the day has come when, in ununited fracture of the femur, we had better do a reconstruction operation on the hip joint than the old dowel graft operation. I should like to ask Dr. Albee one question: In contradistinction to Dr. Whitman, who chops off the trochanter and then implants it down farther on a freshened portion of the shaft, Dr. Albee splits the trochanter and part of the shaft of the femur with it, and abducts it. Dr. Albee did not tell us how he keeps this wide angle open. To my mind, something must go well in between this split portion of the trochanter and part of the shaft, and the remains of the shaft of the femur itself.

Dr. F. J. Gaenslen, Milwaukee: This discussion with reference to the Lorenz operation is really quite apropos, because in a measure the operation done by Dr. Albee is a bifurcation operation, although it is not done in the way that Lorenz or von Bayer (who devised this practically simultaneously or perhaps just prior to Lorenz' first publication) does it. In my travels abroad in 1922, I found that the operation had received a great deal of attention and a great deal of enthusiastic support, and while I myself have done the operation in only two cases, I am going to continue it, choosing my cases carefully and withholding further judgment until further time has demonstrated the usefulness of it.

Dr. F. H. Albee, New York: For fear that Dr. Smith-Petersen misunderstood the technic in my reconstruction operation, I would say that in that particular instance the bone saw is not necessary at all. But any man who is doing reconstruction bone surgery should have the bone saw on his table all the time, in case it is needed. The argument against the operation does not appeal to me. In reference to the necessity of removing the head, I take it that it is felt that it may be possible to leave the head in place and do exactly the same operation as I have done. I do not know but that may be so. I have been fearful of that for these two reasons: First, that if fibrous union results, will it not cause pain? I am afraid that weight bearing would produce pain. Then, as to motion, I am very fearful of getting bony union in these very bad cases with just a shell of the head left. If one does leave the head, it is similar to a fracture in a joint. In reference to the bifurcation operation of Lorenz, I absolutely condemn it because it is not surgical. We should have things wide open and see what we are doing, and put our parts together as they ought to be put. I have seen excellent results produced by that operation, but what percentage of results is one going to get by such an inaccurate method? With reference to Dr. Stern's remark about the wide angle, of course, the lever is automatically held to that wide angle by the posture of the limb that is put up in strong abduction, completely out beyond the limits of physiologic abduction. I have used small bone grafts in that V cavity, and at other times, I have not. Of course, we have a greenstick fracture there at the lower end and it is very favorable to union.

THE ETIOLOGY OF INCRUSTED CYSTITIS WITH ALKALINE URINE *

BENJAMIN H. HAGER, M.D.
Fellow in Urology, the Mayo Foundation
AND
THOMAS B. MAGATH, M.D.
ROCHESTER, MINN.

Incrusted cystitis is a chronic inflammatory condition of the urinary bladder manifested clinically by symptoms of dysuria, urgency and frequency, and the passage of gritty material or sand. In certain cases the urine is strongly alkaline, the degree depending somewhat on the severity and chronicity of the process. Usually the urine contains a large amount of blood and mucus, and sometimes pus. The marked discrepancy between the number of red blood corpuscles and pus cells in the urine in this form of cystitis has often been contrasted with the ratio in ordinary cystitis. Because of the nature of the gritty material and the alkaline condition of the urine, this particular type of cystitis has been referred to as chronic alkaline phosphatic cystitis. On cystoscopic examination the bladder presents crusted material which is hard, is firmly embedded in the mucous membrane, and may be limited, affecting only a small area of the bladder surface, usually in the trigonum, or generalized, covering almost the entire mucous membrane. Often these deposits are found when patients give a history suggestive of previous ulcer of the bladder or mild cystitis, and they sometimes appear in the bladder after fulguration following catheterization, or when tumor growths have been previously observed.

Without considering the clinical characteristics of the disease further than to state that this rebellious form of cystitis is much more prevalent than is generally supposed, and that the treatment has often been unsatisfactory because of the obscure nature of the infection, we shall review some of the results obtained by an intensive study of three cases and a series of experiments on animals.

Various etiologic factors and numerous types of bacteria have been regarded as specific causes of this disease. Since a large percentage of bladder infections descend from the kidney or are carried by the blood from remote primary foci, a systematic clinical study of patients so infected was made. While no particular focus could be found in the patients we felt it desirable to carry on some experimentation along the lines that have been so successfully pursued by Rosenow, Meisser, Hayden and others. It was difficult to obtain accurate information concerning the kidneys on account of the technical difficulties encountered in catheterizing the ureters. The small size of the bladder and the tendency of hemorrhage to follow overdistention, together with the marked irritability and incrustation around the ureteral orifice, made it impossible to insert catheters into the ureters, except with the aid of sacral anesthesia and the intravenous injection of indigocarmin. Eventually the ureters were catheterized in each of the three cases. Altogether, these three patients were under observation for more than a month, and during that time many cultures were made of catheterized urine. We obtained almost always a streptococcus that produced green colonies on glucose blood agar and showed slight hemolysis on plain blood agar. Staphylococci and colon bacilli were also obtained. Along with these organisms we isolated a gram-negative bacillus which produced white colonies on Endo medium, and formed a moist, more or less sticky bluish gray, glistening colony on agar. This organism fermented, with the production of acid and gas, glucose, galactose and xylose, and produced acid in glycerin, and to some extent in litmus milk. The following sugars were not fermented at all: maltose, lactose, sucrose, mannite, dulcite, inulin, inosyte, salicin, arabinose, raffinose, rhamnose and dextrin. Occasionally there was slight acid formation in levulose, but this we attribute to the impurities often found in that particular sugar. These characteristics, together with certain others, suggest that this is similar to that bacillus (*Salmonella foetida*) which Perez isolated from the nasal discharges of children suffering with ozena. However, certain differences present themselves, so that we feel for the present, at least, that it is better to call the particular bacillus described above *Salmonella ammoniae*. The significance of the name lies in the fact that this organism is capable of breaking urea into ammonia and carbon dioxid in a very short time. Sterile urine, when inoculated with this bacillus, will have all its urea converted into ammonia within at least six hours. It will also convert the urea of blood into ammonia.

Following the method of Rosenow, attempts were made to induce localization within the urinary bladder of experimental animals by injecting urinary sediment and the organisms isolated from the urine into the blood stream of rabbits. Some animals were injected with pure cultures of single organisms, while others were injected with combinations of organisms. When cultures were used, the urine was inoculated into brain-broth tubes; then the broth suspension was injected in varying amounts after twenty-four or forty-eight hours' incubation. Also, organisms recovered from the urine or heart's blood of these animals were injected into the blood stream of other animals, and in some instances a second and a third animal passage was made. Some of these animals were allowed to live as long as possible, while others were killed in from twenty-four hours to several weeks after injection. In all, about 200 animals were injected for these experiments. As might be expected when animals were allowed to live longer than three or four days, lesions were rarely found which were acute enough to be attributable to the injection. There were seven animals whose bladders contained distinct inflammatory lesions, but none of these showed incrustations or deposits in the bladder mucosa. Of these seven, only four showed lesions when injected with urine or cultures of urine from the patients. The other three lesions were in animals injected with bacteria after animal passage. Twelve animals showed slight or questionable lesions in the bladder. However, there were just as many lesions in other parts of the body, and many more in the kidneys than in the bladders.

* Read before the Section on Urology at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

Since the results of these experiments were so inconstant, it did not seem wise to try to tabulate them at all, but they show that under the conditions it was not possible to cause incrusted cystitis in rabbits by injecting intravenously the organisms obtained from urine of patients suffering with incrusted cystitis.

† Determinations are in terms of grams for each 100 c c

At this stage of our work, we attempted to find out a little more specifically the nature of the urine in these cases Accordingly, ureteral catheters were inserted, and when these were in place a urethral catheter was passed. The urine was collected for twenty-four hours in two cases, and for one hour in the third, the urine from bladder and kidney being kept separate. The flasks in which the urine was collected were embedded in ice, and the chemical analyses were carried on immediately after the experiment.

Table 1 gives in detail the results of these studies, and shows that whereas the urine as it comes from the kidney is acid and contains the normal ratio of urea nitrogen to ammonia nitrogen, the urine from the bladder, although collected simultaneously, is markedly alkaline, this alkalinity being accounted for by the change of urea into ammonia. Since this is so characteristic of the action of *Salmonella ammoniae*, it seems evident that the production of an alkaline urine within the bladders of these patients was due to *Salmonella ammoniae*. We were therefore inclined to consider this organism of importance in this disease, since the production of an alkaline urine would result in the precipitation of certain insoluble salts.

Table 2 shows an analysis of some of the incrustations removed through the cystoscope. They consist chiefly of calcium carbonate, calcium-ammonium phosphate and magnesium-ammonium phosphate.

Table 3 gives a more complete analysis of twenty-four hour samples of urine of two of these patients and shows the high percentage of ammonia nitrogen, a part of which probably resulted in the action of *Salmonella ammoniae* while the urine was standing awaiting analysis.

In the next experiments we attempted to implant a culture of *Salmonella ammoniae* in the bladder of experimental animals. Five guinea-pigs were catheterized, and 0 5 c.c. of a twenty-four hour broth suspension of this organism was introduced into their bladders. Two of the guinea-pigs were killed and examined three days later, and the remaining three, a week after the injection. The bladders were entirely normal and the organism could not be recovered from the urine. We next attempted to implant *Salmonella ammoniae* in the bladder of animals in which we had induced an artificial chemical cystitis. After some experimentation we determined that the instillation of from 0.5 to 1.0 c.c. of a 0.1 per cent. alcoholic solution of salicylic acid would produce a rather intense cystitis. This varied from small patches of ulcerated areas to general sloughing of the entire mucosa of the bladder. In some instances perforation of the bladder resulted and the animals died from peritonitis. Usually at the end of ten days healing in the bladder had progressed until it was difficult to detect grossly that the bladder had been injured, and by the end of two weeks 98 per cent. of the animals had recovered and new mucosa had practically covered the bladder.

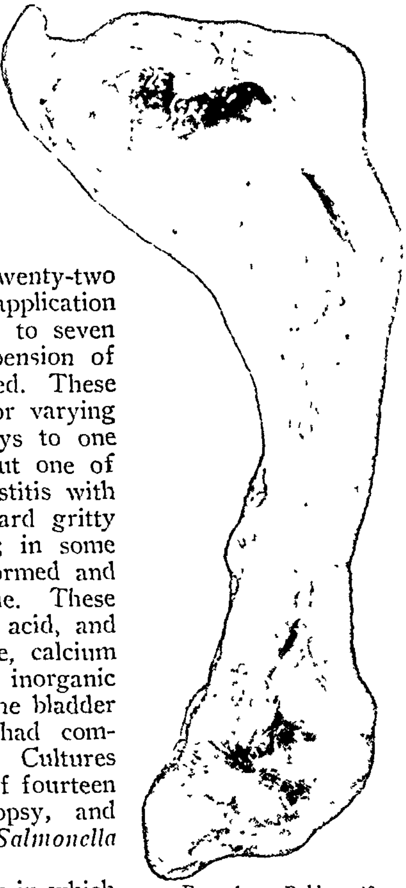

Fig 1. — Rabbit 40: 1 c.c. of a 1:1,000 alcoholic solution of salicylic acid injected into the bladder, followed five days later by the injection of 1 c.c. of a broth suspension of Salmonella ammoniae. Necropsy performed fourteen days later.

The most acute stage of this ulceration and cystitis occurs about two days after the instillation of salicylic acid. Twenty-two guinea-pigs were given this application of salicylic acid, and from two to seven days later 1 c.c. of broth suspension of *Salmonella ammoniae* was injected. These animals were allowed to live for varying periods, ranging from four days to one month. On examination, all but one of the bladders showed intense cystitis with ulceration and deposition of hard gritty material on the affected areas; in some bladders, definite stones had formed and were found floating in the urine. These deposits were soluble in acetic acid, and proved to be calcium phosphate, calcium carbonate and mixtures of other inorganic salts of the alkaline metals. One bladder showed no incrustations and had completely healed after one month. Cultures of the urine from the bladders of fourteen animals were taken at necropsy, and each gave a pure growth of *Salmonella ammoniae*.

A control series of six animals in which we injected *Bacillus coli* instead of *Salmonella ammoniae* gave no incrustations or stone formation, the bladders healing just as if the treatment with salicylic acid had been followed by no other procedure.

Rabbits were also used in similar experiments. After treatment with salicylic acid only, the bladders healed in about the same length of time as in the guinea-pigs. Ten rabbits were injected with *Salmonella ammoniae* after treatment with salicylic acid. Of these, six showed definite incrustations superimposed on the chemically induced ulcerative cystitis (Figs. 1 and 2). The other four did not develop these incrustations. Stones were also developed in the bladders of the rabbits, and one of these was 22 mm. long and 7 mm. wide. It was found obstructing the outlet of the bladder. *Salmonella ammoniae* was isolated from the urine of the six rabbits which had shown incrustations, while it was absent in the other four. It is not certain whether we succeeded in injecting the organisms into these four bladders. Sometimes the catheter passed into the bicornate uterus, and if the bladder was empty it was not possible to determine by aspiration that the catheter was not in the bladder. In all of the animals with incrusted cystitis the urine was very alkaline, the figure of the hydrogen-ion concentration being as high as 9.6 in some instances. A very definite odor of ammonia was detected, but no chemical analyses were made.

These experiments led us to obtain from patients who had been at the clinic previously with the diagnosis of alkaline phosphatic cystitis a specimen of urine for examination. The urine was sent to us in a sterile container; it was taken under as sterile precautions as possible in dealing with patients at a distance. Sixteen patients responded to this request, and of these seven had alkaline urines. In each of these seven *Salmonella ammoniae* was recovered, while in the others, being acid urines, this organism was not obtained. Table 4 is an analysis of these urines, and it shows how consistently they ran.

SUMMARY

From our study and experiments, we conclude that the inorganic salts which are deposited in the mucous membrane, in cases of incrusted cystitis with alkaline urine, are due to a secondary invader, a gram-negative bacillus, which in its growth liberates an enzyme, a urease capable of converting urea into ammonia, thereby causing an alkaline reaction in the urine. The resulting alkalinity precipitates the calcium, magnesium and ammonium salts. We believe that the process may be superimposed on any type of bladder lesion, the initial lesion being produced by some method which we have not investigated, but quite likely often being that formed from a focus of infection, as Rosenow, Meisser and Bumpus have demonstrated. It is interesting to note that Perez' bacillus, which is credited with producing crusts in the nose and a foul odor, also has the ability to convert urea into ammonia.

Since this type of cystitis appears far more commonly in women than in men, and since the organisms of the Salmonella group are common inhabitants of the intestinal tract, we believe it not unlikely that the source of *Salmonella ammoniae* is the gastro-intestinal tract and that the disease is caused by implantation of this organism on some already existing lesion in the bladder. This conclusion is all the more justifiable because so often the history dates, in the case of women, from childbirth or from catheterization. Indeed, we have succeeded in isolating this organism once from a culture of a stool.

Incrusted cystitis with alkaline urine is caused by the implantation of *Salmonella ammoniae* in a bladder which is already the seat of some form of inflammatory or tumorous lesion. If the organism gains a foothold, it rapidly changes urea into ammonia, with resulting precipitation of alkaline inorganic salts. This condition can be reproduced experimentally in laboratory animals.

ABSTRACT OF DISCUSSION

Dr. George Gilbert Smith, Boston: I have met a number of these cases. They are very obstinate and very confusing. The diagnosis is not easy to make. I have seen some cases in which the lesion so closely resembled carcinoma that it was almost impossible to decide whether the case was one of malignancy or of incrusted cystitis. I think Dr. Hager's work will be very valuable in enabling us to *do something in these cases in the future, and* we shall be able to apply the therapeutic test more quickly, so that we can come to a decision as to the diagnosis.

Dr. A. L. Chute, Boston: Dr. Hager has put on a firm basis those conditions that we used to speak of as infections with urea-splitting organisms. I wonder whether those cases following childbirth, in which there is a sloughing of the whole vesical mucosa, which is passed later as a cast, if the patient survives, do not belong to that type of infection. These patients always present an intense alkaline infection of their bladders which, in combination with the trauma that so often accompanies confinement and the retention that follows it, leads to a sloughing of the whole mucosa and its separation from the muscular coats. I saw a patient of this sort, some years ago; it was some weeks after she had passed the slough, and her bladder was nothing but a hollow scar. The condition was the same some years later when I last saw her again. I wonder whether this infection may not be with the same organism Dr. Hager describes.

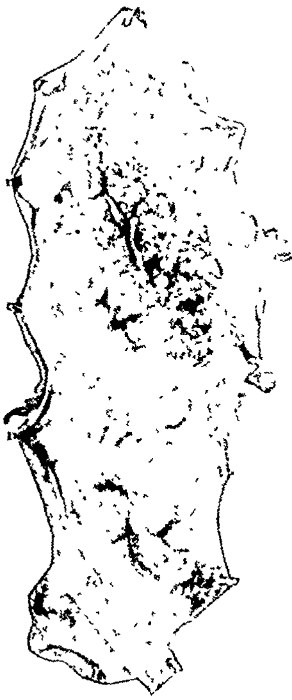

Fig. 2.—Rabbit 8: 1 c.c. of a 1: 1,000 alcoholic solution of *salicylic acid injected into* the bladder, followed five days later by the injection of 1 c.c. of a broth suspension of Salmonella ammoniae. Necropsy performed eighteen days later.

Dr. B. A. Thomas, Philadelphia: I have been accustomed to think of two types of incrusted cystitis: the usual type, in which the incrustations surmount the surface of tumors and ulcers, and another type, in which the whole interior of the bladder is incrusted, like an egg shell. To my mind this is the most classic type of incrusted bladder one can imagine. It occurred in one case under unusual circumstances, particularly so far as the subject of etiology is concerned. The patient was a boy, aged 13, and weighed 69 pounds (31 kg.). He was sent to me for stone in the bladder, with request for immediate operation. The bladder was opened, and a typical egg shell lining was found. The incrustation could not be pulled off without pulling off the mucous membrane. The whole interior of the bladder was incrusted. The urine was clear, alkaline in reaction most of the time, occasionally neutral, and occasionally acid. Culture showed *Bacillus proteus-vulgaris.* I was much interested in the case from the etiologic standpoint, because of the fact that the boy's father had died of tuberculosis a few years before, and I was anxious to see whether there was any relationship. The crusts were made up of a salt of calcium. I had the urine examined repeatedly for tubercle bacilli, but the examinations were negative and we could not clinch that suspected causation at that time. In this connection I think the great value of injections into the bladder of cultures of Bulgarian bacilli in the treatment of these cases should be remembered. At the time of operation it was impossible to remove all the crusts, but within two weeks after the injection of cultures of Bulgarian bacilli, followed by a single irrigation of 1:20,000 mercuric chlorid, the bladder was entirely cleared of the crusts, and remained clear for eight years, when the patient died. He had grown to manhood and had gained 64 pounds (29 kg.) in eight years. A few months before death his physician found tenderness in the lumbar region and discovered a psoas abscess, from which they isolated the tubercle bacillus by smear and guinea-pig inoculations.

Dr. Robert V. Day, Los Angeles: One possible mistake is to say that incrusted cystitis is always due to the same organism. We should say it is due to an enzyme; namely, urease, produced by bacterial growth or bacteriolysis. Doubtless these ureases produced by different organisms are not all exactly alike any more than trypsin, pepsin or papain are all exactly alike. Yet all split up proteins. Likewise ptyalin, amylopsin and taka-diastase all have similar actions, and doubtless the presence of similar enzymes could be found widely spread throughout the vegetable kingdom. Rosenow's work has proved that certain strains of streptococci produce a urease, and we find this frequently clinically. In other words, any organism that produces an enzyme resulting in ammoniacal urine is capable under certain conditions of producing an incrusted cystitis. Aside from relief of stasis and obstruction by drainage and otherwise, we have only one specific, namely, one of the silver salts, which act by fixing the ammonia in a double salt with the silver as fast as it is formed. Other metallic salts and oxids, to a certain extent, have the same tendency. For example, ammoniated mercury is formed very readily, and even manganese oxid to some extent fixes ammonia; but, in actual practice, only silver salts are efficient. I could never procure any results from the method suggested by Caulk of introducing the Bulgarian bacillus in lactose solution. The obvious reason was that the patient's bladder was so irritable that the solution could seldom be retained more than one-half hour. Of course, the formation of lactic acid is slow, and to obtain any appreciable acidity, its presence for many hours would be necessary. Moreover, ammoniacal urine is sometimes formed in the kidney pelvis.

Dr. B. H. Hager, Madison, Wis.: I have not seen any acute fulminating forms of incrusted cystitis. The cases that I have been dealing with have all been chronic, but it is quite likely that the acute forms do occur, for we know how rapidly the incrustations reform after they have been removed by curettement. Dr. Thomas' case was very interesting, but I think we must regard the incrustations in his case as different from those occurring with alkaline incrusted cystitis. Here we have an extremely irritable bladder, which bleeds easily with a high ammonia concentration of the bladder urine and incrustations which are chiefly phosphates. I agree with Dr. Day. We must consider that there are other forms of incrustations occurring in the bladder which are apparently quite different from those of alkaline incrusted cystitis. As we have been able to isolate this specific type of bacillus in three cases under intensive study, and seven at random, I believe that it is a very important organism in the production of this condition.

MANIPULATIVE (CHIROPRACTIC) DISLOCATIONS OF THE ATLAS *

EDWARD S. BLAINE, M.D.
Associate Professor in Roentgenology, Northwestern University Medical School; Consulting Roentgenologist, Wesley Memorial Hospital; Attending Roentgenologist, Garfield Park Hospital
CHICAGO

Unintelligent manipulations of the structures of the region of the upper cervical spine may result in undesired sequelae, such as have occurred in the three cases here presented. A forward dislocation of the atlas on the axis has been a consequence in each of the cases, one with fracture of the odontoid process; all of the cases were apparently the result of chiropractic treatments. One of them resulted in death, the second in constant dull pain and limitation of motion, with a material loss in efficiency of the patient, while the third appears to be progressing satisfactorily in spite of the dislocation of the atlanto-axial joint, although there is a marked reduction in the movements of the head.

ANATOMIC CONSIDERATIONS

The articulation of the atlas with the axis is a joint of complicated nature, as it is made up of four distinct parts or joints. These are: (1) a pivot articulation between the odontoid process of the axis and the posterior surface of the anterior arch of the atlas, called the atlanto-odontoid joint of Cruveilhier; (2) a sliding joint between the posterior surface of the odontoid process and the interior surface of the transverse ligament, called the syndesmo-odontoid joint; and (3 and 4) two gliding joints between the right and left articular processes. The two bones are connected by ligaments; namely, the anterior and posterior atlanto-axial, the right and left capsular and the ligamentum transversum atlantis. Four synovial membranes are located between the two bones, two in the joints formed by the odontoid process and two inside the capsular ligaments. All these structures provide facilities for rotation of the atlas on the axis, and, with it, the head. Lying posterior to the odontoid process and the transverse ligament, and anterior to the posterior arch of the atlas and the laminae of the axis, is the spinal cord with its meningeal coverings. On the integrity of the ligaments just described depends the maintenance of the proper position of these two bones in the formation of the neural canal, and it will be readily seen that any loss of these ligamentous supports, as, for example, a rupture, will result in a dislocation and consequent compression of the spinal cord. It is also evident that the bony processes concerned with this particular joint do not provide much material support against violence and, as the ligaments themselves are of exceedingly small bulk and length, they cannot stretch or lengthen sufficiently to overcome much tension. Therefore, they will of necessity yield by rupture only, thus permitting the atlas to slide forward on the axis, with a resulting cord compression.

The articulation of the atlas with the base of the skull (the articulatio atlanto-occipitalis) is likewise a relatively weak joint as to bony relations, but its ligamentous support is very much greater than is the case in the atlanto-axial joint. The flattened articular surfaces themselves offer very little resistance to forward or backward forces, but the occipito-axial and the three odontoid (or check) ligaments, together with the support offered by the ligamentum nuchae, provide an ample resistance to disarticulating stresses. The anatomist Gray tells us that "dislocation of the occiput from the atlas has only been recorded in one or two cases; but dislocation of the atlas from the axis, with rupture of the transverse ligament, is much more common; it is the mode in which death is produced in many cases of execution by hanging. Occipito-atloid dislocation is certainly fatal. Recoveries are on record after atlo-axoid dislocation. Immediate death occurs if the transverse ligament is torn or the odontoid process is broken." (An exception to the last statement can be made based on the first case of this series, in which death occurred many months after the injury.) The mechanical details of the joints under consideration are such that a backward displacement of the atlas on the axis is hardly possible. It might occur as a result of an extreme violence producing hyperextension of the head, such as a severe lifting force under the chin, causing an overextension of the head and rupture of the anterior ligaments whereby the anterior arch of the atlas will slip over the top of the odontoid process, if the latter is not broken. A transverse fracture of the odontoid process at its base will permit either a forward or backward dislocation of the atlas even if the transverse ligament of the atlas remains intact.

In all the instances detailed, the important point is the resulting compression of the spinal cord and its coverings and the efferent and afferent nerve structures of the region, as well as the associated blood vessels. In a forward dislocation of the atlas on the axis, there may also occur an interference with the free passage of blood through the verterbral arteries as they pass through the foramena in the transverse processes of the atlas. Interference with the venous flow will also occur in this injury, and the amount of obstruction due to pressure of the bony parts will depend largely on the degree of dislocation, which may be so slight as to result in no disability, as is evident in one of the cases included in this presentation (Case 3).

ROENTGEN-RAY ANALYSIS

The demonstration of this lesion is best accomplished by projections of the craniocervical region, with the patient in the lateral recumbent posture. The binocular shadow visualization of the bones and joints of the region is preferable to the two dimension shadows of the single film. The patient's head should be so placed that its sagittal plane is parallel to the plane of the roentgen-ray film, thus bringing it in direct alinement with the long axis of the spine, the weight of the body resting on the lateral aspect of the nether shoulder. This can be accomplished by use of a hard pillow or block of suitable thickness on which the film casette is laid. An anteroposterior projection is also of value in the determination of this lesion, particularly for demonstration of lateral displacement of the involved bones. This view is not easy to produce, owing to the fact that on direct anteroposterior roentgen-ray projection, the atlas and part of the axis are covered by the shadows of the occipital bone or those of the body of the inferior maxilla, or both. The patient is placed in a supine posture; the mouth is opened to the maximum extent and is kept so by means of a cork or other roentgen-ray transparent material placed between the teeth. The central axis of the roentgen-ray beam is directed to pass through the center of the mouth, to emerge just below the lowest point of the occiput. The

---

* Read before the meeting on radiology in the Section on Miscellaneous Topics at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

resulting shadows will show the atlas, the odontoid process and the body of the axis free from superimposing shadows and will permit a reading of certainty, as to the minute relationship of the osseous structures in the region under study.

The lateral view in the normal presents the shadow characteristic shown in Figure 1 *A*, in which particular note should be made of the position of the shadow of the anterior arch of the atlas in relation to the shadow of the odontoid process, these being in close apposition with each other. The foramen magnum of the skull fits exactly over the space behind the shadow of the odontoid process and in front of the shadow of the posterior arch of the atlas. All the bodies of the cervical vertebrae are found to be in line with one another, when normal, being so arranged that a convexity forward makes an even curve, which is a continuous one. A line drawn on the roentgen-ray film starting from the anterior edge of the atlas will connect all the anterior margins of the cervical vertebrae in an uninterrupted line, as advocated by A. W. George, while a similar line, if drawn on the posterior surface of the odontoid process downward, will also present an uninterrupted curved line connecting all the vertebral bodies. This line indicates the anterior margin of the spinal cord. This is illustrated in diagram form in Figure 1 *B*. In the normal, the shadow of the angle of the jaw always lies close to the anterior edge of the cervical bodies, when the head is held in the normal position. The roentgen-ray shadows of the normal, resulting from the technic here described for an anteroposterior projection through the open mouth, will show an even spacing of the two lateral masses of the atlas with the odontoid process between. In dislocations of the upper cervical vertebrae, these relations are disturbed according to the degree of lateral luxation present. Usually the shadow of the angle of the jaw will be found much farther away from the cervical vertebrae than in the normal, a wide space being apparent, which is often the first clue to the forward dislocation. The degree of compression of the structures in the neural canal can be estimated on this view by inking in the limits of the spinal cord on the roentgen-ray film, as previously suggested.

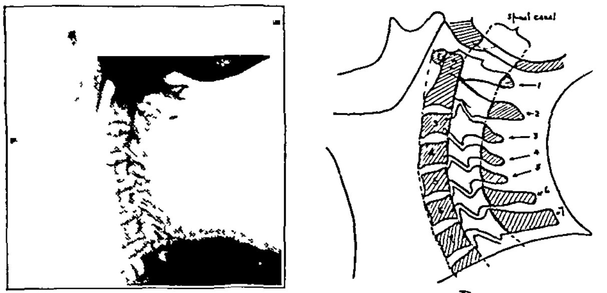

Fig 1.—*A*, lateral projection of normal occipito atlanto-axial joints and cervical spine; the relation of the atlas to the odontoid process of the axis and the formation of the neural canal may be noted. *B*, diagram of roentgen-ray shadow outlines.

REPORT OF CASES

Case 1.—*History*.—F. M., a man, aged 18, a day laborer, brought to the Cook County Hospital, Dec. 28, 1917, complained of pain in the heart, pain in the neck, inability to move his head, and weakness and numbness of the hands. In the summer of 1917, he had a good deal of pain in his back and in the chest, for which he consulted a chiropractor for relief. He was given several chiropractic treatments. The treatment, as described by the patient, consisted of punching and rubbing the back up to the base of the skull while the patient was lying prone on a table, followed by a manipulation of the head, the patient being in supine posture with the head drawn over one end of the table. In manipulating the head, the chiropractor held it with both hands and forced it violently in all directions over the edge of the table. During the course of one of these treatments he felt his neck "snap," and experienced severe pain. He called the attention of the chiropractor to this and was informed that that was part of the treatment and that the snap proved that there was "a faulty position of the seventh [sic] vertebra, which," said the chiropractor, "I now have put back in proper place and the pressure on the nerves, which was making you sick, is now taken off and you'll get well" (patient's statement). However, the patient suffered so much pain that after several more visits he refused to go on with the treatments. He found that, although he had full motion of the head previous to these treatments, he now could not move it without pain, and there was limited motion. The pain got so bad that he could not work and had to spend much of his time in bed. Being without funds, he went the rounds of dispensaries and clinics of Chicago seeking help and finally was taken to the County Hospital.

The patient reported that he had measles and scarlet fever, when a child, and had had attacks of "rheumatism." Four years before, his tonsils and adenoids were removed, and three years before he was told that he had a "heart lesion."

Inquiry was made in an attempt to elicit any previous injuries to the head or neck that would be in accord with the roentgen-ray findings, but no such history was obtained, the patient insisting that his head and neck were perfectly normal prior to the spine treatments.

Physical Examination.—The patient was fairly well nourished; he lay quietly in bed without moving his head. This was held rigidly in extension, and there was a prominence in the neck below the occiput which was very tender to pressure, resulting in a feeling "like an electric shock." He was found to have definite signs of a cardiac lesion, the details of which are not pertinent in this presentation and, therefore, are omitted.

Roentgen-Ray Analysis.—A roentgen-ray examination of the cervical spine and adjacent regions revealed a forward dislocation of the atlas on the axis, with a fracture of the odontoid process, the fragment being carried forward with the atlas (Fig. 2 *A*). In all probability the transverse ligament of the atlas remained intact. The degree of dislocation was extreme, and it was difficult to understand why a greater degree of interference with the spinal cord has not resulted. A roentgen-ray study of the thorax revealed an abnormal median shadow, the configuration of which was similar to that usually found in pericarditis with effusion, in that its outline was distinctly bilateral and of "water bottle" or "gourd" shape, with a relatively normal sized aorta. (This configuration is also found in some cases of right auricular dilatations, as in mitral valve lesions.) Both cardiophrenic angles were acute and, therefore, clear. Both pulmonary fields presented normal roentgen-

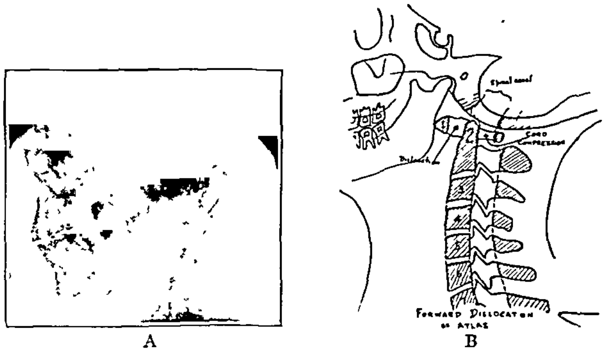

Fig 2 (Case 1).—*A*, roentgen-ray shadow of original examination, showing the forward dislocation of the atlas on the axis; *B*, tracing diagram.

ray transparencies with clear pleural margins; the costophrenic angles were normal.

It is obvious that this patient, prior to having had his spine "adjusted," was suffering from a heart lesion, which was found by an internist to be "mitral stenosis and regurgitation." He complained of no trouble in his neck. The chiropractor, therefore, presumably assumed that the sharp stabbing pain in this man's chest, which he complained of and sought relief from, was caused by a "misplaced seventh cervical vertebra impinging on a nerve" and proceeded to relieve the pressure my manipulating the spine. In the course of his "putting the displaced vertebra back in place" he, by violent force, actually dislocated the atlas forward on the axis and fractured the odontoid process, as shown by the roentgen-ray shadows (Fig. 2 *B*) and the subsequent course of the case.

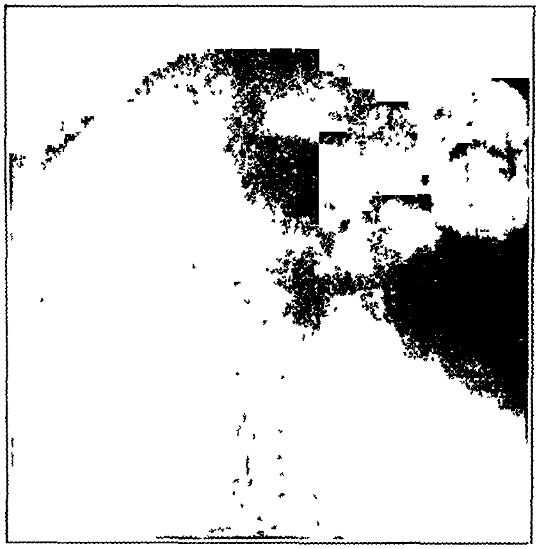

Fig 3 (Case 2) —Forward dislocation of the atlas on the axis

Subsequent Course.—This patient was treated in the orthopedic section by Dr. Charles A. Parker, who put on the patient a plaster collar and suspended his head with a jury-mast, thus relieving the pressure on the spinal cord. He improved very slowly and was made an ambulatory case. Unfortunately, his friends and neighbors interfered because they did not like the appearance of the appliance and they cut off the collar. It was not long after this that he returned to the hospital (October, 1918) in a worse condition than ever, having become bedfast because of a slowly increasing paralysis of the limbs. Day by day the paralysis progressed, and he died in March, 1919, nearly two years after the injury The necropsy report confirmed the roentgen-ray findings and included such items as the following: obliterative chronic fibrous pericarditis, chronic fibrous myocarditis, old traumatic fracture of the second cervical vertebra and an old forward dislocation of the atlas, with pressure on meninges of the upper end of the spinal cord, edema and spinal pachymeningitis and local necrosis of the cord.

Case 2.—*History.*—M. G., a man, aged 29, referred to us by Dr. M. S. Coffler, May 17, 1922, had complained of a "pressing" pain under the sternum, heart pounding and swelling of the ankles. He had been under the care of a chiropractor, who gave him several treatments for a "misplaced sixth (?) cervical vertebra." During the last treatment he felt a sudden sharp pain in his neck and told the chiropractor that it hurt too much to continue. He found that his neck was not only painful but was stiff, and so did not return for more "replacements." Seeking relief, he applied to Dr. Coffler, who found some limitation of motion of the head and a prominence below the occiput, which was painful to pressure; there were signs of a heart lesion. He was referred to me for roentgen-ray study of the neck. The man reported that at no time did he have an injury to the head or neck that would account for the subsequent roentgen-ray findings.

Roentgen-Ray Analysis.—The shadows on lateral projection revealed a forward dislocation of the atlas, indicating a probable 30 per cent. reduction in the neural space between the odontoid process and the posterior arch of the atlas. All other bones and joints of the region were normal. A compression of the cord and its coverings was indicated by the roentgen-ray evidence, although there were no other definite signs of cord pressure.

On being informed of the roentgen-ray findings, the patient arose from his chair and astonished the physician by stating: "Then the chiropractor was right when he told me that I have a displaced vertebra in my neck. He's the only one who diagnosed it correctly, and he is giving me a square deal, so I'm going back to him," and he walked out. Several attempts to reach this man have not been successful, so the subsequent developments cannot be reported at this time. From the roentgen-ray evidence, together with the symptoms in the case, it is obvious that this man received a dislocation of the atlas at the hands of the chiropractor.

Speculation as to the future course of this man's condition suggests that sooner or later there will develop signs of a paralysis of greater or less degree, as there is very little probability of a successful reduction of the dislocated atlas. Whether the tissues of the cord can tolerate indefinitely the pressure caused by such a lesion is questionable.

Case 3.—*History.*—F. G, a boy, aged 6, was referred to me by Dr. G. H. Miller, May 31, 1923, to determine the cause of stiffness in the neck and limitation of motion. There was a history of having fallen off his velocipede and hurting the dorso lumbar spine. A few days later the boy still complained of pain in his chest and back, but not of his neck. He was taken to an uncle, who was a chiropractor, and a "spinal adjustment" in the cervical region was made, after which the stiffness in the neck developed. The boy was then seen to hold his head at an angle to the spine. As the condition did not improve, the mother took him to Dr. Miller, who referred him for roentgen-ray investigation of the cervical spine and base of the skull.

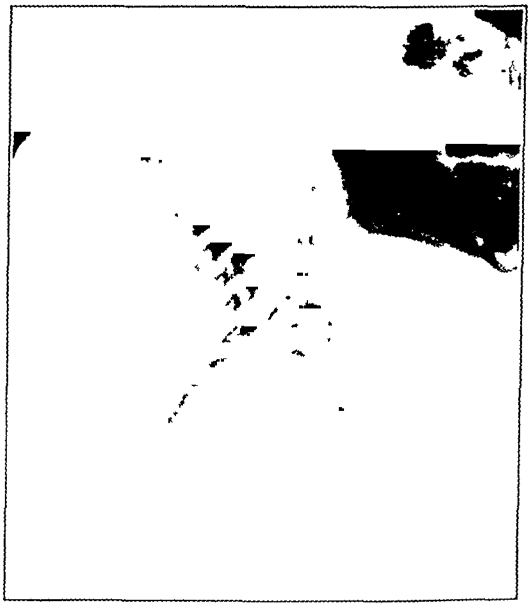

Fig 4 (Case 3).—Forward dislocation of the atlas on the axis

Roentgen-Ray Analysis.—A forward dislocation of the atlas on the axis is evidenced by the shadows of the lateral view (Fig. 4). The spinal cord space is reduced almost one half the normal size, which is conclusive evidence of some impingement of the cord. The remaining vertebrae are normal from the roentgen-ray point of view.

As the boy showed no signs of cord pressure, nothing was done in the way of reduction of the dislocation. His stiffness moderated, and the limitation of head rotation decreased. I made a reexamination of this boy, March 11, 1925, and his dislocation was still as was found on the first observation. He is of a bright and cheerful disposition and does not mind in the least his dislocation. Thus it seems that nature may overcome unnatural conditions such as this one, probably by some manner of accommodation to the new situation, with no apparent interference with the general well being of the individual.

COMMENT

Evidence is presented of dislocations apparently produced by the chiropractors through their so-called spinal adjustments or replacements to relieve supposed pressure on a nerve. On accidentally producing the dislocation described in one of the cases, the claim was made that the "snap" felt by the patient indicated the slipping back of the dislocated vertebra! To treat a heart lesion resulting from acute exanthems, inflammatory joint disease, etc., by replacing the nonexisting dislocated vertebra, claimed to cause the abnormal condition, is preposterous. So long as the laws governing the health of the individual permit such methods as the chiropractic system to be practiced and thus fail to protect an unsuspecting public, just so long will occurrences such as are detailed in this presentation take place. Another case in point that received considerable newspaper notice in the Chicago papers in February, 1923, may be cited. A girl, aged 11, with a tuberculous caries of an upper cervical vertebra was taken to a chiropractic school by her parents; there the students gave her "spinal adjustments" that resulted in a cord injury due to collapse of the diseased bone. Her death followed immediately after this unintelligent, nonscientific and essentially criminal manipulation.

As this is being written, an additional case comes to my notice. It concerns a child, aged 5, who had bronchial pneumonia. The chiropractor to whom she was taken placed the child face downward on two tables separated about eight inches and began manipulating the child's spine; when he came to the portion unsupported by the two tables (he is said to have used great force), the child cried out with pain and died. At the coroner's inquest, it was found that death resulted from the chiropractor's treatment.

ABSTRACT OF DISCUSSION

DR. I. S. TROSTLER, Chicago: I want to report two similar cases to the first three that Dr. Blaine mentioned; one in a highly intelligent woman of 40, the wife of the president of an insurance company, who ought to know better than to send his wife to a chiropractor, but apparently did not. She had a fracture dislocation of the first and second cervical vertebrae with marked deformity but very little paralysis. She is getting along comfortably now after having worn a jury mast for three or four years. I had another case in a man, about 55, an insurance agent and a very intelligent man, who had a student chiropractor attempt to relieve his headache while sitting in a barber chair. He was put in a jury mast, and is quite comfortable. This case was directly the means of defeating the chiropractic bill in Illinois four years ago.

DR. B. F. BUZBY, Philadelphia: I saw a patient last fall with the following history: The child had had her tonsils removed in September. Three days afterward she went home holding her head to one side and complaining of a good deal of pain in her neck. She went back to the laryngologist, who gave her a liniment to rub on her neck. That did not seem to satisfy her parents, so they went to a chiropractor, who gave her treatments for about two months. I saw her four months following the removal of her tonsils. Roentgenograms showed a forward dislocation of the atlas with no damage to the odontoid process. She had no symptoms of paralysis. She held her head in a position of right torticollis and was exquisitely tender at the base of the occiput on the right. I attempted under deep ether narcosis to relieve this luxation, but without any benefit. Two days later, I put on a plaster-of-Paris collar with the torticollis overcorrected and renewed it after three months. I substituted for the second collar a Thomas leather collar reinforced with steel after a second period of two months. The child now holds her head erect without any pain or tenderness, and has practically full motion. *However, the dislocation is still present,* and she wears the Thomas support most of the time.

DR. EDWARD S. BLAINE, Chicago: Since writing this paper I have learned of at least four other cases of similar nature. These give the same story—chiropractic treatment or adjustment of supposed dislocated vertebrae, sudden pain during rolling of the neck over the edge of a table, and roentgen-ray proof that what has actually occurred is a dislocation produced by improper manipulation.

HYPODERMIC DIGITALIS PREPARATIONS *

HAROLD E. B. PARDEE, M.D.
NEW YORK

The intravenous administration of digitalis preparations has been recommended because of certain advantages claimed for this method of giving the drug. It has been considered that:

1. The digitalis effects would be produced more quickly because the time needed for absorption from the gastro-intestinal tract would be eliminated.
2. The digitalis effects would be more certain, because of avoiding the variable absorption from the gastro-intestinal tract.
3. Because of these things, a smaller dose would be needed to obtain effects.

In the course of using these products in the treatment of patients with cardiac decompensation, it became plain to me that the manufacturers' claims as to potency, and particularly their recommendations as to dosage, were far from correct. It has never been properly demonstrated that any of these supposed advantages of the intravenous use of digitalis are actual facts, and so it seemed advisable to investigate the activity of these preparations. It seemed especially important because they are commonly and widely used in the most severe cases and in emergencies, when the difference between a sufficient and an insufficient dose might be vital to the patient.

To test the preparations by animal experiment might give an indication of the relative strength of their activity, but we do not know exactly how to transfer the effect on the animal to a human intravenous dosage. Moreover, the promptness of action on the human heart after injection can be ascertained only by experiments on the human being, so it seemed best to do the whole work with the human heart, using the change in the T wave of the electrocardiogram as an indicator of digitalis activity and also the slowing of the rate of a previously untreated auricular fibrillation. These two are the earliest digitalis effects to appear after the administration of a sufficient dose of the drug, and the use of the T wave change as a method of testing various tinctures of digitalis has been recently reported on.[1]

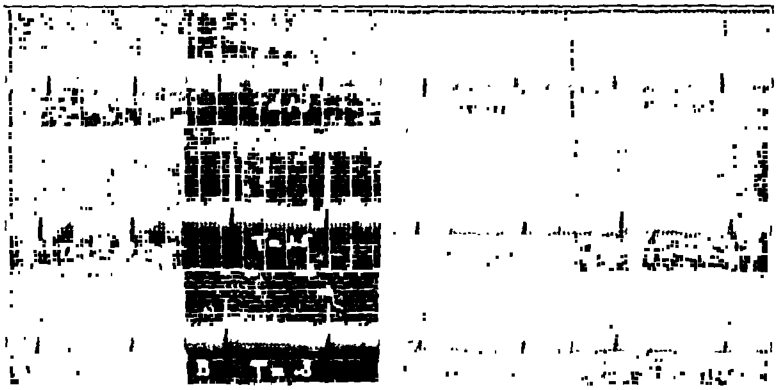
* Read before the Section on Practice of Medicine at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

[1] Pardee, H. E. B.: The Standardization of Digitalis by Its Action on the Human Heart, J. A. M. A. **81**: 186 (July 21) 1923.

Under the influence of the drug, the amplitude of the T wave diminishes in one or more leads of the electrocardiogram, as seen in the accompanying illustration. As more digitalis is taken or as the effect of a large dose increases hour by hour, the T wave may come to be turned downward in one or more leads. I have used as a measure of the potency of a digitalis preparation the smallest dose that will diminish the amplitude of the T wave, calling this the T wave unit. I have expressed this dose in fractions of a minim per pound of the patient's weight, because Eggleston's[2] demonstration of the relation of body weight to digitalis dosage has been well proved by experience. It was found that the clinical activity of the different tinctures tested was inversely proportional to the size of the dose that would affect the T wave. Less of the more potent tinctures would be needed than of the weaker ones.[1]

At present I wish to report on the testing of digifolin Ciba, the digitan ampules of Merck, digalen (Cloetta) and the Burroughs Wellcome tablets of amorphous digitalin.

Table 1 shows the results with these preparations, the results *with the samples of the tincture previously tested being included for comparison.* The minimal effective dose—the T wave unit—for different tinctures, by mouth, varied from 0.20 minim per pound for the strongest to 0.30 minim per pound for the weakest, with an average of 0.25 minim. Intravenously the T wave unit for digifolin was 0.30 minim per pound; for digitan solution it was 0.25 minim per pound; for digalen it was 0.3 minim per pound, and for the Burroughs Wellcome amorphous digitalin it was 1/100 grain per 70 pounds.



Record of typical experiment: *A*, control record of a patient weighing 115 pounds, with duodenal ulcer; Leads 1, 2 and 3 from above downward. *B*, record eight hours after 105 minims (7 c.c.) of digitan solution intravenously. *C*, record three days later after an additional 150 minims of tincture of digitalis by mouth. *D*, record taken six days after *A*, the patient having had 300 minims of tincture of digitalis by mouth. The figures given for the height of T are the averages of several estimations for each lead. One may note the slight diminution in the height of T in record *B*, the inversion of T in Lead 3 of record *C*, with sinking of the S-T interval and in record *D*, the frank inversion of T in Leads 2 and 3.

Table 1.—*Results of Tests**

Different samples of tincture of digitalis by mouth.	0.20 to 0.30 minim.
Digifolin intravenously	0.30 minim
Digitan solution intravenously	0.25 minim
Digalen intravenously	0.30 minim
Tablets of digitalin, B. W. & Co., intravenously	1/100 grain per 70 lbs.

* Amount to produce slightest effect on T wave of electrocardiogram. In this table and in Table 2, potency is expressed in minims per pound of patient's weight.

The minimal effective dose of each of these preparations was found to be much larger than suggested by the manufacturer for the therapeutic dose, so much larger that if the printed suggestions as to dosage were followed the patient would certainly fail to receive an effective dose, and so to benefit from the medication.

Table 2.—*Results Obtained by Clarke*

Different samples tincture of digitalis by mouth (Eggleston)	1.7 to 3.8 minims average 2.2 minims
Digifolin by mouth (Clarke)	1.4 to 4.4 minims average 3.56 minims
Digifolin intramuscularly (Clarke)	1.8 to 2.8 minims average 3.0 minims
Digifolin intravenously (Clarke)	2.0 to 2.7 minims average 2.36 minims

In the case of tincture of digitalis by mouth it has been found that the full therapeutic dose was from eight to ten times the minimal effective dose as determined by the T wave change. I do not believe it is ever proper to give the full calculated therapeutic dose of a digitalis preparation at one time, because of the likelihood of producing a considerable degree of poisoning in some susceptible patients. One half of this amount by mouth, four or five times the minimal effective dose, is safe, however, and will produce definite digitalis effects.

From this and from the facts of Table 1, it appears that the initial dose of these intravenous preparations for a patient who has had no digitalis previously should be four times the minimal effective dose as here determined. This works out to about 1 minim per pound of the liquid preparations, slightly more for the digifolin and digalen than for digitan, and 1/100 grain of the digitalin per 70 pounds, which would be eight of the 1/100 grain tablets for a patient of 150 pounds.

Digifolin has been investigated by Clarke of Ann Arbor by a different method. Table 2 summarizes his results. He gave 5 c.c. doses every twelve hours by mouth, intramuscularly, or intravenously, *until a marked* therapeutic or minor toxic effect appeared. He found that the total amount of the drug to produce these effects by intravenous administration varied from 2 minims per pound to 2.7 minims, averaging 2.36 minims. This is seen to be about eight times the minimal effective dose I have found for intravenous administration by the T wave method. By intramuscular injection, Clarke found that the average full therapeutic dose of digifolin was 3 minims per pound, slightly more than needed intravenously; while by mouth it was 3.56 minims per pound, which is twelve times the amount producing the minimal T wave change when given intravenously.

These figures for total dosage of digifolin are in agreement with those I have obtained for partial dosage of this preparation, so it seems still more certain that this one at least, if not all of these intravenous preparations, must be given in much larger amounts than has been the custom when it is desired to obtain prompt therapeutic effects. Doses of the size here recommended, from 90 to 160 minims (6 to 11 c.c.) of the liquid preparations, have been given *to previously untreated patients* in the course of these experiments without unpleasant effects.

---

[2] Eggleston, Cary: Digitalis Dosage, Arch. Int. Med. **16**: 1 (July) 1915.

It is always necessary, when suggesting large doses of any digitalis preparation, to emphasize the need of making certain that the patient has not been receiving digitalis in any form during the previous two weeks. The drug is sometimes so slowly eliminated that a patient may retain an unexpectedly large proportion of a previous dose, and the additional effect of the later dose may cause unpleasant toxic symptoms. The doses here recommended are only for patients who have not had any digitalis within the previous two weeks. For patients who are under the influence of digtalis at the time, the dose should be reduced to one quarter or one half of that recommended, to from 30 to 60 minims, depending on our estimate of the degree of the patient's previous digitalis saturation. This reduced dose should be repeated at six hour intervals if needed, and perhaps one should reduce it further each time, making certain before each dose that no signs of a digitalis effect have made their appearance.

The second claim for intravenous medication, its greater promptness of action, I have not yet fully investigated, but the facts so far are as follows:

1. With the minimal effective dose or a dose but slightly larger, the T wave and the rate with untreated auricular fibrillation are not affected until from five to ten hours after intravenous administration.

2. After doses of the tincture by mouth equal to 1 minim per pound or more, the T wave and the rate with untreated auricular fibrillation may be affected as early as the second hour, and the effect reaches its maximum about the sixth or seventh hour.[1]

3. After rectal administration of digitalis in doses larger than 1 minim per pound [3] (proportion not stated by the investigator) the T wave was affected on the average in two and one-half hours.

Further observations are needed to settle this question. The facts just noted make it seem likely that the promptness of action is more dependent on a mass effect of digitalis—the large size of the dose—than on the greater promptness with which the drug comes in contact with the heart muscle after intravenous administration.

We must not rely then on minimal intravenous doses when in need of a prompt effect, though it is possible that somewhat smaller doses are needed by vein than by mouth. This matter is being further investigated.

160 East Sixty-Fourth Street.

Bacteriology of "Colds."—Little is definitely known about the bacteria causing the common colds Undoubtedly, the term "cold" is used for a variety of affections etiologically distinct. Pneumococci and streptococci, as well as the influenza bacillus and even the tubercle bacillus, may be responsible for the train of symptoms to which the name "cold" is popularly applied Colds are apparently largely spread by close personal contact and by the infectious droplets discharged in sneezing and coughing Whether certain micro-organisms are more commonly concerned in the production of colds than others is quite uncertain. Some specific organisms have been implicated An anaerobic organism has been found in some series of cases of acute and chronic rhinitis and has given rise to rhinitis when introduced experimentally into the nose of a healthy person. Specific antibodies are present in the serums of persons infected experimentally and of those suffering from a natural infection with this bacillus.—Jordan, E. O.: General Bacteriology, Ed 8, Philadelphia, W. B Saunders Company, 1924

NONSYPHILITIC AORTITIS *

LESTER NEUMAN, M.D.

WASHINGTON, D. C.

Aortitis, an inflammatory condition of the aorta, has been recognized as a clinical and pathologic entity for many years. From the purely pathologic standpoint, it has been described so frequently and in such detail that the picture seems complete. This refers especially to the literature of fifteen or twenty years ago, and to a few recent reports. A striking commentary is the comparative scarcity of references in the American and English literature. Very early references are those of Aretaeus [1] and Morgagni,[2] and later of Scarpa.[3] The more modern work dates from the report of Portal,[4] in 1803, and Hodgson,[5] in 1815. Portal was the first to describe acute aortitis clinically; and, while there has remained no doubt that aortitis occurs as a pathologic fact, clinicians have been inclined to avoid positive statements, especially regarding early diagnosis. In fact, the feasibility of making an early diagnosis of aortitis remains a real question in the minds of some of our best medical men. This refers particularly to the nonsyphilitic variety. Aortitis of syphilitic etiology is well established, and one that is confirmed in daily practice. That other infections may play a similar rôle is equally evident, but this some deny and many others seem to forget.

That both acute and chronic aortitis not due to syphilis are not rare disease conditions is quite evident from only a partial review of the literature. While it is true that many of these reports are entirely clinical, a sufficient number include complete pathologic and bacteriologic studies. Excellent general discussions have been contributed by Satterthwaite,[6] Hirschfelder,[7] McCrae,[8] Pitt,[9] Brown,[10] Spiro [11] and others.

Evidence in support of the protean etiology of aortitis is to be found in the following abbreviated summary of this angle of the disease: Aortitis due to tuberculosis has been reported by Flexner [12] and von Zalka;[13] influenza, by Fiessinger,[14] Marmorstein,[15] Allbutt [16] and Oetiker;[17] typhoid fever, by Thayer,[18] Landouzy and Siredey,[19] and Marchiafava and Nazari;[20] streptococcus infection, by McCutcheon[21] and Koritschoner;[22] pneumococcus infection, by D'Antona;[23] gout, by Mougeot,[24] and rheumatic fever, by McCrae,[8] Navarro[25] and Luzzatto.[26] Rheumatic fever seems worthy of special mention as it plays such an important rôle in cardiovascular infections, and it is interesting to note that Klotz has observed small areas of sclerosis with cellular infiltration in the adventitia and media of arteries in cases of this disease. These areas bear some resemblance to the Aschoff bodies found in the heart. Recently, Oetiker[17] conducted a bacteriologic study in twenty-three cases, and he was able to isolate an organism in twenty cases. He found streptococci, staphylococci, pneumococci, influenza bacilli and, in one case, anthrax bacilli.

After reading the comparatively scanty literature and noting with surprise the lack of attention given to the subject in standard textbooks, I was still somewhat hesitant to discuss again what should be a familiar and well understood disease. However, I have observed acute and chronic nonsyphilitic aortitis so frequently, usually after being classed as some other condition, that I feel justified in this presentation. It offers the opportunity to emphasize that many of the cases are of nonsyphiltic etiology; that aortic disease is much more common than generally supposed; that early diagnosis can and should be made, and that more attention should be given to the aorta in our routine examinations. It is to be regarded as a not uncommon disease, commonly overlooked.

At this time it would seem wise to limit the discussion to that of the thoracic aorta, as it was this portion of the vessel which was affected in the series studied, and it is the portion usually involved. On the other hand, the abdominal aorta is also subject to similar inflammatory processes. The French recognize an "abdominal aortitis" (aortite abdominal aigue) as a clinical disease entity. As described by them, it is accompanied by angiospasm, with symptoms similar to those of angina pectoris in the chest.

THE AORTA

Certain special anatomic and physiologic characteristics of the aorta now present themselves for consideration. Like all arteries, it consists of three coats, intima, media and adventitia. The inner coat consists of a single layer of endothelium with a thin underlying layer of connective tissue stroma. The middle coat, or media, consists of connective tissue with varying amounts of smooth muscle fibers and elastic fibers. The outer coat, or adventitia, is essentially connective tissue, loosely arranged, and contains numerous nerve plexuses. Nutriment to the vessel wall is obtained either by imbibition through the endothelial cells from the blood in the lumen, or through the small vessels to the artery, the vasa vasorum. Infection may likewise follow either course. The aorta differs essentially from the other arteries of the body in that, in the latter, the media consists of a large proportion of muscle fibers. On the other hand, the aorta contains relatively few muscle fibers, but many elastic fibers. The difference in the structure of the aorta from the rest of the arterial system is due to the difference in the function of the two. The body contains only a limited quantity of blood, which must be distributed according to the ever-changing needs of the various systems. Thus, for example, the arteries of the splanchnic area must contract to supply the brain, or the arteries of the skin must contract to supply the intestines, and so on indefinitely. However, the aorta does not enter actively into this system of reciprocal supply. Therefore, it is poor in muscle tissue, but rich in elastic fibers, as it must dilate and immediately return to the normal, continuously. Probably no organ in the body bears the brunt of such constant lashing as the aorta. It must withstand the shock of each systole twenty-four hours every day, and in addition it must bear the burden of all excess activity. Little wonder, then, that this overworked artery seldom passes middle life without showing some damage, and that it is so frequently the site of acute or chronic infection.

Another fundamental consideration is the generally accepted fact that muscle and elastic fibers do not regenerate, in contradistinction to connective tissue. For this reason, infection and subsequent damage sufficient to destroy muscle and elastic fibers are not followed by regeneration but by fibroblastic proliferation. The contractility and elasticity of the aorta are thus lost, and dilatation becomes permanent. With this in mind, early diagnosis is of paramount importance.

PREDISPOSING FACTORS

The predilection of the ascending aorta and the arch for any type of infection has been clarified by the work of Klotz.[27] He has shown that the lymphatic supply of the aorta is not uniform; in certain areas the lymphatics are present in great numbers, while in other regions the distribution is meager. The ascending aorta appears to have lymphatics in common with the pericardium and also communications with a group of nodes that join the lymphatics of the anterior mediastinum. Around the arch of the aorta are found lymphatics supplying the aortic wall. These connect with nodes in the anterior mediastinum, with those around the trachea, and with those at its bifurcation. The descending aorta has a variable number of lymph nodes, particularly along its right border, which form a plexus around the exit of the intercostal arteries. This lymphatic system is in direct communication with the two large drainage beds of the body, the one in the thorax and the other in the abdomen.

Another predisposing factor, according to Westenhöfer,[28] is based on phylogenetic grounds. He believes that aortitis, like appendicitis, tuberculosis of the apex of the lungs and certain diseases of the pelvis of the kidney, originates on a phylogenetic basis. Aortic disease is seldom found in animals, and is directly associated with man's upright position. Like tuberculosis, this disease develops from childhood and becomes more pronounced with age because of the changing growth and position of the thorax and spinal column. In the case of the aorta, the relation between the thorax and the vertebral column becomes particularly unfavorable, because a certain disproportion takes place between the growth of the spinal column and that of the aorta. The former grows more rapidly than the aorta, which produces a displacement of the exits of the intercostal arteries, so that the original proportion between the parts is disturbed. A similar disturbance occurs within the spinal canal, between the spinal column and the spinal cord. Also, while in the animal the spinal column forms a softly curving posteriorly convexing arch, against which bone pressure is reduced to a minimum, the human spinal column in the upright position is convexing forward in its lower half. To this protruding, often very uneven, column, the aorta is to a certain extent attached. It is constantly pulled lengthwise and sidewise under the influence of the blood stream, while the posterior wall is to a certain extent squeezed between the blood stream and the spinal column. The greater the disproportion between the growth of the aorta and the spinal column, the narrower and the more stretched lengthwise the aorta becomes. But in spite of the phyletic disposition of the apex of the lungs or of the appendix, not everybody develops tuberculosis of the lungs or appendicitis; and so, not everybody develops aortic disease. Westenhöfer believes that there is the added stimulus of constant physical, mental, moral and toxic strain of our present-day life. It is evidently a disease of civilization.

PATHOLOGIC ANATOMY

The pathologic anatomy of aortitis not caused by *Spirochaeta pallida* is well described by Adami,[29] Benda,[30] Sbrocchi,[31] Mallory,[32] Escudero [33] and others. It may be acute or chronic, and may be either an endaortitis or a mesaortitis. The causative agent, bacterial or toxic, may be brought to the site of infection by the blood circulating in the lumen of the aorta, by that of the vasa vasorum, or very occasionally by direct continuity from a neighboring infection. That infection of the intima may be brought by the vasa vasorum was demonstrated by H. F. Swift at the recent meeting of the American Association of Physicians at Washington. Endaortitis is usually verrucose and occasionally ulcerative. If fibrin is deposited, fibrosis usually follows and often calcification. In mesaortitis, the muscle and elastic fibers are attacked and if the involvement is sufficiently extensive, the continuity of these fibers is interrupted.

As stated above, they are not susceptible of regeneration, and fibrosis follows. The inevitable result is dilatation of the aorta. There are attracted to the sites of these infections leukocytes, lymphocytes, endothelial leukocytes and, very rarely, mast cells. The response of these cells to the infection follows the usual rule that only those cells respond that are able to combat the particular type of irritation. These inflammations may occur in the course of any infectious disease, as typhoid, smallpox, scarlet fever, erysipelas, diphtheria, pneumonia, puerperal fever, influenza, rheumatism or tuberculosis, and in any condition in which there are foci of infection. While one hesitates to point an accusing finger again at infected teeth and tonsils, sufficient evidence has been accumulated to warrant the statement that they may be the source of infection.

In passing, it would seem fit to mention that both endaortitis and mesaortitis have been produced experimentally in animals, and that the lesions are closely allied to those seen in men. This refers in part to the work of Josue,[34] Gilbert and Lion,[35] Saltykow[36] and others.

CAUSATION

From the evidence at hand, it also seems reasonable to assume that certain other factors play a decided rôle in the production of this disease. Continuous overactivity of either the physical or nervous varieties, excesses of tobacco, alcohol and overeating seem to be secondary factors, although no scientific data can be furnished to fortify this statement. The present-day high pressure methods of both work and play probably assume the same rôle in the causation of this condition as they do in other degenerative diseases, especially those of the cardiovascular system.

SYMPTOMS

The aortic syndrome presents a picture in which there is a fairly constant group of subjective and objective symptoms. Since the object of this paper is propaganda for its recognition in early and mild cases, a word of warning is sounded that these symptoms are present in varying degrees in different cases. To detect them, therefore, it is necessary to use considerable vigilance.

Pain is one of the most constant symptoms. It is usually of the retrosternal variety in the region of the upper third, occasionally a little lower. It sometimes radiates into either arm, but this is not common. While it occasionally assumes the character of angina pectoris, it is more often a sensation of fulness, pressure or tightness. It frequently interferes with deep inspiration, and the patient sometimes complains that the heart feels as if it were turning over. It may occur without any known stimulus, but it usually follows physical exertion, such as climbing stairs or even a slight incline. Even walking on the level may produce it, and the person finds relief by stopping for a few minutes, after which the walk may be resumed. It is always more noticeable in cold weather, and it may be activated by simply coming into the cold from a warm room. This aortic discomfort, varying from a slight feeling of pressure to one of actual anginoid pain, is probably due to changes in intra-aortic pressure reacting on a diseased aortic wall. The source of the pain is in the nerve plexuses in the loose areolar tissue of the adventitia, according to the work of Thomas [37] and of Allbutt.[16] It has not been possible to demonstrate any relation between the amount of involvement of the aortic wall and the degree of pain, the anatomic damage being estimated by physical examination, roentgen-ray study and postmortem examination. The pain is to be differentiated from cardiac pain, which is usually precordial and near the apex, while that of aortitis is definitely retrosternal, usually in the upper third.

Dyspnea usually accompanies the sensation of pain, and it may occasionally be the predominating symptom. It may be present without pain. It is activated by the same conditions as in pain, especially physical exertion and cold. Along with the dyspnea there may be a more or less severe cough, and Boinet [38] believes that both of these symptoms may be due to an irritation of the first part of the aorta. In cases of extreme dilatation of the aorta, a chronic cough may appear as the result of pressure on the recurrent laryngeal nerve. Babin[39] classifies aortic dyspnea under three heads: (1) dyspnea from exertion appearing on the slightest provocation; (2) paroxysmal dyspnea, especially during inspiration and usually occurring after the subject has been asleep for a short time, at least in the early stages of the disease, and (3) dyspnea, almost always painful, and accompanied by very disagreeable sensations.

Tachycardia is frequently an outstanding symptom and is one that the patient often observes himself. It is seldom accompanied by any irregularity. It may appear on slight exertion, but it may be entirely spontaneous. Even when fever is present, it is out of proportion to the rise of temperature. In some cases, it persists even after long periods of absolute rest in bed. The blood pressure is never high in uncomplicated cases. It is seldom above normal and is quite frequently subnormal, the latter condition probably being due to the dilated and rigid condition of the aorta and its interference with the normal blood stream.

Fever is present in many cases of acute and chronic aortitis. Popoff[40] has discussed this feature in detail. It seems probable that it is not recorded more frequently because it has not been taken regularly, many of the patients are not hospitalized, and those remaining at home do not require the services of a nurse. It is usually not very high, seldom reaching above 101. It is extremely irregular. It varies in its diurnal excursions, appears for a few days or weeks, and disappears for similar indefinite periods. It resembles somewhat the irregular fever of subacute endocarditis. In the absence of any other demonstrable cause for the hyperpyrexia, and with the other symptoms of aortitis present, the reasonable inference is that it is due to an active aortic inflammation. It is interesting to note that the usual antipyretics, such as the salicylates and coal tar products, fail to influence the fever.

Edema of the extremities of a very slight degree has occasionally been noted and has been reported, but it is not common. When it is present, cardiac disease as a cause must be eliminated.

RESULTS OF EXAMINATION

Physical examination offers a most interesting study in this group of cases. Changes in the aortic wall are the first to be considered, and are caused by a weakened wall, especially the media. Stretching of the aortic wall first produces an elongation and shortly afterward an increase in diameter. With the lengthening, the arch is raised, thus producing one of the most typical signs, suprasternal pulsation. Concurrently, both subclavian arteries are elevated above the clavicles, the right appearing first, on account of its anatomic position. There are then produced visible supraclavicular pulsations, also typical findings in this condition.

Widening of the aorta may be demonstrated by percussion to the right of the sternum in the second and third interspaces, although this is very difficult in very early cases. In fact, the actual widening in the incipient cases is probably so slight that it is impossible.

The signs to be elicited by auscultation over the aortic area remain a matter of some discussion. There is usually a distinct soft blowing or roughened murmur best heard in the second interspace close to the border of the sternum. If it is at all distinct, it can be followed along the course of the aorta, even down the left side of the sternum. It is sometimes transmitted to the great vessels of the neck. In the incipient and very mild cases, it sometimes requires a little exercise to make it audible, and is best heard in the upright position. Kukovieroff[41] has called attention to a most interesting phenomenon in this connection. Following the suggestion of Sirotinin, he states that this systolic murmur can be heard in the incipient cases with the patient in the upright position with the hands on the head, and that it is not audible when the hands are at the side. It is heard in the second right interspace or over the sternum in this region, and it is to be differentiated from the murmurs of pericarditis, venous hums and cardiopulmonary murmurs that are also heard in this region. I have confirmed these findings in observations in a few cases, and also find a marked accentuation of a systolic murmur, which is already present. Another important sign is an accentuated, second aortic sound. The latter is loud, ringing and bell-like. A diastolic murmur, due to involvement of the aortic valves, or a stretching of the aortic ring, is certainly not a necessary accompaniment. In fact, it is seldom found in the nonsyphilitic variety of aortitis.

Sensitiveness to pressure over the sternum or of the aorta itself in the suprasternal notch is a symptom occasionally to be found. Pressure symptoms are not frequent and are usually seen late in the disease. They are most unusual in the early and mild cases. They include pressure on the recurrent laryngeal nerve, the bronchi, the trachea and the sympathetic nerves, the latter with pupillary changes. While not frequent, they are very important when observed. Gerber[42] states that paresthesia of the neck is frequently an early symptom due to irritation of the sensory fibers of the recurrent laryngeal nerve. The galvanopalpation methods proposed by Zak[43] and Kahane[44] apparently do not possess definite diagnostic value.

Roentgen-ray studies have proved to be of tremendous diagnostic and corroborative value in the conduct of this disease. Reports have been made by Leconte,[45] Bailey,[46] Frazer and MacRae,[47] and many others. Spiro[11] has proposed the use of the angle finder in these studies. Varying with the severity of the disease process, roentgenographic examination will show the following important variations from the normal: (1) an increase in the size of the aorta; (2) an accentuation of the aortic opacity, and (3) a more or less marked increase in the size of the heart. The size of the heart is of some prognostic moment since it shows the amount of cardiac resistance.

REVIEW OF CASES

The cases presented here have been selected with age as the deciding factor, all of the patients being under 40. This has been done to refute the general conception that nonsyphilitic aortitis and dilatation are essentially a sclerosis and an incident of advancing age. There are twenty-nine cases, and at the following ages: one, 18; two, from 20 to 25; six, from 25 to 30; twelve, from 30 to 35, and eight, from 35 to 40.

There were nineteen females and ten males, which does not correspond with the usual statistics, but this is unimportant in a small series. Syphilis was excluded by careful examination and repeated Wassermann reactions, and in some cases, a provocative Wassermann reaction. Every possible effort was made in the exclusion of syphilis. These patients either presented themselves with symptoms referred to the thorax, or were discovered in the course of a general examination. The latter group described symptoms on careful questioning, and many of these symptoms were found to have been present for some time, but had been disregarded by the patient. Nine of these cases were of the mild or incipient type, seventeen were moderately severe, and three were of the severe type.

None of these cases appeared to be secondary to an infectious disease, so that some other etiologic factor had to be sought. Apology is again offered in mentioning foci of infection in the teeth and tonsils, but, in the absence of other sources of infection, suspicion naturally pointed in this direction. For this reason, all possible sources of infection from the teeth and tonsils received thorough and radical treatment. The gastro-intestinal tract also received attention on the theory that it might be the source of toxemia.

In four of the nine mild cases there was spontaneous pain or dyspnea, and in the other five, discomfort after physical activity. Tachycardia was not present, and the blood pressure was slightly subnormal in all. Fever of the usual irregular type was present in only one case. A systolic aortic murmur in the second right interspace was found in eight, exercise in the other case being required to make it audible. In these mild cases, the murmur was transmitted very little. The second aortic sound was accentuated in all, and was usually ringing. Slight suprasternal pulsation was present in seven, and sternal and aortic tenderness in two. Three of these persons showed a marked secondary type of anemia. In none of these cases could a widening of the aorta be demonstrated by percussion. Roentgen-ray examination showed a slight lengthening in two.

In the moderately severe group, all seventeen patients complained of some degree of retrosternal discomfort, always increased by activity or excitement, and tenderness was present in eight. Dyspnea on slight provocation was present in all. Tachycardia, varying from 90 to 130, was observed in eleven. The blood pressure was slightly increased in one case (145 systolic, 90 diastolic); was normal in six, and was subnormal in ten. Fever lasting from one month to six months was found in six cases and was of the irregular type desscribed above. A distinct systolic aortic murmur was present in all the cases, increased by exercise and by placing the hands on the head. It was transmitted according to its intensity. The second aortic sound was always definitely accentuated. Suprasternal pulsation accompanied by pulsations above the clavicles were also always present. Roentgen-ray examinations made in ten showed positive evidence of aortic disease in seven. Sternal and aortic tenderness was found in six.

The three severe cases presented all the classical symptoms to a marked degree. They showed marked retrosternal pain and fulness, two presenting rather typical aginoid paroxysms. There was also dyspnea and tachycardia. The suprasternal and supraclavicular pulsations were very striking, and there was also sternal and aortic tenderness. One patient was afebrile; the other two had fever ranging between 99 and 101 F., lasting from five months, in one case, to nine months, in the other. As usual, there were frequent periods during this time when there was no fever. The blood pressure was slightly elevated in one (155 systolic, 95 diastolic); slightly subnormal in one (100 systolic, 64 diastolic), and in the third showed striking variations from subnormal to elevated blood pressure. Roentgen-ray studies showed aortic dilatation in all three cases. Complications were practically absent. The case showing variations in blood pressure showed evidence of myocardial weakness during the periods of subnormal blood pressure. It is very interesting to note that none of these severe cases showed any suggestion of impairment of kidney function.

The laboratory examination of most value was the Wassermann reaction in the exclusion of syphilis, and of course it is realized that a negative reaction is not an absolute assurance that syphilis is not present. Estimations of the hemoglobin, red cells and white cells was of no great moment except in several cases of complicating anemia. Blood cultures were made repeatedly in the febrile cases, but in no case was a positive result obtained.

Fortunately for the patients, there were no deaths in this series, and therefore no postmortem evidence can be furnished. The lack of this information is to be regretted from the scientific standpoint.

PROGNOSIS

The prognosis in the mild cases is very good, all nine patients making a complete recovery. In the moderately severe cases it is relatively good, and twelve of the seventeen patients made complete recoveries, the remaining five showing an estimated 90 per cent. improvement. The severe cases are a rather poor prospect for complete recovery, although remarkable improvement can be obtained. Two of the three severe cases showed an estimated 75 per cent. improvement, and one, only 50 per cent. At the outset, it is important to warn the patient that it is a matter of months and not weeks that will be required in the treatment of his case.

TREATMENT

Treatment first should be directed to the removal of all foci of infection. Rest in bed is usually necessary, and the time may vary from several weeks to six months or more. The severity of the disease will regulate the length of time to be spent in bed. In cases not requiring rest in bed, and in those after such a rest, careful regulation of daily habits and exercise is necessary. Rest in the recumbent position for one or two hours in the middle of every day is especially recommended, for the mild and convalescent cases, over long periods of time. Iodids are usually given in large doses for a long time, on purely empiric grounds. Symptoms are to be treated as they arise. The careful regulation of the diet is important. Overeating in general is to be avoided, and especially animal protein and the meat extractives. Tea, coffee, alcohol and tobacco are to be used in great moderation. In fact, moderation in all things is a very good rule.

SUMMARY

1. Twenty-nine cases of nonsyphilitic aortitis showed a sufficient number of the classical symptoms to warrant a definite diagnosis. The patients were all under 40 years of age.

2. The aortic syndrome, with its well established group of symptoms, should occupy a more important place, not only in our textbooks, but in the minds of medical men.

pressure on the recurrent laryngeal nerve. Babin[39] classifies aortic dyspnea under three heads: (1) dyspnea from exertion appearing on the slightest provocation; (2) paroxysmal dyspnea, especially during inspiration and usually occurring after the subject has been asleep for a short time, at least in the early stages of the disease, and (3) dyspnea, almost always painful, and accompanied by very disagreeable sensations.

Tachycardia is frequently an outstanding symptom and is one that the patient often observes himself. It is seldom accompanied by any irregularity. It may appear on slight exertion, but it may be entirely spontaneous. Even when fever is present, it is out of proportion to the rise of temperature. In some cases, it persists even after long periods of absolute rest in bed. The blood pressure is never high in uncomplicated cases. It is seldom above normal and is quite frequently subnormal, the latter condition probably being due to the dilated and rigid condition of the aorta and its interference with the normal blood stream.

Fever is present in many cases of acute and chronic aortitis. Popoff[40] has discussed this feature in detail. It seems probable that it is not recorded more frequently because it has not been taken regularly, many of the patients are not hospitalized, and those remaining at home do not require the services of a nurse. It is usually not very high, seldom reaching above 101. It is extremely irregular. It varies in its diurnal excursions, appears for a few days or weeks, and disappears for similar indefinite periods. It resembles somewhat the irregular fever of subacute endocarditis. In the absence of any other demonstrable cause for the hyperpyrexia, and with the other symptoms of aortitis present, the reasonable inference is that it is due to an active aortic inflammation. It is interesting to note that the usual antipyretics, such as the salicylates and coal tar products, fail to influence the fever.

Edema of the extremities of a very slight degree has occasionally been noted and has been reported, but it is not common. When it is present, cardiac disease as a cause must be eliminated.

RESULTS OF EXAMINATION

Physical examination offers a most interesting study in this group of cases. Changes in the aortic wall are the first to be considered, and are caused by a weakened wall, especially the media. Stretching of the aortic wall first produces an elongation and shortly afterward an increase in diameter. With the lengthening, the arch is raised, thus producing one of the most typical signs, suprasternal pulsation. Concurrently, both subclavian arteries are elevated above the clavicles, the right appearing first, on account of its anatomic position. There are then produced visible supraclavicular pulsations, also typical findings in this condition.

Widening of the aorta may be demonstrated by percussion to the right of the sternum in the second and third interspaces, although this is very difficult in very early cases. In fact, the actual widening in the incipient cases is probably so slight that it is impossible.

The signs to be elicited by auscultation over the aortic area remain a matter of some discussion. There is usually a distinct soft blowing or roughened murmur best heard in the second interspace close to the border of the sternum. If it is at all distinct, it can be followed along the course of the aorta, even down the left side of the sternum. It is sometimes transmitted to the great vessels of the neck. In the incipient and very mild cases, it sometimes requires a little exercise to make it audible, and is best heard in the upright position. Kukovieroff[41] has called attention to a most interesting phenomenon in this connection. Following the suggestion of Sirotinin, he states that this systolic murmur can be heard in the incipient cases with the patient in the upright position with the hands on the head, and that it is not audible when the hands are at the side. It is heard in the second right interspace or over the sternum in this region, and it is to be differentiated from the murmurs of pericarditis, venous hums and cardiopulmonary murmurs that are also heard in this region. I have confirmed these findings in observations in a few cases, and also find a marked accentuation of a systolic murmur, which is already present. Another important sign is an accentuated, second aortic sound. The latter is loud, ringing and bell-like. A diastolic murmur, due to involvement of the aortic valves, or a stretching of the aortic ring, is certainly not a necessary accompaniment. In fact, it is seldom found in the nonsyphilitic variety of aortitis.

Sensitiveness to pressure over the sternum or of the aorta itself in the suprasternal notch is a symptom occasionally to be found. Pressure symptoms are not frequent and are usually seen late in the disease. They are most unusual in the early and mild cases. They include pressure on the recurrent laryngeal nerve, the bronchi, the trachea and the sympathetic nerves, the latter with pupillary changes. While not frequent, they are very important when observed. Gerber[42] states that paresthesia of the neck is frequently an early symptom due to irritation of the sensory fibers of the recurrent laryngeal nerve. The galvanopalpation methods proposed by Zak[43] and Kahane[44] apparently do not possess definite diagnostic value.

Roentgen-ray studies have proved to be of tremendous diagnostic and corroborative value in the conduct of this disease. Reports have been made by Leconte,[45] Bailey,[46] Frazer and MacRae,[47] and many others. Spiro[11] has proposed the use of the angle finder in these studies. Varying with the severity of the disease process, roentgenographic examination will show the following important variations from the normal: (1) an increase in the size of the aorta; (2) an accentuation of the aortic opacity, and (3) a more or less marked increase in the size of the heart. The size of the heart is of some prognostic moment since it shows the amount of cardiac resistance.

REVIEW OF CASES

The cases presented here have been selected with age as the deciding factor, all of the patients being under 40. This has been done to refute the general conception that nonsyphilitic aortitis and dilatation are essentially a sclerosis and an incident of advancing age. There are twenty-nine cases, and at the following ages: one, 18; two, from 20 to 25; six, from 25 to 30; twelve, from 30 to 35, and eight, from 35 to 40.

Dyspnea on slight provocation was present in all. Tachycardia, varying from 90 to 130, was observed in eleven. The blood pressure was slightly increased in one case (145 systolic, 90 diastolic); was normal in six, and was subnormal in ten. Fever lasting from one month to six months was found in six cases and was of the irregular type desscribed above. A distinct systolic aortic murmur was present in all the cases, increased by exercise and by placing the hands on the head. It was transmitted according to its intensity. The second aortic sound was always definitely accentuated. Suprasternal pulsation accompanied by pulsations above the clavicles were also always present. Roentgen-ray examinations made in ten showed positive evidence of aortic disease in seven. Sternal and aortic tenderness was found in six. The three severe cases presented all the classical symptoms to a marked degree. They showed marked retrosternal pain and fulness, two presenting rather typical aginoid paroxysms. There was also dyspnea and tachycardia. The suprasternal and supraclavicular pulsations were very striking, and there was also sternal and aortic tenderness. One patient was afebrile; the other two had fever ranging between 99 and 101 F., lasting from five months, in one case, to nine months, in the other. As usual, there were frequent periods during this time when there was no fever. The blood pressure was slightly elevated in one (155 systolic, 95 diastolic); slightly subnormal in one (100 systolic, 64 diastolic), and in the third showed striking variations from subnormal to elevated blood pressure. Roentgen-ray studies showed aortic dilatation in all three cases. Complications were practically absent. The case showing variations in blood pressure showed evidence of myocardial weakness during the periods of subnormal blood pressure. It is very interesting to note that none of these severe cases showed any suggestion of impairment of kidney function.

The laboratory examination of most value was the Wassermann reaction in the exclusion of syphilis, and of course it is realized that a negative reaction is not an absolute assurance that syphilis is not present. Estimations of the hemoglobin, red cells and white cells was of no great moment except in several cases of complicating anemia. Blood cultures were made repeatedly in the febrile cases, but in no case was a positive result obtained.

Fortunately for the patients, there were no deaths in this series, and therefore no postmortem evidence can be furnished. The lack of this information is to be regretted from the scientific standpoint.

PROGNOSIS

The prognosis in the mild cases is very good, all nine patients making a complete recovery. In the moderately severe cases it is relatively good, and twelve of the seventeen patients made complete recoveries, the remaining five showing an estimated 90 per cent. improvement. The severe cases are a rather poor prospect for complete recovery, although remarkable improvement can be obtained. Two of the three severe cases showed an estimated 75 per cent. improvement, and one, only 50 per cent. At the outset, it is important to warn the patient that it is a matter of months and not weeks that will be required in the treatment of his case.

TREATMENT

Treatment first should be directed to the removal of all foci of infection. Rest in bed is usually necessary, and the time may vary from several weeks to six months or more. The severity of the disease will regulate the length of time to be spent in bed. In cases not requiring rest in bed, and in those after such a rest, careful regulation of daily habits and exercise is necessary. Rest in the recumbent position for one or two hours in the middle of every day is especially recommended, for the mild and convalescent cases, over long periods of time. Iodids are usually given in large doses for a long time, on purely empiric grounds. Symptoms are to be treated as they arise. The careful regulation of the diet is important. Overeating in general is to be avoided, and especially animal protein and the meat extractives. Tea, coffee, alcohol and tobacco are to be used in great moderation. In fact, moderation in all things is a very good rule.

SUMMARY

1. Twenty-nine cases of nonsyphilitic aortitis showed a sufficient number of the classical symptoms to warrant a definite diagnosis. The patients were all under 40 years of age.

2. The aortic syndrome, with its well established group of symptoms, should occupy a more important place, not only in our textbooks, but in the minds of medical men.

3. It is apparently one of the few diseases of the cardiovascular system that offers a chance for complete restoration to the normal when a diagnosis is made in its incipiency.

4. It is a not uncommon disease, commonly overlooked.

1638 Sixteenth Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. PARDEE AND NEUMAN

Dr. William D. Reid, Boston: In regard to the question of nonsyphilitic aortitis, I agree with Dr. Neuman. We should all think about this condition more. One point is the systolic murmur at the base: what produces this? It is said to be due to the roughness of the valve or of the aortic wall. In his work, Chauveau denied this. I did some experimental work with Professor Chaffee of Harvard, and we were able to confirm this statement. In the postmortem findings of 100 cases I found that there were many other reasons for the murmur than roughness of the aortic wall. If we consider why we have murmurs in stenosis, it is found to be because of a sudden change in the caliber of the vessel; we get a jet provided there is sufficient pressure and velocity of the stream. Dr. Neuman says that the aorta both elongates and widens. This would produce the jet mechanism. I think that many persons classified as normal have systolic murmurs in the aortic region. We should remember the diagnosis that Dr. Neuman has emphasized, and also that some persons may have such a systolic murmur for years without detriment to health. These people can be kept under observation. At postmortem, other physical changes than roughness alone will be found. These patients need not go to bed or be considered as ill.

Dr. Eugene S. Kilgore, San Francisco: I agree with Dr. Pardee, but cannot go quite all the way with Dr. Neuman in his suggestion of the prevalence of nonsyphilitic aortitis. Possibly geography is partly responsible for the difference in our point of view, since rheumatic infection is relatively uncommon in California, while we have our share of syphilis. The controversy over relative importance of syphilitic infection in the etiology of aortitis has gone on ever since the English physician Welch, fifty years ago, called general attention to the frequent syphilitic etiology. In recent years continental writers have continued to emphasize the frequency of nonsyphilitic aortitis, while American students of the subject have generally come to regard syphilis as the commonest or nearly sole cause of the disease. Syphilis is always difficult to "rule out." A large percentage of its victims are ignorant of the source of infection and give a negative history; and the physical examination and blood tests are often negative. McCrae, while emphasizing the occurrence of nonsyphilitic aortitis, describes one of his own cases of aortitis believed to be nonsyphilitic for several years, until the evidence of syphilis was finally obtained from the spinal fluid. Many patients with syphilitic aortitis undoubtedly lose valuable time before obtaining antisyphilitic treatment, through failure to obtain an early diagnosis. I believe in the existence of nonsyphilitic aortitis, but as a comparative rarity. Such diagnosis can doubtless be made with reasonable certainty if, in the presence of such an infection as rheumatic fever, definite changes in signs relating to the aorta, tenderness in the episternal notch, etc., are observed to develop. But the ordinary case presenting symptoms and signs described by Dr. Neuman, should, in my opinion, be kept under strong suspicion of being syphilitic regardless of all other findings.

Dr. Louis Faugeres Bishop, New York: We have listened with a great deal of pleasure to these papers, but there are certain points that can be considered. In regard to Dr. Neuman's paper, which was a beautiful clinical study of cases actually observed: There have been two schools of cardiology under two great leaders, Sir Clifford Allbutt and Sir James MacKenzie. Dr. Allbutt had the aorta in mind in interpreting such symptoms; Dr. MacKenzie had the heart muscle in mind primarily. I have always been on the side of MacKenzie. I do not take much stock in the theory of the importance of slight signs in the aorta. A tortuous aorta does not do much harm. The blood pressure may increase and cause it to get larger, or the blood pressure may fall and cause it to get smaller. I believe the aorta is usually as good as the heart back of it, and that most of the symptoms attributed to the aorta are cardiac muscle symptoms. I believe the patient should be treated for the heart rather than the aorta. It has been a great pleasure to me in the course of my office consultations to divest patients of worry, who come to me thinking that they are suffering from aortitis. They may have slight changes, but they are not important. I have watched such patients as long as fifteen years, and they finally died of something else. I have never known patients to come to harm from slight changes in the aorta. We have a few cases of aneurysm and a few cases of syphilitic aortitis, but the vast majority of patients with slight changes in the aorta need not cause us any worry. I can think of nothing more productive of misery than to take such a patient with slight changes in the aorta and order complete rest with large doses of iodids. I give nitroglycerin symptomatically. I try to build up the heart muscle and I order exercise outdoors. The aorta looks the same, but the patients are soon well symptomatologically. One can either ignore the aorta and have the patients well, or one can emphasize it and have them invalids. I believe we should build up the heart and keep the patient well. Systolic murmurs due to dilatation of the aorta are due to change in the caliber of the blood vessels. I feel, however, that Dr. Neuman has done good service in pointing out a clinical group of patients of this type. It is a nice study, even if it is one that need not be considered as severely as he does. Dr. Pardee's paper is a valuable contribution to the question of digitalis. There are one or two points of importance. One valuable clinical point is that the dosage of digitalis should be regulated by the size of the heart. When I get a child or young person with a very large heart, I have to give large doses to get the effect. When the heart is of normal size, the dosage is not so great. The recognition of the importance of adequate doses of digitalis is one of the chief accomplishments of modern cardiology. There is one practical point which is not often thought of; that is, the giving of digitalis by rectum. Sometimes one is called on to treat a serious case with vomiting, and by giving large doses by rectum, well diluted, we can accomplish the desired result. It is a point worth remembering. I think these are the chief points to cover: the relative unimportance of slight changes in the aorta, because the aorta is generally as good as the heart back of it, and the importance of adequate doses of digitalis.

Dr. Lester Neuman, Washington, D. C.: An important conclusion by Westenhofer after long study is that aortitis is much like tuberculosis of the apex of the lungs and also like appendicitis, in that it can be explained on a phylogenetic basis. He bases his conclusions on the fact that there is a marked difference in the development of the thoracic cage and spinal column, producing a marked disproportion between the spinal column, the spinal cord and also the aorta. Another predisposing factor is that no organ in the body must withstand such constant lashing as the aorta. It is subjected to the shock of every systole twenty-four hours every day, and no other organ is subjected to such punishment. Few aortas, therefore, pass middle life without some damage. I wish to emphasize again that muscle fibers and elastic fibers fail to regenerate after being destroyed, and for this reason early diagnosis is of great importance. In emphasizing the observation of Kukovieroff that the systolic murmur of aortitis could be heard best with the hands on the head, I did not wish to give the impression that the diagnosis was based on this systolic murmur alone. It is based, however, on the entire symptom complex. I agree with Dr. Kilgore that the majority of cases are due to syphilis. On the other hand, there is no reason for neglecting the smaller group not due to syphilis. I hesitate to disagree with Dr. Bishop, but I must take the side of Allbutt. I do not believe that we are warranted in disregarding any pathologic condition, whether it be in the aorta or anywhere else in the body, and I therefore do not see how Dr. Bishop can disregard a diseased aorta. While the number of cases is not very large, this group of patients require advice and guidance. I also want to emphasize that every patient is not put to bed and thereby made an invalid. Only the more severe cases require such strenuous treatment. Many of these patients have fever without any other symptoms except those referred to the aorta, and the logical assumption is that the inflammatory condition exists in this organ. Again, referring to the question of rest, whether in bed or not, many of these patients are very uncomfortable after exercising. This is especially true among golf players. I have seen a number of patients who complain of pain and distress in the chest after playing a few holes. It was not possible to demonstrate any cardiac disease, but there were definite signs of the aortitis, and a limitation of their activities produced a marked improvement

Dr. Harold E. B. Pardee, New York: The initial dose of all these drugs must be larger than one ampule if we wish to obtain definite digitalis effects. I have used with good effect one-half minim to the pound of body weight For a person of 150 pounds, 5 c.c., by vein, is the initial dose. I think it might be larger without danger, and am at present attempting to determine how much larger Furthermore, it appears that the action by vein is not much quicker than by mouth, when comparing small doses by vein with large doses by mouth. This gives a still stronger reason for not depending on small intravenous doses for emergency effects in a previously untreated patient.

VISUAL EFFICIENCY OF VARIOUS DEGREES OF SUBNORMAL VISUAL ACUITY

ITS EFFECT ON EARNING ABILITY *

ALBERT C. SNELL, M.D.
ROCHESTER, N. Y.

Among the many complex problems encountered in a study of visual economics is the one relating to the range of useful industrial vision. What is the threshold in the Snellen scale that indicates the beginning of industrial incapacity, and also what is the threshold of complete industrial incapacity?

One may find many expressions of opinion in regard to these two points, but there are not available any recorded and tabulated statistics relating thereto. For this reason I offer a tabulated record of 100 selected cases of defective vision, with a range *in the better eye* from 20/40 Sn. to 5/200 Sn., showing particularly the effect of these various degrees of lowered visual acuity on the individual's ability to work and on his earning capacity.

Magnus and Würdemann[1] state that there is no loss to earning capacity when visual acuity is not less than 0.75 Sn. in those vocations requiring the highest degree of visual acuity; and that there is no loss when visual acuity is 0.5 Sn. or better for those occupations which do not require a high degree of visual acuity. Holt[2] considers that there is no loss to earning ability when visual acuity is 0.8 or better. The Veterans' Bureau of War Risk Insurance does not compensate for loss of visual acuity when the defect is 20/30 Sn. or less. Thus, from these authoritative sources we find that a visual acuity of not less than 20/30 or 20/40 is regarded as causing no loss to earning capacity.

There is a wider range of opinion in regard to the point of total industrial incapacity. Zehender[3] states that 1/100 Sn. renders the individual totally incapacitated for industrial work, while, by a ruling of the New York State Industrial Commission, a 20/100 Sn. is the point of visual acuity from which it computes a total loss of use of an eye. Many points between these extremes have been suggested by various authors and by various committees.

In order to obtain first hand information with regard to the effect which various degrees of loss of visual acuity might have on the earning ability of the individual, I have made a careful investigation of these tabulated cases. I obtained information in most cases by questioning the person as to the nature of his occupation, any difficulty experienced, forced change of occupation, and finally any loss in wages or loss in time as the result of the visual incapacity. I myself examined and interviewed all the patients except 32 to 54, inclusive. The latter were investigated and examined by Dr. Ira Hinsdale, the data being obtained at the Eastman Kodak plant. These people were observed at their work. They were not only personally interviewed in regard to any conscious visual difficulty, but the quality of the work and the efficiency of each employee also was investigated by the foremen or the superintendents of the various departments under whom these persons were working, and their observations were recorded.

In the selection of these cases I have attempted to include only those who were dependent on vision to perform their assigned tasks, and I attempted also to select working people from as many different kinds or classes of employment as was possible. No case of high myopia, with one exception, is included in the list, as I found that many persons with comparatively high myopia, even when such have a considerable reduction to visual acuity for distance (some cases with 20/100 Sn. or less) had very good visual acuity for near, being able to read six point or pearl print at from 10 to 12 inches. All these cases, which would thus have a more favorable effect on the statistics, were rejected.

It is so generally conceded that a visual acuity better than 20/40 Sn. and less than 20/20 Sn. has little or no effect on visual efficiency that only those cases with acuity of not better than 20/40 Sn. are included in the tabulation. However, I have made a study of several hundred industrial employees with visual acuity of 20/25 or 20/33 Sn. in the better eye, and in no instance, no matter how fine or delicate the work might be, did I find that these trivial defects ultimately influenced either the efficiency of the worker or his earning capacity. I give the history of a single case of this class to illustrate this point:

F. T., a man, aged 36, employed as a tool and die maker, has a visual acuity of 20/33 in the right eye and 20/100 in the left eye; he has never used any glasses. For the fine tool work he uses a monocular loop, but for ordinary bench work and other ordinary duties pertaining to the trade of a tool worker, he has never used any glass. He received a serious injury to his left eye two years ago from a penetrating piece of steel. At present there are vitreous and retinal changes, and the eye diverges from 10 to 12 degrees, so that he is dependent entirely on the vision of the right eye. This man receives maximum wages as a tool maker and states that he has not lost a day's work because of any eye trouble; never has headache; has no other symptoms of eye strain, and states further that he has been able to do all his work in a first class and efficient manner. The right eye shows a moderate degree of far sighted astigmatism. His visual acuity is not better at the near point.

---

* Read before the Section on Ophthalmology at the Seventy Sixth Annual Session of the American Medical Association, Atlantic City N. J., May, 1925.

[1] Magnus and Würdemann: Visual Economics, p. 117. Würdemann: Am. J. Ophth., April, 1922, p. 321.

[2] Holt: Tr. Am Acad. Ophth. & Oto-Laryngol, 1914.

[3] Zehender: Klin. Monatsbl. f. Augenh, 1889, p. 268.

Visual defects even of this minor class, when recently acquired, do cause some degree of inefficiency for a time, but after two or three months have elapsed this is overcome entirely. Despite this fact, I wish to point out that with repeated trivial injuries causing slight defect in vision, there follows an accumulated effect. The total effect of two or more injuries which alone would cause only a slight disturbance to acuity will be sufficient often to interfere with the worker's efficiency. For example, a single injury, that reduces visual acuity to 20/30 Sn. would not interfere with one's working ability. But assuming a second injury of the same degree that would reduce the acuity to 20/40, and a third

One Hundred Cases of Visual Acuity Impairment, Ranging from 20/40 to 3/200 Snellen in the Better Eye

Case	Present Age, Sex*	Occupation	Vision with Correction		Glasses	Refraction	No of Years Defective	Cause for Defect	Loss to Earning Ability	Lost Time, Pay	Comment
			O D.	O. S							
1	32, ♀	Tailor	L	20/60	Yes	H	20	Corneal opacity	None	Married, did not work 1 year	Always received the maximum wages
2	42, ♂	Mail carrier	20/40	20/100	Yes	H	4	Retinitis, left eye	None	No lost time	Right eye: congenital amblyopia
3	18, ♀	Saleswoman	20/65	20/100	Yes	M-A	10+	Conical cornea	None	....	Finished two years high school, six months saleswoman
4	19, ♀	Box factory	20/100	20/40	Yes	H, H-A	19	Congenital amblyopia	None	....	Completed seventh grade; strabismus
5	31, ♂	Clerk, wholesale	20/65	F	Yes	M	31	Congenital cataract	None	First and only job, 2 years	Completed high school; reads 7 point at 8 inches
6	45, ♀	Shoe factory	20/40	20/100	Yes	H	40	Amblyopia	None	Fifteen years shoe mkg.	Advanced to floor lady
7	28, ♀	Kodak	20/50	20/30	No	H-A	20	Lent. astigmatism	None	No lost time	Glasses improve, but does not wear them
8	44, ♀	Tailor	20/40	20/40	Yes	H, H-A	40	Amblyopia	None	Six years as tailor	Since marriage, has done all her own sewing
9	74, ♂	Paper mill	20/40—	B	Yes	H, H A	2	Glaucoma	None	Full pay	Reads 7 point; no trouble with work
10	59, ♂	Factory	5/200	20 50	Yes	H, H-A	50	Amblyopia	None	Maximum pay	Twelve years foreman in power house; at times a painter
11	48, ♀	Kodak	20/50	20/50	Yes	M-A	20+	Conical cornea	None	Full pay	Works on leather
12	69, ♀	Proofreader	20/40	20/65	Yes	H-A	5+	Choroiditis	None	Full pay	Has worked continuously, last five years
13	75, ♂	Judge	20/65	20/50	No	E	3+	Vitreous opacities	Retired	Age limit	Now acts as referee; reads 3 to 4 hours at a time; says he thinks he is 20 per cent. defective
14	47, ♂	Electrician	20/100	2/200	Yes	Cat glass	7	Cataract elec oph	Nearly total	Incapacitated as electrician	Could not work as a lineman; has done janitor work three years
15	62, ♂	Sawmill	B	20/65	Yes	M	6+	Glaucoma	Some	Full pay when at work	Operates a mill saw; field contracted to 35 degrees concentrically
16	60, ♂	Laborer	B	20/65	No	. ..	1	Corneal scars	None	. ..	Worked all year in stone quarry since recovery from accident
17	69, ♂	Laborer	B	20/40	No	M	2	Glaucoma	None	......	Worked in salt mine 1 year since loss of eye; 1 year as janitor
18	31, ♂	Molder	20/50	20 40	Yes	H, H A	15+	Amblyopia	None	Maximum pay	No difficulty with his work as a molder
19	30, ♂	Factory	20/65	20/100	No	E	30	Amblyopia	None	Equal pay with others	Making insulators for several years; no difficulty
20	42, ♂	Machinist	20/50	20/80	Yes	M	7	Corneal scar, vitreous opac	None	Full pay	Has received compensation for partial loss
21	51, ♂	Machinist	20/150	20/65	Yes	M, M-A	6+	Corneal opacity	None	Worked continuously	A blacksmith; high myopia
22	41, ♂	Molder	20/40	B	Yes	H-A	5	Corneal scars	None	Worked most of time	Vision at first was 20/100
23	39, ♂	Machinist	20/50	5/200	Yes	H, H-A	12	Amblyopia	None	Works steadily	Had an attack of iritis following accident to right eye
24	10, ♀	School	20/250	20/250	No	+0 25 S +0 50 Cy	4	Retinitis	.. ..	School	Completed the three lower grades in school
25	58, ♂	Policeman	L	10/200	No	..	8	Cataract	None	. ...	Has worked past 2 years with vision less than 20/200
26	70, ♂	Elevator	10/200	B	No	—1 50 Cy	7	Glaucoma	None	Worked continuously until 1923	Vision: 1917, 20/50; 1918-1920, 20/200; 1921-1923, 10/200, 5/200
27	54, ♂	Policeman	12/200	L	No	.. . ...	2	Cataract	None	No lost time	For two years vision in better eye was 20/200 and less
28	25, ♀	Stenographer	5/200	20/50	Yes	M, M-A	10+	Conical cornea	None	Lost time occasionally	Recurrent central corneal ulcerations; highest pay at present
29	57, ♂	Stationary engineer	20/200	20/200	No	H, H-A	57	H & H-A	None	None	Twelve years at present job; has never worn glasses at work
30	73, ♂	Driver delivery	5/200	5/200	No	H	3+	Nuclear cataract	None	None	Drives a horse about city, delivering tobacco
31	38, ♂	Painter	10/200	10/200	No	E	6+	Retinitis centralis	One half	Considerable	Has not been able to secure a position, but has been working for himself at his trade
32	25, ♂	Kodak	20/65	20/200	No	M, H-A	5+	Amblyopia	None	None	Works as inspector of plates, dark room
33	65, ♂	Shoemaker	20/200	20/200	No	....	2+	Nuclear cataract	Yes	Not able to work	Near vision is much worse than distant; 20 point at 10 inches
34	39, ♂	Draftsman	20/40	20/65	Yes	H, H-A	39	Amblyopia	None	None	Has worked 10 years as a draftsman
35	15, ♂	School	10/200	20/40	Yes	H-A	15	Cataract	...	....	Has reached second year junior high school; plays in orchestra
36	27, ♂	Lacquer sprayer	20/100	20/50	Yes	H-A	..	. .. .	None	None	Work good
37	30, ♂	Lacquer sprayer	20/40	20/200	Yes	Mixed astig.	..	Choroiditis	None	None	Work good
38	63, ♂	Assembling, camera repair	20/70	20/70	Yes	M	..	Large central opacity	None	None	Work good, close but not fine
39	58, ♂	Dipping	20/40	20/40	Yes	H	..	Presbyopia	None	None	Work good
40	23, ♀	Factory worker	20/40	20/40	Yes	H-A	..	....	None	None	Work good
41	51, ♂	Tool maker	20/40	20/40	Yes	....	..	Presbyopia	None	None	Work is close; quality is excellent
42	21, ♀	Clerical work	20/50	20/50	Yes	H-A	..	....	None	None	Work good
43	43, ♂	Clerical work	20/40	20/40	Yes	H-A	..	....	None	None	Quality of work is excellent
44	17, ♀	Mail delivery	20/70	20/70	Yes	M-A	..	. ...	None	None	Work satisfactory
45	21, ♂	Shipping department	20/70	20/70	Yes	M-A	..	Interstitial keratitis	None	None	Lays out orders and clerical work, good
46	56, ♂	Roll coating department	20/70	20/40	Yes	Mixed astig.	..	. ...	None	None	Dope coating, not fine; work excellent
47	63, ♂	Finishing department	20/50	20/40	Yes	H	..	. ...	None	None	Mixes chemicals; work excellent

55	45, ♀	Bookkeeping; stenography	20/40	20/40	No	M	45	Congenital cataract	None	None	Stenographer 20 years; no difficulty in holding position
56	40, ♂	Shoemaker	20/100	20/50	Yes	M, H-A	8+	Neuroretinitis	None	None	Operates a machine
57	20, ♂	Student	20/50	20/40	Yes	H, H-A	20	Amblyopia	.	....	No trouble with study; working at mechanics
58	50, ♂	Merchant	20/40	20/50	Yes	H, H-A	20	Keratitis	None	None	Trophy winner at tennis and "horse shoes"
59	19, ♂	Farmer	20/40	20/65	Yes	Cat Gl	19	Congenital cataract	None	None	General farm work without difficulty
60	70, ♂	Teamster	20/60	20/50	Yes	Cat Gl	70	Congenital cataract	None	None	Has driven a team for 30 years
61	48, ♂	Farmer; laborer	20/40	20/100	Yes	Cat Gl	48	Congenital cataract	None	None	Never worked at skilled trade
62	40, ♀	House	20/40—	20/40	Yes	M, M-A	20+	Amblyopia	None	None	No trouble with usual duties pertaining to house work
63	32, ♂	Mechanic	20/70	20/40	Yes	M-A	20	Corneal scars	None	None	Has always done close work since leaving school
64	30, ♀	Housewife	10/200	20/40	No	Irreg astig.	25	Corneal scars	None	None	Usual duties of housekeeper
65	58, ♀	Housewife	20/100	20/50	Yes	H-A	50	Amblyopia	None	None	Never any trouble with reading or sewing
66	58, ♂	Grocer	20/40	20/70	Yes	M, M-A	20+	Retinitis	None	None	Proprietor of grocery store 20 years; has kept own books, etc.
67	24, ♂	Farmer	20/200	20/200	No	...	24	Congenital cataract	None	None	Has worked on the farm for 20 years; no difficulty with any kind of work; lower grades at school
68	30, ♀	Housewife	3/200	Field	No		10	Optic atrophy	.	....	Does all her own housework
69	23, ♂	Office	20/100	20/100	Yes	H, H-A	23	Nystagmus	None	None	Ten years' clerical work in office, book keeping, typing, etc.; cannot run an auto.; three jobs in 10 years
70	60, ♂	Machinist	20/100	20/100	Yes	—0 75 S	4	Tobacco amblyopia	None	None	Has worked continually at various operations in machine shop
71	13, ♀	School	20/65	20/50	Yes	H, H-A	8	Corneal scars	....	. ...	Fifth grade; no trouble with school work, but reported slow and dull
72	54, ♀	Housewife	20/40	20/65	Yes	H, H-A	15+	Iritis	......	....	Fine sewing and very fond of crocheting
73	13, ♀	School	20/50	20/65	Yes	H, H-A	..	Amblyopia	......	....	Has never failed to pass any grade in school
74	20, ♂	School	20/50	20/50	Yes	M	15+	Retinitis pigmentosa	......	....	Fields cut to 25 ecc; has reached second year normal school
75	16, ♀	Laundry machine	20/100	20/65	No	. ...	..	Interstitial keratitis	.... .	....	Works in steam laundry; no difficulty with machines
76	59, ♂	Mechanic; elevator	20/200	20/200	No	H	5	Cat. Ret. Cent.	Yes	Considerable loss in pay	Mechanic for years; has operated elevator last 5 years
77	34, ♀	Housewife	20/100	5/200	Yes	H	6	Retinitis gravidarum	None	....	Does all housework and sewing; trouble threading needle
78	72, ♂	Lawyer	20/40	20/50	Yes	H	8	Vit. Opac., right eye; amblyopia, left eye	None	....	Prodigious reader; large, active legal practice
79	70, ♀	Physician	20/40	20/40	Yes	H, H-A	60+	Amblyopia	None	....	General medical practice; some minor surgery
80	29, ♂	Road builder	20/50	20/70	No	. ....	3+	Optic atrophy	None	None	No trouble with work; does grading satisfactorily
81	36, ♀	Stenographer; off. work	20/40	Fin	Yes	Low M-A	10+	Choroiditis	None	Maximum pay	All kinds office work 15 years; trouble reading some script
82	20, ♀	Student	20/100	20/100	Yes	M-A	16+	Nystagmus	.. ...	....	Second year in college; no difficulty with work
83	19, ♂	Tool maker	20/65	20/50	Yes	M-A	19	Congenital cataract	None	Maximum wages	"Snow blind"; regarded as first class toolmaker
84	64, ♂	Baker	20/200	20/200	No	E	2+	Retinitis, diabetic	None	Maximum wages	Has not lost a day at his trade; trouble doing fancy pastry, white on white
85	35, ♂	Laborer	20/100	20/100	No	E	35	Amblyopia	None	Low wage scale always	Factory laborer; never tried to operate machine; not skilled
86	27, ♂	Undertaker	20/100	20/100	Yes	M	15+	Amblyopia	None	Successful business	No trouble with any detail of his work
87	67, ♂	Grocer	20/50	20/65	Yes	H, H-A	50+	Amblyopia	None	Successful business	Keeps his books and does general grocery business
88	62, ♂	Librarian	20/320	20/320	Yes	H	8+	Tobacco amblyopia	None	35 years librarian	Continued to work and read books until v. = 20/320 both eyes; but used magnifying glass
89	80, ♂	Watchmaker	10/200	20/40	Yes	H, H-A	10+	Cataract	Some	Some loss of time	Continued to repair watches until v fell below 20/60
90	50, ♂	Commercial traveler	20/200	20/40	Yes	H	50	Congenital amblyopia	None	Successful salesman	Never any trouble in figuring or making reports
91	24, ♂	Canning factory	20/100	20/200	Yes	H	20	Specific congenital retinitis	....	Never had good job	Finished 1 year at high school; fills boxes in canning factory; janitor in winter
92	41, ♂	Metal finisher	20/65	20/200	No	E	3	Diabetic retinitis	Some	Lost time, no loss in pay	Says he can do work all right; vision blurred
93	30, ♀	Clerk	20/200	20/200	Yes	M-As	20	Con cornea	None	Not highest pay	Been clerk 8 years; reads book print; eyes tire
94	25, ♀	Tailoring	20/40	20/40	Yes	H, H-A	20+	High degree H	None	Highest pay	Considered first class tailoress
95	70, ♀	Librarian	20/70	20/65	Yes	H, H-A	15	Glaucoma	None	Full pay	20° conc. contract in better eye; considerable reading and all library work
96	31 ♂	Tailor	20/40	20/40	Yes	H	31	Amblyopia	None	Full pay	No trouble at all with work
97	47 ♂	Painter	20/65	20/40—	Yes	H, H-A	47	Amblyopia	None	No lost time	Work satisfactory; not conscious of any defect or handicap
98	37, ♂	Tailor	20/40	20/40	Yes	H, H-A	37	Post-pol cat.	None	None	Tailor, various departments, 25 years
99	39 ♂	Carpenter	20/65	L P	Yes	H-A	7	Corneal scars	Some	Considerable; not empl. as car.	In dynamite explosion; lost one eye; farming last 5 years; work on farm
100	42, ♂	Carpenter	20/65	20/200	No	H	12	Right eye, cor. scars; left eye, amblyopia	None	Not lost day in 4 years	Right eye hit by flying nail; has done cabinet work

---

* In this column, ♂ indicates male; ♀, female

that would reduce it to 20/60, acuity would be reduced to the extent that is a distinct impairment to efficiency for many occupations. Obviously, the latter injury cannot be regarded as solely responsible for the incapacity, but the final incapacity must de due to the accumulated effect of all.

FINDINGS

An analysis of these 100 cases will reveal the following pertinent and interesting facts regarding age, sex, number of years defective, refraction, occupation, general nature of cause for visual defect, and the degree of visual acuity. All these facts have some bearing on the further study of these persons in connection with their earning ability.

Age.—These persons range from 10 to 75 years of age. Fifteen were under 21, and ten were over 65. Seventy-five per cent. were therefore in their years of greatest vigor and earning ability.

Sex.—Thirty are women and seventy are men.

Years Defective.—All the persons included in the tabulated list had defective vision for at least one year, and most had had their defect much longer, many having had the visual defect ten, twenty or more years. In each case, sufficient time had elapsed to permit that person to become at least partially accustomed to the altered visual acuity and thereby to learn how to make most use of his eyes despite the defect.

Refraction.—Visual acuity recorded in every case represents the best vision obtainable with correcting glasses. There are twenty-four cases of moderate myopia (less than —2. S.), (one, Case 21, had —6. S.), seven were emmetropic and fifty-nine hypermetropic.

Occupation.—There are seven students; five professional men, including two librarians, one physician, one lawyer and one judge; eighteen with nonprofessional occupations, including six wives working at home; six clerks or sales people, two merchants, two policemen, and two farmers; sixty-five are classed as skilled workers, this list including two stenographers, one proofreader, two mail clerks, and three deliverymen or truck drivers. The other skilled workers were employed as draftsmen, tailors, painters, electricians, elevator operators, mechanics, tool makers, machine operators, mill workers, carpenters, engineers, molders, bakers and road builders. The tabulated cases include only five nonskilled laborers, so that all except five required the use of good eyesight for their work or employment.

Visual Defects.—In every case of moderate myopia or myopic astigmatism included in this tabulation, there was found always some cause other than the myopia for the defective vision. Twenty-four cases of this class are included. The cases were selected in order to include as great a variety of visual defects as possible. In general the visual defects may be divided into two classes: the congenital defects and the acquired defects. Of the former there are forty-two cases, thirty-two being amblyopias and ten congenital cataracts. Of the latter, the acquired defects, there are fifty-eight cases. These include corneal opacites, conical corneas, glaucoma, choroiditis, retinitis, vitreous opacities, senile and traumatic cataract, tobacco amblyopia, optic atrophy, iritic exudates, and irregular astigmatism.

Working Ability and Earning Capacity.—A perusal of these tabulated cases will reveal that no patient had any loss either to his working or to his earning ability until visual acuity fell at least to 20/65 Sn. in the better eye. A visual acuity of 20/40 Sn. or 20/50 Sn. or 20/60 Sn. had in no case proved a sufficient impediment either noticeably to lessen efficiency or to lessen earnings. However, in my experience, when vision is reduced to these degrees by some recent lesion, there is experienced at first some degree of difficulty and a loss of efficiency, which is always overcome within a few months. This is true also when vision is reduced to much lower ranges.

Visual Acuity

39 had maximum acuity of 20/40 in the better eye
21 had maximum acuity of 20/50 in the better eye
12 had maximum acuity of 20/65 in the better eye
5 had maximum acuity of 20/70 in the better eye
8 had maximum acuity of 20/100 in the better eye
6 had maximum acuity of 20/200 in the better eye
1 had maximum acuity of 20/250 in the better eye
1 had maximum acuity of 20/320 in the better eye
5 had maximum acuity of 10/200 in the better eye
1 had maximum acuity of 5/200 in the better eye
1 had maximum acuity of 3/200 in the better eye

A reduction of acuity to 20/60 Sn. is the beginning of the threshold of permanent partial loss to efficiency. This is shown in Case 89, that of a watch maker who continued at his work until the acuity in the better eye fell below 20/60 Sn. Patient 99, a carpenter, with vision of 20/65 Sn. in one eye and light perception in the other, could not work at his trade. Yet Patient 100, with not better vision than 20/65 Sn., said that he had not lost a day in four years and was working at his trade. There were fifteen additional persons with vision of 20/65 or 20/70 Sn., none of whom experienced any permanent difficulty with their work or any loss in earnings, and some were employed at fine near work.

Of the eight persons who had an acuity of 20/100 Sn. in the better eye, I found that five had experienced no loss in earnings. Two of these five did work that was not fine and three did fine work, one being employed as a clerk and bookkeeper, one as a machinist, and one being a college student, all working without conscious difficulty. Of the two in this class, Patients 14 and 91, who were incapacitated, one was a lineman who, following a severe electric shock, developed retinitis and cataracts. After removal of the cataracts, in the better eye there was obtained finally a vision of 20/100 Sn. The other person (Patient 91) had considerable trouble with school work, but finished one year of high school. He never could get a "good" or satisfactory job, and his wages were always low. In the first case there were complications, and the second person was of low intelligence.

Of the fifteen persons having not better than 20/200 Sn. in the better eye, three (26, 33 and 49) were totally incapacitated, two (31 and 76) were partially incapacitated, and ten continued at their particular occupations despite the handicap of poor vision. Of those totally incapacitated, Patient 26, an elevator operator, continued at his job until his acuity fell to 10/200 Sn. Patient 33, a shoemaker, gave up his employment, operating a machine, when vision fell to 20/200 Sn. in both eyes. Patient 49, a camera factory worker, resigned when his acuity fell to 10/200 Sn. Of those partially incapacitated, Patient 31, a painter, worked at his trade with an acuity of 10/200 Sn. in each eye by securing work directly, but he could not get work through an employer or contractor; and Patient 76, after working a number of years as a skilled mechanic, found it necessary to give up this kind of employment when vision fell to 20/200 Sn. in each eye, but was able to operate a factory elevator for five years with this degree of visual acuity.

Of the ten remaining persons who continued at their work with acuity in the better eye of 20/200 Sn. or less, one was a school child (Patient 24), aged 10, with an acuity of 20/250 Sn. in each eye who had finished three lower grades in school. Two (Patients 25 and 27) were policemen, both continuing at their work until visual acuity fell to 10/200 Sn. One (Patient 29) worked for twelve years without loss of any time or pay as a stationary engineer, with an acuity of 20/200 Sn. in each eye. A farmer, a baker and a clerk (Patients 67, 84 and 93), each with vision of 20/200 Sn. in the better eye, continued at their work without serious difficulty. One (Patient 68), a wife and housekeeper, did all her own housework, with an acuity of only 3/200 Sn. in the better eye and only field vision in the other. There remain two remarkable cases, 88 and 30. Both happen to be cases of tobacco amblyopia with complications. The former patient was a librarian who continued at his post, which required the reading of many books, consulting card indexes and the constant daily use of his eyes, until his acuity fell to 20/320 in each eye. He used a very near glass—a 6 inch focus—and in addition a hand magnifying lens. The second was a driver and deliveryman who continued to drive his horse all about the city and deliver orders of goods, with a central visual acuity of only 5/200 Sn. in each eye. He had done this with no better vision for more than three years while under my observation. His vision had been poor for several years prior, as he had nuclear cataracts in addition to his tobacco amblyopia. Of course, both man and horse were familiar with the job.

COMMENT

Familiarity with the kind of work to be performed is a valuable asset to those having defective sight. When one has become accustomed to some particular operation on a machine or other process of labor, he may continue at the same employment successfully and efficiently, whereas the same person would not be able to take up new employment, even when the nature of the work might require a less degree of visual acuity. Although some men may continue at their old employment with a 20/200 Sn. or less, such would always have considerable difficulty in securing new jobs, and do have difficulty with new and unfamiliar kinds of work.

There is still another aspect of our theme. Many employers will retain an old and faithful employee, without reduction in wages, even when it is known that such an employee has defective vision and difficulty with his work. However, in the study of these tabulated cases I have focused our attention on the kind of work actually accomplished by the worker and his ability to accomplish his particular task, and have not regarded full pay as always meaning full visual efficiency.

The length of time that the defect in sight has existed and the rapidity of its onset are factors of importance in considering visual working ability. It seems clear that those who have congenital defects, causing a lowered degree of visual acuity, overcome their handicap and learn to work more efficiently than do those who suffer visual losses later in life after having had good or normal vision, so that the older one is when vision becomes defective by accident or by disease, the more difficult it is to make efficient use of the remaining vision. Nevertheless, I have found that many (mostly those under 50), even with acquired visual impairment, and even when the impairment was serious, from 20/200 to 20/320 Sn., can in the majority of instances be employed in some productive capacity with earning power. Time, encouragement and some degree of pertinacity are required to rehabilitate these. Eighty per cent. of the patients had substantial visual earning power with an acuity not better than 20/200 Sn. and not less than 20/400 Sn. A 10/200 Sn. was the point of total incapacity for all except two, who should be regarded as exceptional and extraordinary.

I wish to call attention to those persons having an acuity not better than 20/40 Sn., as this point in the Snellen scale is often regarded as marking the crisis in vision. By some, this notation is regarded as expressing one-half vision or half blindness, simply because the visual angle by which the 20/40 Sn. is measured is twice the size of the Snellen unit. In the tabulation there are sixty persons having a 20/40 or a 20/50 Sn., and not a single one of these experienced any loss whatever either in ability to use the eyes or in earning capacity. From the point of view of efficiency or usefulness, a 20/40 Sn. does not express one-half vision, no matter how fine the work may be at which such an acuity may be employed. The Snellen standard unit, one minute visual angle, represents an average normal; therefore it is correctly inferred not only that many persons have a normal visual acuity better than this, but also that many have less acuity as their normal.

Statistics of visual acuity defects compiled by the Surgeon General's Office[4] show that 22.58 per thousand of all men called by the draft during the late war had less than a 20/40 Sn. in the better eye, since this number was rejected solely because of defective acuity, the minimum visual requirements for acceptance in the unlimited service being a 20/40 Sn. in each eye with correction, and less than this being a cause for rejection. My own statistics, obtained by a complete survey of one factory, the data being obtained by Dr. Kennedy, are in substantial agreement with the foregoing; i. e., between 2 and 3 per cent. of our population have not better visual acuity than a 20/40 Sn., which is normal for these persons. In no sense are these half blind or only 50 per cent. efficient. A 20/40 Sn. is a handicap for new men seeking employment in various lines of public service, as many railroads and electric service roads have made rules that fix a standard visual acuity for new employees. This rule does not apply to old employees already in service. Most railroads do not consider a 20/40 Sn. as a cause for demotion even for first class locomotive engineers.

SUMMARY

1. No loss to earning ability even for the highly skilled work was found until visual acuity was reduced to 20/60 Sn. The threshold for the beginning of visual disability as reflected in earning ability lies between 20/60 and 20/100 Sn.

2. The accumulated effect of repeated trivial injuries must not be ignored from an economic point of view for those cases in which a single injury does not reduce

---

[4] "Defects Found in Drafted Men," Surgeon General's Office, Government Printing Office, 1920

acuity to 20/40 or less, as repeated injuries of the same degree may finally cause loss to earning capacity.

3. A 20/200 Sn. caused a total incapacity to 13.3 per cent. and a partial incapacity to an additional 13.3 per cent, so that 26.6 per cent. in this class with vision of not better than 20/200 Sn. were either completely or partially incapacitated for earning. Eighty per cent. had earning capacity with acuity between 20/200 and 20/400 Sn.

4. A 10/200 Sn. was the point of visual acuity reduction which became the point of total incapacity in all except two cases, and this may be regarded as the lowest limit of visual earning capacity.

5. The threshold of total incapacity lies between 20/200 and 2/200 Sn., depending on the nature of the employment, age of the defective person, the duration of the subnormal vision, and on his individuality (his will to work).

6. An acuity of not better than 20/40 Sn. in the better eye does not cause a loss of 50 per cent. either in efficiency or in earning ability. This degree of acuity, in fact, causes no direct loss to earning capacity. However, its direct influence from two economic points of view must be considered: (1) that of the accumulated effect of these degrees of loss due to repeated injury, and (2) the effect of such degree of substandard vision on the competitive ability.

53 South Fitzhugh Street.

ABSTRACT OF DISCUSSION

Dr. John A. Donovan, Butte, Mont.: Compensation has become a very serious subject. Juries are giving terrific verdicts, and beware—each one of us is constantly liable to become the prey of these vultures who are forever looking up and advising lawsuits—the grasping corporations, the labor unions whose sole teachings are less work, more pay—never once do they advise as we do, efficiency, but always what? Read the reports coming from their conventions. Lastly, the public, never considered, never even interested, yet it pays all the bills. It is the public that we here should represent. In every village is the man of note, reading the law at a distance of 3 inches with his myopic eye, and with his hypertropic eye supervising the neighbors. The man with 20/60 vision who has told that he needs no glasses, that he can tell a horse from a cow a mile away, is telling the truth. We could leave this room and within twenty minutes find twenty men in whom, if they slowly lost vision down to 20/40, even if they themselves knew it, it would never make the difference of one single penny in their earning ability throughout the remainder of their lives. Who has not seen the derelict, totally unable to work, move off to greener fields the day following receiving a large compensation? Of course I am not talking of the really honest man for whom no law is necessary. The factors of quality of work, earning, competitive and saving ability, contributory negligence, all ultimately should be entered as factors in our table. Consider the high myope, ignorant of any visual defects, the astigmatic patient and even the hyperope, who by squinting sees sufficiently. Then we supply one of these with glasses after careful examination under a cycloplegic, and the patient suddenly enters a new world, but never again, as he tells his innumerable friends, can he see without glasses as he could before the drops were used. He does not, and does not want to, understand. One may record 20/25, and another man with the same patient will record 20/20, and a third man equally careful may record 20/30—all in the same patient, and all are absolutely right. Men come to me because the examiner in another division rejected them for train service. I request their reappointment, and vice versa. Who was right and at which time? We who have to deal daily with claim agents and claim attorneys of our employers and yet must give satisfaction and advise conscientiously our patients, anticipate the difficulty of making any iron bound standards, yet know it must be done. Many a man has a blind eye for months before he finds it out.

Dr. E. E. Holt, Portland, Maine: Dr. Snell refers to me as an authority on the amount of vision that may be lost without affecting the earning ability. This standard was largely based on the work of Magnus on Visual Economics as translated by Wurdemann, a work of great value on the subject of which it treats. In working out the efficiency of the various degrees of subnormal visual acuity, we should realize that we must be guided not by the extremes, but by the law of averages, the same as that on which the life table is based. Dr. Snell speaks of the effect of the visual efficiency of various degrees of subnormal visual acuity on the earning ability. Of course the ultimate effect is on that, but the first effect is on the other indispensable factor of the earning ability, namely, the competing ability, thus obtaining the two factors of the earning ability which are necessary to solve the compensation problem by mathematics in a scientific manner. Visual efficiency has no earning ability unless it is put to work in some vocation and thereby acquires a competing ability; and the two together make the product, namely, the earning ability. At the Industrial School for the Blind at Portland, I was struck with the great efficiency and competing ability of one of the boys, who was totally blind, as he sat at a typewriter writing out dictations as fast as the ordinary person talks. He took out a sheet of the typewritten letter in which he had purposely left out a letter in a word, and he put it back into the typewriter and put in the proper letter in the word so quickly that it was astounding, so that person with extreme loss of vision may acquire great competing ability and thereby have a corresponding earning ability. But it is not so much on their poor vision, but on their competing ability to do the work in spite of the poor vision, or, as in the case of the boy in the Industrial School for the Blind, with no vision.

Dr. Edward Jackson, Denver: We have had many discussions about methods of measuring visual acuity and demonstrations that a certain visual acuity meant something with reference to disability. But Dr. Snell has taken a very important step in setting the example of studying the patient with diminishing visual acuity and finding out the facts in the individual case, as to whether that diminution of visual acuity caused diminution of efficiency in their work and their earning ability. It is something that every individual ophthalmologist will have to take up, before his testimony will help a great deal, as to the effect of an injury to the eye, on the financial production of the person who has been injured. To gain an understanding of what we are talking about, it will help to try with our own eyes what we can see and what we can do, with a certain visual impairment, artificially produced for the purpose. This question was brought up before the committee of the Colorado Ophthalmological Society, with regard to the case of a claimant for blind benefits. The standard had been established that the vision must be below 1/10, in order to entitle any person to blind benefit. This woman had very noticeable optic atrophy, pallor of the optic disks and shrinking of the vessels, that showed with the ophthalmoscope. But her neighbors said she could play cards, that indeed she had made a living at teaching card playing to seeing persons. The question of playing cards is simple to decide: Just try cutting down your own vision to 1/10 and then see whether you are able to play cards. I tried it on myself and on other people; and I find with 1/10 vision one can see the cards readily. If we study carefully along the lines that Dr. Snell has indicated, how much people with impaired vision can learn to do, it will give us a better mastery of these problems that are increasing in importance every day.

Dr. Albert C. Snell, Rochester, N. Y.: The measurement of acuity is not the measurement of the physiologic function of macular vision. As Dr. Jackson has mentioned that the expression "1/10 vision" is not an accurate statement. I think we should get into the habit of expressing our notations which have a precise meaning. If we mean 1/10 Snellen we should say that. The Snellen notation is one of comparative acuity, and not a fractional expression of vision If we say 1/10 Snellen we shall be using a scientific terminology and we shall not be open to the criticism of expressing visual acuity in fractional terms when we do not mean to express fractional vision.

CHEMICAL ANALYSIS OF SWEAT

A PRELIMINARY STUDY [*]

ROBERT E BARNEY, M.D
Instructor in Dermatology and Syphilology, University of Michigan Medical School
ANN ARBOR, MICH.

Previous investigations on the chemical analysis of sweat have been handicapped because of the inability to obtain sufficient quantity, and because, until recent times, chemical methods were inexact Hence, there are few studies in the literature bearing on this subject

In 1900, Hoelscher,[1] made a rather extensive analysis of human sweat, investigating chiefly the nitrogenous elements; as he nowhere mentions his chemical methods, however, the value of his observations is questionable. In 1911, Riggs [2] made a short study of six normal cases, using more exact chemical methods. Perhaps the most valuable contribution along this line was made by Plaggemeyer and Marshall.[3]. These authors investigated eighteen normal fluids for nitrogenous constituents, comparing the excretory power of the skin with the kidneys. Their results in part are expressed in terms of total nitrogen, whereas it seemed to us more desirable to determine the nonprotein nitrogen, so that a comparison could be made with the blood. The average urea nitrogen per hundred cubic centimeters in their series is slightly higher than in ours.

Before attempting to investigate the chemistry of sweat in disease, it is obvious that a normal must be established.

We were concerned chiefly with the nonprotein nitrogen and urea. Urea is the principal end-product of protein metabolism. The nonprotein nitrogen includes those nitrogenous substances remaining after the protein has been precipitated, embracing chiefly urea, amino-acids, ammonia and creatinin. In an examination of five specimens, we were unable to determine the presence of uric acid either qualitatively by the murexid test or by Benedict's direct quantitative method as applied to blood.

In addition, we determined the total solids, which embrace chiefly protein, the nitrogenous elements mentioned above, and salts.

PROCEDURE

Method of Collection.—The subjects chosen for sweating were patients entering the dermatologic clinic of the University Hospital. The normals presented no dermatoses and were healthy young adults on a well balanced diet The sweat was collected about two hours before lunch and was analyzed within an hour following collection After a short cleansing bath, the subject was placed in bed between two rubber sheets. Since in two instances urine contaminated the sweat, the patient was warned in this respect. Four hot water bottles were placed on each side below the lower rubber sheet, and the subject was covered generously with blankets. One-fifth grain (0 01 gm.) of pilocarpin was injected subcutaneously, and fluids were forced. The patient remained in the sweat bath for about an hour and a half. This time was sufficient to collect amounts as high as 690 c.c. of sweat. When the patient was removed from the bath, care was taken not to lose any of the sweat. At this time, blood was drawn for a nonprotein nitrogen determination and a urinalysis was made. In every instance, the urine examination was negative.

TABLE 1—*Normal Sweat*

As obtained for analysis, the sweat was a slightly turbid fluid, as a result of the admixture of dirt and epithelial débris. In order to remove this, the sweat was filtered. This filtrate was analyzed for total solids, urea nitrogen and nonprotein nitrogen, according to the following procedure:

Methods of Analysis.—The methods devised by Folin and Wu for the analysis of blood were used with slight modification. In the precipitation of the blood protein, according to the original method, the blood is diluted with 7 volumes of water and 1 volume each of sodium tungstate and sulphuric acid added. Since sweat is already a very dilute fluid, further dilution was inadvisable Hence, the precipitation was made by adding 1 volume of sodium tungstate to 2 volumes of sweat and then adding drop by drop 1 volume of a 0 66 normal sulphuric acid. This mixture was shaken for fifteen minutes, and filtered until a clear filtrate was obtained. The filtrate gave a negative biuret test for protein

One cubic centimeter portions of this tungstic acid filtrate were used for the determination of nonprotein acuity to 20/40 or less, as repeated injuries of the same degree may finally cause loss to earning capacity.

3. A 20/200 Sn. caused a total incapacity to 13.3 per cent. and a partial incapacity to an additional 13.3 per cent, so that 26.6 per cent. in this class with vision of not better than 20/200 Sn. were either completely or partially incapacitated for earning. Eighty per cent. had earning capacity with acuity between 20/200 and 20/400 Sn.

4. A 10/200 Sn. was the point of visual acuity reduction which became the point of total incapacity in all except two cases, and this may be regarded as the lowest limit of visual earning capacity.

5. The threshold of total incapacity lies between 20/200 and 2/200 Sn., depending on the nature of the employment, age of the defective person, the duration of the subnormal vision, and on his individuality (his will to work).

6. An acuity of not better than 20/40 Sn. in the better eye does not cause a loss of 50 per cent. either in efficiency or in earning ability. This degree of acuity, in fact, causes no direct loss to earning capacity. However, its direct influence from two economic points of view must be considered: (1) that of the accumulated effect of these degrees of loss due to repeated injury, and (2) the effect of such degree of substandard vision on the competitive ability.

53 South Fitzhugh Street.

ABSTRACT OF DISCUSSION

Dr. John A. Donovan, Butte, Mont.: Compensation has become a very serious subject. Juries are giving terrific verdicts, and beware—each one of us is constantly liable to become the prey of these vultures who are forever looking up and advising lawsuits—the grasping corporations, the labor unions whose sole teachings are less work, more pay—never once do they advise as we do, efficiency, but always what? Read the reports coming from their conventions. Lastly, the public, never considered, never even interested, yet it pays all the bills. It is the public that we here should represent. In every village is the man of note, reading the law at a distance of 3 inches with his myopic eye, and with his hypertropic eye supervising the neighbors. The man with 20/60 vision who has told that he needs no glasses, that he can tell a horse from a cow a mile away, is telling the truth. We could leave this room and within twenty minutes find twenty men in whom, if they slowly lost vision down to 20/40, even if they themselves knew it, it would never make the difference of one single penny in their earning ability throughout the remainder of their lives. Who has not seen the derelict, totally unable to work, move off to greener fields the day following receiving a large compensation? Of course I am not talking of the really honest man for whom no law is necessary. The factors of quality of work, earning, competitive and saving ability, contributory negligence, all ultimately should be entered as factors in our table. Consider the high myope, ignorant of any visual defects, the astigmatic patient and even the hyperope, who by squinting sees sufficiently. Then we supply one of these with glasses after careful examination under a cycloplegic, and the patient suddenly enters a new world, but never again, as he tells his innumerable friends, can he see without glasses as he could before the drops were used. He does not, and does not want to, understand. One may record 20/25, and another man with the same patient will record 20/20, and a third man equally careful may record 20/30—all in the same patient, and all are absolutely right. Men come to me because the examiner in another division rejected them for train service. I request their reappointment, and vice versa. Who was right and at which time? We who have to deal daily with claim agents and claim attorneys of our employers and yet must give satisfaction and advise conscientiously our patients, anticipate the difficulty of making any iron bound standards, yet know it must be done. Many a man has a blind eye for months before he finds it out.

Dr. E. E. Holt, Portland, Maine: Dr. Snell refers to me as an authority on the amount of vision that may be lost without affecting the earning ability. This standard was largely based on the work of Magnus on Visual Economics as translated by Wurdemann, a work of great value on the subject of which it treats. In working out the efficiency of the various degrees of subnormal visual acuity, we should realize that we must be guided not by the extremes, but by the law of averages, the same as that on which the life table is based. Dr. Snell speaks of the effect of the visual efficiency of various degrees of subnormal visual acuity on the earning ability. Of course the ultimate effect is on that, but the first effect is on the other indispensable factor of the earning ability, namely, the competing ability, thus obtaining the two factors of the earning ability which are necessary to solve the compensation problem by mathematics in a scientific manner. Visual efficiency has no earning ability unless it is put to work in some vocation and thereby acquires a competing ability; and the two together make the product, namely, the earning ability. At the Industrial School for the Blind at Portland, I was struck with the great efficiency and competing ability of one of the boys, who was totally blind, as he sat at a typewriter writing out dictations as fast as the ordinary person talks. He took out a sheet of the typewritten letter in which he had purposely left out a letter in a word, and he put it back into the typewriter and put in the proper letter in the word so quickly that it was astounding. so that person with extreme loss of vision may acquire great competing ability and thereby have a corresponding earning ability. But it is not so much on their poor vision, but on their competing ability to do the work in spite of the poor vision, or, as in the case of the boy in the Industrial School for the Blind, with no vision.

Dr. Edward Jackson, Denver: We have had many discussions about methods of measuring visual acuity and demonstrations that a certain visual acuity meant something with reference to disability. But Dr. Snell has taken a very important step in setting the example of studying the patient with diminishing visual acuity and finding out the facts in the individual case, as to whether that diminution of visual acuity caused diminution of efficiency in their work and their earning ability. It is something that every individual ophthalmologist will have to take up, before his testimony will help a great deal, as to the effect of an injury to the eye, on the financial production of the person who has been injured. To gain an understanding of what we are talking about, it will help to try with our own eyes what we can see and what we can do, with a certain visual impairment, artificially produced for the purpose. This question was brought up before the committee of the Colorado Ophthalmological Society, with regard to the case of a claimant for blind benefits. The standard had been established that the vision must be below 1/10, in order to entitle any person to blind benefit. This woman had very noticeable optic atrophy, pallor of the optic disks and shrinking of the vessels, that showed with the ophthalmoscope. But her neighbors said she could play cards, that indeed she had made a living at teaching card playing to seeing persons. The question of playing cards is simple to decide: Just try cutting down your own vision to 1/10 and then see whether you are able to play cards. I tried it on myself and on other people, and I find with 1/10 vision one can see the cards readily. If we study carefully along the lines that Dr. Snell has indicated, how much people with impaired vision can learn to do, it will give us a better mastery of these problems that are increasing in importance every day.

Dr. Albert C. Snell, Rochester, N. Y.: The measurement of acuity is not the measurement of the physiologic function of macular vision. As Dr. Jackson has mentioned that the expression "1/10 vision" is not an accurate statement. I think we should get into the habit of expressing our notations which have a precise meaning. If we mean 1/10 Snellen we should say that. The Snellen notation is one of comparative acuity, and not a fractional expression of vision If we say 1/10 Snellen we shall be using a scientific terminology and we shall not be open to the criticism of expressing visual acuity in fractional terms when we do not mean to express fractional vision.

CHEMICAL ANALYSIS OF SWEAT

A PRELIMINARY STUDY *

ROBERT E BARNEY, M.D
Instructor in Dermatology and Syphilology, University of Michigan Medical School
ANN ARBOR, MICH.

Previous investigations on the chemical analysis of sweat have been handicapped because of the inability to obtain sufficient quantity, and because, until recent times, chemical methods were inexact. Hence, there are few studies in the literature bearing on this subject.

In 1900, Hoelscher,[1] made a rather extensive analysis of human sweat, investigating chiefly the nitrogenous elements; as he nowhere mentions his chemical methods, however, the value of his observations is questionable.

Table 1—*Normal Sweat*

In 1911, Riggs[2] made a short study of six normal cases, using more exact chemical methods. Perhaps the most valuable contribution along this line was made by Plaggemeyer and Marshall.[3] These authors investigated eighteen normal fluids for nitrogenous constituents, comparing the excretory power of the skin with the kidneys. Their results in part are expressed in terms of total nitrogen, whereas it seemed to us more desirable to determine the nonprotein nitrogen, so that a comparison could be made with the blood. The average urea nitrogen per hundred cubic centimeters in their series is slightly higher than in ours

Before attempting to investigate the chemistry of sweat in disease, it is obvious that a normal must be established.

We were concerned chiefly with the nonprotein nitrogen and urea. Urea is the principal end-product of protein metabolism. The nonprotein nitrogen includes those nitrogenous substances remaining after the protein has been precipitated, embracing chiefly urea, amino-acids, ammonia and creatinin. In an examination of five specimens, we were unable to determine the presence of uric acid either qualitatively by the murexid test or by Benedict's direct quantitative method as applied to blood.

In addition, we determined the total solids, which embrace chiefly protein, the nitrogenous elements mentioned above, and salts.

PROCEDURE

Method of Collection.—The subjects chosen for sweating were patients entering the dermatologic clinic of the University Hospital. The normals presented no dermatoses and were healthy young adults on a well balanced diet The sweat was collected about two hours before lunch and was analyzed within an hour following collection. After a short cleansing bath, the subject was placed in bed between two rubber sheets Since in two instances urine contaminated the sweat, the patient was warned in this respect. Four hot water bottles were placed on each side below the lower rubber sheet, and the subject was covered generously with blankets. One-fifth grain (0 01 gm.) of pilocarpin was injected subcutaneously, and fluids were forced. The patient remained in the sweat bath for about an hour and a half. This time was sufficient to collect amounts as high as 690 c.c. of sweat. When the patient was removed from the bath, care was taken not to lose any of the sweat. At this time, blood was drawn for a nonprotein nitrogen determination and a urinalysis was made. In every instance, the urine examination was negative.

As obtained for analysis, the sweat was a slightly turbid fluid, as a result of the admixture of dirt and epithelial débris. In order to remove this, the sweat was filtered. This filtrate was analyzed for total solids, urea nitrogen and nonprotein nitrogen, according to the following procedure:

Methods of Analysis.—The methods devised by Folin and Wu for the analysis of blood were used with slight modification. In the precipitation of the blood protein, according to the original method, the blood is diluted with 7 volumes of water and 1 volume each of sodium tungstate and sulphuric acid added. Since sweat is already a very dilute fluid, further dilution was inadvisable. Hence, the precipitation was made by adding 1 volume of sodium tungstate to 2 volumes of sweat and then adding drop by drop 1 volume of a 0.66 normal sulphuric acid. This mixture was shaken for fifteen minutes, and filtered until a clear filtrate was obtained. The filtrate gave a negative biuret test for protein

One cubic centimeter portions of this tungstic acid filtrate were used for the determination of nonprotein nitrogen and urea nitrogen according to the usual Folin-Wu technic.

The total solids were obtained by evaporating to dryness 5 c.c. of filtered sweat in a weighed crucible at 90 C.

RESULTS OF INVESTIGATIONS

The results of our investigations are expressed in the accompanying tables.

Table 1 gives a detailed account of the fourteen normal specimens examined and, in addition, the nonprotein nitrogen per hundred cubic centimeters of blood.

The percentages of nonprotein nitrogen and urea nitrogen in the total solids are so variable as to be of little comparative value.

In order to determine whether the injection of pilocarpin altered the composition of sweat, five fluids were examined without injecting the drug. Table 2 gives our results in these cases. Although the amounts of nonprotein nitrogen and urea nitrogen per hundred cubic centimeters of sweat are lower than the normals in which pilocarpin was used, the amounts excreted hourly are practically the same.

It will be seen that the composition of sweat as regards the amounts of nonprotein nitrogen and urea nitrogen per hundred cubic centimeters varies within rather wide limits. The nonprotein nitrogen ranges from 28 mg. to 200 mg. and the urea nitrogen from 14 mg. to 63 mg. per hundred cubic centimeters. It is also evident that the amount of sweat excreted bears no definite relationship to the amounts of these substances. For this reason, we were of the opinion that the best index of the excretory power of the skin could be obtained by a comparison of the amounts of nonprotein nitrogen and urea nitrogen excreted hourly.

We were particularly interested in the possible relation of the faulty excretion of sweat to the general breakdown, especially of the cardiorenal system that occurs in so-called senile eczema. In this particular condition, it might readily be assumed, as a result of the general arteriosclerosis with its associated chronic nephritis, that a failure of excretion of the nitrogenous elements through the skin might occur, and that thus held back, these substances could act as irritating factors in the production of the dermatitis.

In addition, we investigated six cases of psoriasis and three miscellaneous cases, embracing one case each of lymphoblastoma, eczema in an adult, and scarlet fever.

Table 3 gives a detailed account of the six senile eczema cases studied

Table 4 gives our results in the six psoriatic cases investigated.

Table 5 shows in detail the three miscellaneous cases examined.

Table 6 gives a summary of our results expressed in amounts per hundred cubic centimeters We found that the normal average nonprotein nitrogen per hundred cubic centimeters of the sweat is over twice that in the blood and that the urea nitrogen tends to be a little higher. The percentage of urea nitrogen in the nonprotein nitrogen of sweat is approximately the same as in blood.

Psoriasis	6	23.1 to 36.3	28.8	0.370 to 1.492	0.831	30.0 to 51.7	42.5	20.9 to 31.5	25.6
Miscellaneous	3	35.8 to 44.1	39.7	0.640 to 0.880	0.727	26.0 to 48.0	36.0	17.8 to 26.0	20.6

Table 7 shows the amounts of nonprotein nitrogen and urea nitrogen eliminated per hour in the fourteen normal cases and in the dermatoses examined, and in addition the percentage of urea nitrogen in the nonprotein nitrogen

TABLE 7—*Elimination of Nonprotein Nitrogen and Urea per Hour*

		Nonprotein Nitrogen per Hour		Urea Nitrogen per Hour		Urea Nitrogen in Nonprotein Nitrogen	
Diagnosis	No of Cases	Range, Mg	Average Mg	Range, Mg	Average, Mg	Range, per Cent	Average, per Cent
Normal (pilocarpin)	14	29.80 to 131.00	78.35	10.80 to 78.40	37.50	31.50 to 66.97	47.77
Normal (no pilocarpin)	5	44.76 to 121.90	75.47	26.64 to 76.00	46.50	58.36 to 64.83	61.34
Senile eczema	6	10.68 to 99.40 (42.30)	40.26 (28.40)	6.00 to 64.00 (23.00)	22.76 (14.60)	39.39 to 58.13	52.08 (50.14)
Psoriasis ..	6	54.00 to 95.55	66.84	33.14 to 54.20	42.18	54.81 to 69.60	60.73

As compared with the normal, the amounts of nonprotein nitrogen and urea nitrogen excreted hourly in the six eczema cases are appreciably diminished This difference is more marked if we exclude from the eczema group one case that showed values abnormally high compared with the other five The average urea nitrogen and nonprotein nitrogen excreted per hour, excluding the eczema case in which abnormally high values were obtained, is expressed in parentheses

It is of interest to note that if we exclude the case of eczema in which such high values were obtained, the greatest amount of nonprotein nitrogen and urea nitrogen excreted per hour in senile eczema is lower than the smallest amounts excreted in the psoriatic cases

The six cases of psoriasis examined show no appreciable change from the normal

The three miscellaneous cases show a distinct decrease in the output of nonprotein nitrogen and urea nitrogen when compared to the normal However, this series is too small to have any statistical value.

CONCLUSIONS

From the foregoing study, there is an apparent diminution in the output of nitrogenous elements of the sweat in so-called senile eczema

This interesting finding may have an important bearing on the etiology of this condition

The disturbance of salt metabolism, as expressed in the urine in chronic nephritis, may have its analogue in the sweat. The study of the salt output in sweat must be undertaken, therefore, to determine whether this bears, together with the nitrogenous elements, on the etiology of this condition

ABSTRACT OF DISCUSSION

DR J FRANK SCHAMBERG, Philadelphia Work of this kind will tend to increase the dignity of dermatology and will serve to indicate to others working in endocrinology and pathology that our members are doing work of fundamental character His work is of great interest and I think the undertaking is worthy of comment Ordinarily, the blood urea nitrogen is about one half of the nonprotein nitrogen, and I observe that this is primarily true when pilocarpin has been given, and when it has not been given the urea nitrogen exists in a much higher degree than the nonprotein nitrogen I presume that unless there was the greatest care of the rubber sheet, and so on, the nonprotein nitrogen might be increased and that therefore the urea nitrogen is the most important guide to the nitrogenous constituents in the sweat I was interested and somewhat astonished to hear that no uric acid was found in the sweat I have no doubt as to the accuracy of the methods employed and that this is a definite finding, but I would suggest that Dr Barney in his further studies keep this in mind Adler found uric acid in the sweat and said it was present in about one-tenth the amount excreted in the urine, almost three times that present in the blood The figures relating to the existence of nitrogenous contents in the blood in eczema are extremely interesting and may be of value in determining the etiology of the disease, and yet I think we should be very cautious before forming conclusions in view of the small number of cases under observation I understand that this is a preliminary report and is so designated, and that no definite conclusions are to be drawn from it The figures are suggestive and should be followed up, for anything that throws light on such a stubborn condition as senile eczema will be of great assistance in therapeutics

DR E E SMITH, New York About twenty-five years ago I was interested in some studies on sweat and particularly the presence of uric acid in sweat I made a very careful study, but failed to find uric acid present in any instance

DR GEORGE C ANDREWS, New York I should like to ask whether Dr Barney has found any differences in the sweat from different parts of the body, and whether the changes in the chemical content of the sweat secretion compared with the chemical changes in the blood It seems to me that Plaggemeyer and Marshall found very little analogy between the changes in the blood and in the sweat. They were quite distinct

DR WILLIAM ALLEN PUSEY, Chicago. Dr Schamberg said that such papers add to the dignity of dermatology. I might add, also to the complexity of dermatology. With the way these youngsters are coming on, this section bids fair to become within a few years a school for the nestors of the section. We are having a great deal of discussion now as to how to prepare our successors in dermatology. It seems to me that the work which is being done by the young men turned out by Wile and Wende and others leaves nothing to fear for the future. I know of nothing more impressive than these young men rising on the shoulders of their predecessors and then flying away. Within a few years we shall have a society of young dermatologists with the older ones trying to get in. I heartily congratulate Dr. Osborne and Dr. Barney on the work they have been doing.

Dr. Robert E. Barney, Ann Arbor, Mich.: Replying to Dr. Andrews, we paid no particular attention to the parts of the body from which sweat was obtained. This is a very interesting thought and perhaps at some future time we may investigate that phase. As to the analogy between the blood and sweat changes, there was no parallelism between the two.

THE PATHOLOGY OF PEPTIC ULCER OF THE STOMACH *

HOWARD T. KARSNER, M.D.
CLEVELAND

This review will be confined to a consideration of the peptic ulcer, round ulcer or simple gastric ulcer, and will omit that interesting group of acute ulcers, all discussed by Schultze,[1] which occur in acute infectious disease or which result from passive hyperemia with petechiae, from erosion by foreign bodies and other causes, and which tend to heal rapidly and leave no serious after-effects. The peptic ulcer is acute in its early stages but is peculiar in that it tends to persist and become chronic, heals slowly if at all, and may exhibit several dangerous complications and sequels.

GROSS MORBID ANATOMY

The peptic ulcer is usually a single, round or oval, sometimes distinctly elongated elliptic ulcer, situated in the posterior wall of the pyloric portion of the stomach near the lesser curvature. Except in the earliest stages, the ulcer is deep, may show a "punched out" appearance, may be funnel shaped or "terraced," usually has somewhat elevated, firm, sometimes overhanging edges, and is indurated about the base and margins. Aschoff [2] and Stromeyer [3] emphasize the fact that, in many of the terraced or conical ulcers, the edge nearer the pyloric orifice is flattened or less steep than the other parts of the margin, presumably because of the rubbing of food as it enters and passes through the narrow pyloric portion of the stomach. The peritoneal surface opposite the early ulcers often shows a local fibrinous exudate which ultimately results in fibrous adhesions between the stomach and neighboring structures. In from 5 to 10 per cent. of the cases, the ulcers are multiple, there usually not being more than two. Gruber and Kratzeisen,[4] however, report that 40 per cent. of ulcers are multiple. Only 6 per cent. are in situations other than the so-called ulcer-bearing area.

Since subtotal gastrectomy for ulcer has been practiced, much more in detail has been learned about peptic ulcer than was possible with necropsy material. With material from a large number of subtotal gastrectomies, Askanazy [5] has described the newer pathology of peptic ulcer, which we have been able to confirm by the study of ten cases in which operation was done by Dr. M. E. Blahd. It can now be said that, although the base of large chronic ulcers may be relatively clean, most ulcers are covered, and partly filled in, by an adherent granular or slimy, pale, bloody or brown tinged exudate. Under this is a layer of gelatinous, pallid or sometimes brown tinged, moderately firm material, made up of necrotic and granulation tissue. The next layer is of firm scar tissue, which, if sufficiently extensive, may, by its retraction, produce serious permanent deformity of the stomach. Hyperemia is common not only around the ulcer but often throughout most of the part of the stomach removed surgically. Hemorrhage is frequent in the exudate in the earlier ulcers and may occur in other places in the mucosa and submucosa. Chronic hypertrophic gastritis is a common, but not constant, accompaniment.

MICROSCOPIC APPEARANCE

Although, on the basis of necropsy material, peptic ulcer was formerly regarded as exhibiting little or no acute inflammation, the study of surgical material permits ready confirmation of Askanazy's observation that acute exudative inflammation is constant in the early stages. Our material includes peptic ulcer in the early stage, when there is merely loss of surface epithelium, through intervening stages to large chronic ulcers, one of which shows carcinomatous transformation. It is easily possible to find the four zones of Askanazy; namely, zones of exudation, of fibrinoid necrosis, of granulation and of cicatrization.

The exudate may be purulent, sanguinopurulent, fibrinopurulent or occasionally catarrhal. Polymorphonuclear leukocytes, which are common in the exudate occupying the surface of the ulcer, may collect in small circumscribed masses, and are also found in the zones of necrosis and granulation as well as in the surrounding mucosa and deep in the wall of the stomach. Sometimes lymphoid and plasma cells predominate. Eosinophils are often present in small numbers, but may be found in all the coats of the stomach near the ulcer. Fibrin is frequently present in the exudate on the surface of the ulcer. Fibrinous exudate may occur on the serosal surface in association with even early shallow ulcers. Hyperemia, often with edema, is common. Minute hemorrhages in the exudate, in the ulcer and in the neighboring mucosa, are frequent, as the result either of the inflammatory hyperemia or of rupture of vessels in the granulation tissue.

The zone of fibrinoid necrosis, which is grossly a gelatinous material, varies in thickness and in constitution. In addition to the ordinary cytoplasmic and nuclear changes of necrosis, there are hyaline masses which react chromatically as does fibrin. There are, however, no network, no nodules, no asters, to characterize it as fibrin. Fibrinoid material is variable in amount but may be present in ulcers of any stage. According to Askanazy; it is probably derived from the fixed connective tissue, which becomes hyaline as it undergoes necrosis.

Granulation tissue, variable in extent and not different from granulation elsewhere, appears early in the course of the ulcer and is usually still present in large,

old, chronic ulcers. The zone of necrosis often advances at the expe [illegible] zone.

When an ulcer is [illegible] marked cicatrization, it is usually a deep ulcer that involves the muscular coats. The interruption of continuity of mucosa, and other coats, implies also an interruption of continuity of blood vessels and nerves. The density of the scar appears to inhibit regeneration of the smooth muscle.

Acute lymphoid hyperplasia is frequent, especially in the earlier stages, and involves not only the nodules in the stomach but also the neighboring lymph nodes.

OTHER MORPHOLOGIC FEATURES

An examination of the features pointed out above shows that the peptic ulcer does not differ essentially from other ulcers in inflammatory reaction. The situation and nature of the lesion demand special consideration of the disturbances of blood vessels and nerves.

The vascular lesions include inflammations, sclerosis and hypertrophy. Acute periarteritis, with its perivascular infiltration of polymorphonuclear leukocytes, lymphoid and plasma cells, and acute arteritis with penetration of these cells into the vascular wall, are common in and about the earlier ulcers. Similarly, chronic lesions may occur with older ulcers. Endarteritis deformans and obliterans are frequent. These may be due to inclusion of the intima in the inflammation of the vessel walls or to thrombosis with organization and even canalization. Numerous observers have noted the frequency of arteriosclerosis. Ophuls [6] found it not only in older patients but also occasionally, apparently localized to the stomach, in young individuals. Askanazy, however, has found ulcers in patients of from 50 to 60 years or more without sclerosis of the gastric vessels. Hypertrophy of the media is rare in our experience.

As the ulcer extends and penetrates, the intrinsic nerves are severed. We have not observed this local acute neuritis, but subacute and chronic neuritis and perineuritis are common not only in the ulcer margins but also at some distance from the ulcer. In the scar tissue, Askanazy found a reduction in number of ganglion cells and loss of myelin sheath of many of the fibers. In the older ulcers, the nerve fibers may become elongated and coiled to produce masses closely resembling the amputation neuroma. If the pain of ulcer is due to irritation or exposed inflamed nerves, the relief by administration of alkali can be explained by temporary neutralization of acid.[7] The administration of magnesium sulphate probably acts through its depressant action on the nerves.

Peptic ulcers tend to penetrate rather than to extend widely laterally. Crohn, Weiskopf and Aschner,[8] by roentgenoscopic examination, find that the ulcer reaches its maximum size in a few weeks, and does not further increase in lateral diameter.

In many of the early ulcers, there is a fairly widespread acute gastritis, which may be superimposed on the chronic hypertrophic gastritis, which, in our experience, accompanies a large number of ulcers of all stages.

In addition to the marginal hyperemia, edema, hemorrhage and inflammation, the epithelial cells show cloudy swelling, mucinous degeneration with goblet cell formation, necrosis and multiplication. Mitotic figures are not infrequent. The more extensive multiplication of epithelium may result in papilliform projections about the margin of the ulcer or in extension downward of epithelial growth into the deeper tissues. Possibly this downward growth is responsible for the development of cancer. There are intermediate stages in which it is often difficult to distinguish between epithelial hyperplasia and tumor growth.

HEALING

There is no doubt that even chronic ulcers may heal, as demonstrated in scars observed especially in postmortem specimens. The roentgenoscopic observations of Crohn, Weiskopf and Aschner [8] show that the crater often fills in, but this is no evidence of true healing. Ivy,[9] on the basis of experimental work, regards the healing as taking place in two stages; the first, a stage of organization and consolidation of the defect with infolding and apposition of mucosal cells to the organizing tissue; the second, a stage of regeneration of mucosa. Griffini and Vassale [10] long ago pointed out the striking regenerative capacity of the gastric mucosa. New glands are formed from the cells of preexisting glands, and the acid cells represent a differentiation of the primary gland cells. Tunica propria grows, and a complete mucous membrane is formed.

COMPLICATIONS

Numerous complications may arise. Hemorrhage is so frequent as to be regarded as a symptom. The larger hemorrhages are probably often due to a necrosis that involves blood vessels. The necrosis may extend so rapidly that protective thrombi are not secure and are easily displaced by peristalsis, distention or increased blood pressure. General peritonitis following perforation is not as common as it might otherwise be, because of the protective adhesions that form as a result of the early localized fibrinous peritonitis.

There is no doubt that cancer follows peptic ulcer. The chief problem concerns the frequency rather than the possibility of this sequel. Wilson and MacCarty [11] reported that 71 per cent. of peptic ulcers show cancerous change. It is conceivable, however, that among the cancers in this series there were included cases that might be interpreted by others as inflammatory epithelial proliferation. MacCarty [12] subsequently stated that all ulcers exceeding a diameter of 25 mm. might be expected to show cancer. Extraordinary care must be taken, as indicated by Moskowitz,[13] before cancer can be excluded from the pathologic diagnosis, but in one of the ulcers in our material which measured 30 by 25 mm., there was no cancer. Ewing [14] found that only 5 per cent. of ulcers show cancer. The infrequency of cancer is also emphasized by Gruber [15] and Gruber and

Kratzeisen.[4] Clinically, Smithies,[16] and also Moynihan[17] and others, find that a large percentage of cancer cases give a history of preceding ulcer. Friedenwald[18] could not support this view, and Taylor and Miller[19] were able to disclose such a history in only 17 per cent. of their 182 cases of cancer. Pathologically, no information of importance can be obtained by the examination of widespread cancer, and clinically the history of symptoms may be due to the cancer itself. In the peptic ulcers we have studied, the incidence of early cancer does not exceed 10 per cent.

Cicatricial deformity of the stomach, stenoses and small diverticula are too well known to require discussion in this paper.

PREDISPOSING CAUSES

From a study of necropsy material,[20] females are found to be more commonly affected than males. Martin[21] gives the average age for males as 36.7 years and for females 27.1 years. The lesion may, however, occur at any period of life. Draper's[22] studies indicate that one type of individual is more susceptible to peptic ulcer than to gallbladder disease. There is no clear cut evidence that neurotic persons are more susceptible than others, and in any consideration of this feature the difficulty of clinical differentiation between peptic ulcer and neurosis must always be borne in mind. In the material of Gruber and Kratzeisen, peptic ulcer is no more common among victims of grastroptosis than among others. It is difficult to say that anemia predisposes to ulcer, since the ulcer may be responsible for the anemia. Ivy,[9] however, finds that, in animals, exhausting disease seems to be important in the persistence of ulcer and perhaps also in its origin. Pappenheimer and Larimore[23] discover a high incidence of gastric ulcer in animals on deficient diets The frequent occurrence of gastritis, acute and chronic, suggests the influence of these lesions as predisposing.

EXCITING CAUSES

When any disease is ascribed to so many causes as is peptic ulcer, there is great probability that no one cause is responsible. It is difficult, however, to define the interrelations of the various possible causes. In the following discussions, there will be a consideration of the more outstanding features that have been disclosed by clinical, pathologic and experimental studies.

FAULTS OF SECRETION

It is now well known that peptic ulcer is not accompanied by a constant alteration of the acidity of the gastric juice. Nevertheless, it is conceivable that at the time of origin of the ulcer there may have been a significant change of acidity. By anastomosis of the stomach and the small intestine, so that unneutralized acid comes in direct contact with the intestinal mucosa, Mann[24] observed the production of peptic ulcers that tend to become chronic. It is doubtful that these studies can be applied to peptic ulcer of the stomach, since, as Matthes[25] has shown, the intestinal mucosa is more susceptible to the deleterious action of hydrochloric acid than is the gastric mucosa. Small islands of intestinal mucosa are occasionally found in the stomach, but the incidence of these heterotopic inclusions is probably much less than that of peptic ulcer. That gastric mucosa offers some special disposing characters is indicated by the peptic ulcers in gastric mucosa isolated in Meckel's diverticulum.[26] Ivy[9] found that when caution is employed in the application of gastro-enterostomy clamps, duodenal ulcers do not occur. The ulcers in Mann's animals are probably not traumatic in origin. Mann's studies, however, are of great value as concerns human gastrojejunal ulcer, for, in the experience of Moynihan,[27] subtotal gastrectomy, with the coincident removal of the acid secreting part of the stomach, practically eliminates the chance of recurrence of the gastric ulcer and of the development of gastrojejunal ulcer Ivy and his collaborators[28] produced chronic ulcers by doses of roentgen irradiation which coincidentally depress secretion. That hyperacidity leads to persistence of the gastric ulcer is doubtful in view of the frequent incidence of anacidity in patients, but the problem has not as yet been solved experimentally because no permanent neutralization, and therefore no control state, has been effected.

Clinically, it is believed that stasis of gastric contents is important in producing chronicity of the ulcer, and this is supported by the experiments of Bolton,[29] of Friedman and Hamburger,[30] of Ivy,[9] and of others. Bolton considers that this is due to the general irritability of the gastric contents. Sweet and his collaborators[31] take the view that the traction of hyperperistaltic muscle on the margins of the ulcer delays healing. Ivy has demonstrated such hyperperistalsis and has also shown that manipulation of an ulcer in an exposed pouch delays healing. Hyperacidity might dispose to persistence of the ulcer by stimulating peristalsis, but hyperperistalsis can occur in partial obstruction without hyperacidity. Thus, although hyperacidity may play a part in some instances, it is not a necessary feature in the persistence of peptic ulcer.

VASCULAR LESIONS

Although the conical shape of the ulcer suggests that it is due to infarction, the same form might be due to greater destruction of the mucosa and submucosa than of the more resistant deeper coats. Vascular occlusion might be due to spasm, to endarteritis, to thrombosis, to bland embolism or to septic embolism. Vascular spasm will be referred to in the discussion of neuromuscular influences. Acute and chronic endarteritis with thrombosis are common, but it is impossible to say whether they are primary or secondary. Arteriosclerosis is common, but even though it may be local in the stomach of young persons,[6] it is not usually a severe disease at the average age of ulcer incidence, and it is sometimes absent in older victims of ulcer.[5] As shown by Litten,[32] and by Ivy, bland embolism of the gastric arteries, without other lesions, does not produce infarction. The injection, by Cohnheim,[33] of lead chromate, and by Payr,[34] of alcohol and of formaldehyd, led to infarction, but in these experiments there is, in addition to the occlusion of the arteries, an associated direct destruction of tissue. Although, as Berlet [35] has shown, the vascular supply of the pyloric portion of the stomach is poorer than in the cardiac end, infarction is rare in the human stomach, is usually massive, and occurs, as Baumann [36] points out, only when additional vascular lesion reduces the normally rich anastomosis. The result of an infective embolism is to be regarded as an abscess rather than an infarct. It is of interest that those diseases in which bland embolism is common, such as endocarditis and thrombosis, rarely show associated peptic ulcer, and the same is true of septicemias and pyemias.

PARASITES

Various organisms have been found in gastric ulcer, but interest centers about molds and certain bacteria, especially the anhemolytic streptococcus. Molds are common, and Askanazy reports the production of peptic ulcer by their injection. Kratzeisen,[37] confirming Hartwich,[38] regards the molds as saprophytes or symbions that merely tend to delay healing, but Kirsch and Stahnke [39] were unable to establish this view experimentally. Turck's [40] report that feeding of colon bacilli produces gastric ulcer has not been confirmed.

Rosenow [41] states that the "usual ulcer of the stomach and of the duodenum in man is primarily due to a localized hematogenous infection of the mucous membrane by streptococci," a view supported by Nakamura,[42] Haden [43] and others. McMeans [44] was unable "to support the view of elective affinity expressed by Rosenow." Celler and Thalheimer [45] could not convince themselves that anhemolytic streptococci "have been proven as yet to be the factor which either initiates the ulcer or prevents healing." Although many organisms have a certain tissue selectivity, as, for example, the pneumococcus, the gonococcus, the diphtheria bacillus and the dysentery bacillus, these are examples of species rather than strains within a species. The novel hypothesis of strain selectivity requires extraordinarily strong and indubitable support. Holman [46] emphasizes the difficulty in isolating streptococci in pure culture, a fact now well established and not in accord with the rapidity of isolation in Rosenow's work. Equally important is the fact that Rosenow worked with cultures from supposed atria of infection more often than from gastric ulcers. Ulcers were produced in 60 per cent. of the rabbits inoculated, but the number of animals employed allows of a considerable error from random sampling, and it is important to note that ulcers were not produced in 40 per cent. of the inoculated rabbits. Holman [47] has demonstrated that streptococci are extremely common nonexperimental invaders of laboratory and other animals, and may locate in many tissues where local conditions are favorable. Hence, the recovery of streptococci in experimental animals cannot be accepted as necessarily significant. In order to establish the hypothesis of Rosenow, it would seem essential to be absolutely sure of pure cultures, preferably from the ulcer itself rather than from a supposed atrium of infection, to work with animals in which the incidence of nonexperimental invasion is low, to produce ulcers almost constantly, and to recover an organism that can be identified as that which was injected. These criteria may seem severe, but when a revolutionary hypothesis is advanced, it must meet the most rigid criticism before it can be accepted, even though from many points of view it may be exceedingly attractive.

NEUROMUSCULAR INFLUENCES

Von Bergmann [48] points out the possibilities that spasm of muscularis mucosae or of arteries, or both, might cause ischemia and consequent ulcer. Spasm in the retinal arteries may persist long enough to interfere with nutrition, but this principle cannot be conclusively applied to the stomach in view of the unlikelihood of infarct, as pointed out in discussing the vascular lesions. Spasm might be due to acute neuritis of the stomach wall, but although it is possible that this lesion may be primary, it is probably much more often secondary. Mogilnitzkie [49] found atrophy of ganglion cells and gliosis in the sympathetic system of four ulcer patients; but, without controls in other patients, the observation is of questionable value. Bedarida [50] injected neurin, which paralyzes motor nerve terminals, into the stomach and produced ulcers. It is impossible to state that the paralysis caused the ulcer because similar treatment by a wide variety of nonparalyzing agents has the same

effect. According to Durante,[51] ligation and section of the splanchnic nerves is followed by gastric ulcer. Ivy[9] found that, although in dogs which died immediately after section of the vagi and splanchnics there were petechiae in the gastric and duodenal mucosa, in those which survived from one week to four months, no gastric or duodenal lesions were found. Molodaja and Egoroff[52] obtained the same results. The relation of hypermotility to healing has been discussed above. The hypermotility is apparently an intrinsic mechanism, enhanced by the presence of functionating extrinsic nerves (Ivy).

ORGANS OF INTERNAL SECRETION

The influence of ductless glands is no clearer in this connection than it is in many others. Biedl[53] noted erosion of the gastric mucosa following injections of epinephrin, but we hold this to be of little significance because of the fact that injection of many other substances may lead to the same lesion. Friedman[54] found ulcers of the stomach in five of twelve dogs subjected to repeated injections of epinephrin. In contrast, Mann[55] found a high percentage of gastric lesions in bilaterally suprarenalized cats and dogs. In forty suprarenalized dogs, Ivy found only one ulcer, although there were twenty instances of petechiae and hemorrhagic erosion. Friedman found ulcers following injection of the thyroid gland and also following partial thyroidectomy. Removal of part of the thyroid and of one suprarenal was not followed by ulcer formation. In those instances in which abdominal operations are necessary for the experiment, trauma to the stomach may occur. Even ether anesthesia may be followed by petechiae and erosions (Ivy). The assumption that partial removal of ductless glands is followed by hypofunction is unjustified. The injection of such substances as epinephrin or thyroid gland does not lead necessarily to a state identical with hyperfunction. The studies of the relationship of disturbances of ductless glands, whether they are supposed to operate directly or through the intermediation of the autonomic nervous system, have not been sufficiently correlated to permit of satisfactory conclusions.

CYTOLYSINS

Of interest are the experiments of Bolton,[29] who prepared a cytolytic immune serum by injecting gastric cells into animals of heterologous species. In his experiments, the serums appear to be highly specific for gastric mucosa, and on injection into the peritoneum or into the gastric mucosa, produce gastric ulcers. Hemolytic immune serum does not have an equally intense effect. We have obtained essentially the same results (unpublished). In order for this to be applicable to man, it will be necessary to prepare serums by injection, not only into the homologous species, but into the same animal. In other words, there must be not merely an isogastrolysin but an autogastrolysin. We have been unable to produce such a serum, and on the basis of other immune phenomena regard it as an experiment with well nigh insurmountable difficulties.

Kohler[56] has offered the hypothesis that a deficiency of antipepsin in the blood predisposes to peptic ulcer by removing the resistance to autodigestion of the mucosa, but Orator[57] is unable to confirm this supposition in a study of fifty cases.

SUMMARY

The clinical, pathologic and experimental studies briefly referred to above have not resulted in a final conclusion as to the origin of, or the reasons for persistence of, peptic ulcer. The nature of the lesion has been clarified by the study of fresh material removed by operation. The inaccessibility of the field, the abnormalities produced by rendering it accessible, the complexity of nervous and vascular supply, the unsettled state of knowledge concerning the secretory and motor functions of the organ, the difficulty of establishing a norm of form and function, the differences between lower animals and man—these and other factors have led to pitfalls in investigating the condition. The painstaking care and indefatigable energy of the numerous investigators of the disease have, however, thrown important light on the subject and have prepared the way for further and more fruitful investigations.

In summary, it may be said that pathologically peptic ulcer is an inflammatory lesion so situated that gastric juice probably emphasizes the destruction of tissue. That the inflammation is primary is suggested but not proven. Various predisposing causes seem to be operative in the patients, but these are not conclusively established. The direct exciting cause of the ulcer has not yet been disclosed in such a fashion as to be beyond doubt. The persistence or chronicity of the ulcer depends on a variety of factors, none of which can be said to operate in all cases. Probably several of these factors are coincidentally in evidence. Thus, there must be considered especially hyperacidity, stasis of neuromuscular or obstructive origin, the irritative and traumatic influence of gastric contents, and the traction of muscle about the ulcer.

Filtrability of Vaccinia Virus.—Although the filtrability of vaccinia virus has been the subject of dispute, and many careful observers, including Thomson, who has recently investigated this point, have obtained negative results, there is now no doubt that this virus is capable of passing through filters that hold up the ordinary visible pathogenic bacteria. The chief filter that has been used for this purpose is the Berkefeld, and it is generally agreed that only a small portion of the virus comes through, the bulk of it being retained by the filter. Thus, in course of ten filtering experiments with vaccinia, Rouget only got positive evidence of the presence of vaccinia virus in the filtrate in four, and found it necessary, as others have done, to inoculate large amounts of this filtrate in order to demonstrate the presence therein of the virus. All of the successful investigators appear to have taken great care to obtain the "pulp" as fresh as possible, and to break it up thoroughly. In order to set free the virus from the tissue cells containing it, Negri employed in addition maceration in the cold store for from twelve to sixteen days, a procedure that undoubtedly promotes cellular autolysis. Similarly Nicolle and Adil Bey failed to get passage of the viccinia virus through the Berkefeld filter until they first freed the virus from the tissue cells by submitting the suspension of pulp to digestion with a solution of trypsin for five hours at 38 degrees C.—Special Report No. 98, Medical Research Council, London, 1925.

THE ROENTGENOLOGIC DIAGNOSIS OF PEPTIC ULCER*

RUSSELL D. CARMAN, M.D.
Chief, Section on Roentgenology, Mayo Clinic
ROCHESTER, MINN.

Stripped of its minor details, the routine examination at the Mayo Clinic for all gastric and duodenal lesions comprises two principal features: a bariumized carbohydrate meal to test motility, and a screen examination six hours later, at which time an aqueous suspension of barium is given.

The motor test-meal consists of 2 ounces (62 gm.) of barium sulphate in an equal portion of well cooked cereal, and is given in lieu of breakfast. A retention from this meal after six hours, if no food has been taken meanwhile, is of importance for three reasons: (1) It is strongly indicative of an organic lesion of the stomach or duodenum; (2) in conjunction with certain other phenomena, to be mentioned later, it is diagnostic of duodenal ulcer, and (3) the presence of gastric retention has an important bearing on treatment.

At the fluoroscopic examination, the patient drinks a mixture of 4 ounces (125 gm.) of barium sulphate in 8 ounces (236 c.c.) of water. Special note is taken of the first swallows of the mixture as they descend from the esophagus into the stomach. After a small amount has been taken, the walls of the stomach are approximated by palpatory pressure so that their internal topography can be inspected. Attention is then directed to the duodenum, which usually fills to best advantage early. Its filling is also assisted by grasping the gastric antrum, applying the thumb of the right hand to the greater curvature and the fingers to the anterior wall, exerting pressure toward the pylorus. Blocking the distal portion of the duodenum by manual compression will sometimes be of aid. By pressure over the duodenal bulb, its contents are thinned out to permit inspection of its walls. To perform any of these manipulations effectively, it is essential that the patient's abdominal muscles be relaxed; often this relaxation is assisted by seating him for a short time. After the stomach is filled, the patient is turned to various angles so that the gastric and duodenal contours can be shown in different views. Following this, the patient should be examined on the trochoscope in the prone, supine, oblique, lateral and Trendelenburg positions. To conclude the examination, films are made for purposes of record and for further study.

ROENTGENOLOGIC SIGNS OF GASTRIC ULCER

Gastric ulcer has but one sign on which the diagnosis can be made with confidence, and that is the visualized crater of the ulcer, the niche, or its exaggerated form, the accessory pocket. In favorable situations, the niche is visible as a local prominence on the gastric silhouette. Many ulcers are situated so near the lesser curvature that in the sagittal view the niche projects sufficiently to be visible.

Ulcers on the posterior wall, in the vertical portion of the stomach, may often be brought into profile by turning the patient into an oblique or lateral position. These ulcers are sometimes revealed in the early stages of gastric filling. As the barium stream first enters the stomach, it is likely to fill the crater of an ulcer high on the posterior wall so that its site is marked by a denser circumscribed area. A posterior ulcer in the lower portion of the stomach may be revealed as a local density by approximating the gastric walls.

The accessory pocket of a perforated ulcer which has invaded an adjacent organ is so striking that it will hardly escape recognition. It is seen most commonly as a round or oval shadow projecting from the lesser curvature. Its diameter varies from 2 or 3 cm. upward. Quite often its barium content has a level upper margin capped by a bubble of air.

SECONDARY SIGNS OF GASTRIC ULCER

Secondary signs of gastric ulcer include retention from the six-hour meal, hour-glass stomach (either spastic or organic), local fixation by adhesions, hypotonus and anomalies of peristalsis. These signs are inconstant, and may have causes other than ulcer. When a niche is demonstrable, their aid is not needed. They have a certain importance, however, in two types of ulcer; namely, mucous erosions and prepyloric ulcers.

A mucous erosion is too shallow to produce a recognizable niche. An incisura may point to the site of the ulcer, the rugae may converge toward it, and a residue from the motor meal may enhance suspicion of ulcer. It is imperative, however, to construe these signs with care.

Gastric ulcers in the vicinity of the pylorus, even though the depth of their craters is considerable, are extremely difficult to reveal as true niches. Usually the area around the ulcer is irregular, and there may be a residue from the motor meal. The irregularity is, no doubt, partly spastic and partly organic, but from the picture, it is impossible to determine whether the filling defects are due to a gastric lesion or to gastrospasm from extrinsic causes.

Ordinarily, spasm of the stomach from extrinsic causes will be extinguished by antispasmodics, while that due to an intrinsic lesion will persist. Hence, a second examination should be made after giving an antispasmodic to full physiologic effect. Any deformity that persists at the second examination is either organic or, if spastic, due to a gastric lesion. One exception to this rule is to be noted: gastrospasm associated with duodenal ulcer will persist, but the presence or absence of a duodenal ulcer should be obvious at the first examination.

CARCINOMATOUS ULCERS

Ulcers that reveal only microscopic evidences of cancer and produce niches of ordinary size cannot be distinguished roentgenologically from benign ulcers. Very large ulcers are open to suspicion, for those with a diameter of 2.5 cm. or more are often malignant.

Another variety of malignant ulcer, namely, the frank neoplasm with ulcerous excavation, has roentgenologic characteristics which indicate its nature. Its crater is deep but seldom projects externally to the plane of the gastric mucosa. Surrounding it is an elevated, overhanging ridge of neoplastic tissue. If situated near the lesser curvature and subjected to palpatory pressure, the profile of its crater is crescentic. If situated on the posterior wall, distant from the curvature, the crater is seen during palpation as a central density encircled by a translucent zone. Without exception, ulcers with such features have proved at operation to be malignant.

---

* Read before the meeting on radiology in the Section on Miscellaneous Topics at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

ROENTGENOLOGIC SIGNS OF DUODENAL ULCER

The roentgenologic manifestations of duodenal ulcer are of two classes: (1) direct signs, localized to the duodenum, and (2) indirect signs, all of which are gastric.

Direct signs comprise: (*a*) the niche, and (*b*) bulbar deformity without a niche. Usually in the latter case, the niche is too shallow to be visible.

The niche is seldom large and is often extremely small, so that careful observation may be necessary to discover it. Niches are most likely to be found on the mesial border of the bulbar shadow, but they are sometimes on the basal margin, or, very exceptionally, on the lateral border. By manual pressure over the bulb, a niche on the anterior or posterior wall can often be revealed as a small dense fleck within the fainter bulbar shadow.

In most instances, a niche is accompanied by organic or spastic deformity, either in the vicinity of the niche or on the opposite border of the bulb. General deformities seem to be less common when the niche is centrally situated, and it is likely to be overlooked unless the bulb is manipulated as described.

When the bulbar contour is extensively deformed, almost any projecting recess may be assumed to be the niche, and only the most careful comparison with the findings at operation will prove or disprove the assumption. Further, the presence of a niche is not essential for diagnosis, except when no other deformity exists.

Constant deformity of the bulb is the mainstay of diagnosis. At times, cicatricial contraction is largely responsible for it; but, as a rule, it is dominantly spastic and often entirely so. The distortion takes a multitude of shapes. The bulbar shadow may be deformed on one side alone, commonly the mesial side, or on both aspects, or only at the base.

It must be admitted that deformity of the bulbar shadow is not absolutely characteristic of ulcer, and that real or apparent deformity may be due to other causes. When the bulb is but partially filled, the barium may be distributed so erratically that the shadow deformity resembles that of ulcer. By palpatory pressure, the cause of distortion should be obvious, but on single films the deformity might be mistaken for that of ulcer. Inflammatory processes in the region of the duodenum, particularly pericholecystitis, may cause duodenal deformity by adhesions. However, in my experience, less than 2 per cent. of mistaken diagnoses have been attributable to such adhesions. In this connection, it is worthy of mention that extensive adhesions often exist without distorting the duodenal outline. Cancer of the duodenum may produce deformity indistinguishable from that of ulcer, but it is extremely rare. In occasional instances, deformity seems to result from spasm induced by disease of the gallbladder or pancreas, or by more remote lesions, but it occurs so seldom that it may virtually be disregarded. The crescentic indentation of the bulb sometimes produced by the gallbladder, and deformity resulting from pressure of the bulb against the spine, will hardly deceive the examiner.

The indirect signs of duodenal ulcer, which are manifested in the stomach, are interesting, and in certain combinations may be important. Hypertonus is a common feature of nonobstructive ulcer. With the advent of obstruction, the stomach loses its tonicity and becomes enlarged. Hyperperistalsis occurs often. When obstruction is marked, antiperistaltic waves are sometimes seen. Hypermotility, as shown by an advanced position of the motor meal, is observed frequently. Obstructive ulcers cause gastric retention. Gastrospasm is exhibited as an incisura or an antral deformity.

As these secondary signs may be produced by other lesions, none, if taken singly, is diagnostic of ulcer. When bulbar deformity can be demonstrated, their aid is not needed. When obstruction is pronounced, it is difficult or impossible to fill the bulb and establish the fact of deformity. In that event, the combination of a large stomach of normal contour with hyperperistalsis and a six-hour retention is quite as diagnostic of duodenal ulcer as is bulbar deformity.

Ulcers beyond the bulb sometimes set up the triad of signs mentioned, and thus their diagnosis is feasible. In the absence of these signs, local deformities in the distal portions of the duodenum can scarcely be relied on for diagnosis, because of the irregularities of contour produced by the valvulae conniventes in this portion of the bowel. Fortunately, ulcers in this situation are not common.

PEPTIC ULCER FROM THE INTERNIST'S STANDPOINT *

LEWELLYS F. BARKER, M.D.
BALTIMORE

The old idea that chronic gastric ulcer occurs with much greater frequency than chronic duodenal ulcer has been abandoned since clinicians (especially surgeons) awakened the attention of pathologists to the frequency of the latter lesion. In 1833, the relative proportion of gastric ulcers to duodenal ulcers in necropsy reports was 39:1; in 1870, it became 12:1; in 1913, in Berlin statistics, it had fallen to 1:1. These differences in reported incidence at necropsies appear to have been due partly to negligence of close examination of the duodenum in the earlier periods, partly (before the criteria for recognition of the boundary line between pylorus and duodenum had been established) to the assumption that juxtapyloric ulcers were all of gastric origin. The view, too, that gastric ulcer occurs much more often in women than in men and duodenal ulcer more often in men than in women, has given way to the view of approximately equal incidence of both gastric and duodenal in the two sexes.

ETIOLOGY AND PATHOGENESIS

Despite the enormous number of clinical, pathologic-anatomic and experimental researches directed toward the solution of the problems of etiology and toward the recognition of the successive links in the pathogenic chain of peptic ulcers, much still remains obscure.

How far constitutional and conditional factors are responsible for the origin and for the evolution of these ulcers is being much discussed. On the one hand, familial tendency to ulcer, and the relationships of ulcer to habitus, to diathesis, to vascular (especially capillary) anomalies, to the endocrine make up, and to disharmonies of the vegetative nervous system—all speak in favor of a constitutional predisposition, which invites further investigation. On the other hand, (1) the predominant localization of the ulcers in a special narrow pathway in the stomach, in the first portion of the duodenum, and at, or near, the margins of gastroenterostomy openings; (2) the differences in fate of acute erosions occurring in the regions mentioned and of erosions occurring elsewhere; (3) the relationships of ulcers to the degree of acidity of the fluids that bathe the parts and to the force of propulsion of those fluids; (4) the frequent coexistence of ulcers with foci of bacterial infection (in distant parts of the body as well as in the mucosa of the stomach and duodenum), and (5) the periodicity of exacerbations and recurrences of ulcer symptoms, relative to seasons of the year or to periods of physical and psychic stress and strain—all these are suggestive of the importance of environmental influences (mechanical, thermal, chemical, bacterial and psychic), acting directly or indirectly on predisposed areas of the gastro-intestinal tract. There is fairly general agreement at the moment that, in most cases if not all, a multidimensional etiology is responsible, and that both constitutional and conditional factors play a rôle.

---

* Read before the meeting on radiology in the Section on Miscellaneous Topics at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

The separation of the problem of genesis into two parts, (1) that of the origin of the primary nutritive disturbance of the mucous membrane that permits of the loss of substance through autodigestion, which we speak of as an "erosion" or "acute ulcer," and (2) that of a gradual transformation of such an acute lesion into a chronic, round and more or less funnel-shaped, indurated ulcer extending into the deeper tissues, would seem to constitute a real advance. Is the nutritive disturbance that permits of autodigestion and gives rise to the acute ulcer dependent on local vascular, neurotrophic, or metastatic toxi-infectious injury? And, once an acute erosion or ulcer has occurred, why is it that it sometimes heals, sometimes undergoes evolution into a chronically progressive lesion that slowly involves the deeper parts?

Contemporary inquiries are being directed to attempts to answer these two important questions. Attention is being focused on: areas of circulatory inferiority due to developmental anomalies of the capillaries or to spasms of smooth muscle; vagosympathetic dysfunctions; local inflammations of the gastric or duodenal mucosa; bacterial agents with selective affinities for special local tissues and areas; reflex disturbances of the secretion of hydrochloric acid and pepsin; alterations of local resistance due to absence of antiferments; vasospasms of neural or endocrine origin; functional-mechanical, thermal, and chemical conditions in the gastric pathway, and traumas from food particles, violently propelled gastric contents, or (in the case of marginal ulcer) the clamps or sutures applied at a preceding gastroenterostomy. The multiplicity of these inquiries alone is revelatory of the doubts that still exist concerning the etiology and concerning the conditions of evolution of the lesions.

SYMPTOMATOLOGY AND DIAGNOSIS

A striking feature of nearly all cases in which a diagnosis of gastric or duodenal ulcer is made is the long history of subjective digestive disturbances that has usually preceded. The patients recall various discomforts—burning, bloating, gaseous eructations, flatulence, heavy feeling in the abdomen, constipation, etc.—that they have experienced, often over a period of years. Many of them have been self-treated or even professionally treated for dyspepsia, indigestion, hyperacidity, constipation or gastro-intestinal neuroses until the advent of severe pain, of nausea or vomiting, of hematemesis or melena has awakened the idea of the existence of a graver malady. In rare instances, a severe hemorrhage or signs of perforation may appear, like a "bolt out of the blue" in patients who assert that they have earlier suffered from no indications whatever of gastric or intestinal disturbance, or that their symptoms have been so mild and transitory that they have not considered them worthy of especial attention.

The majority of patients, certainly, suffer from epigastric pain, and the character of this pain is often very significant, not only for the arousal of the suspicion of the existence of an ulcer but also as giving the clue to the site of the lesion.

In gastric ulcer, the pain is prone to appear as soon as food is ingested or soon afterward, subsiding gradually but appearing again when more food is taken, so that the patient comes to dread eating and often starves himself because of this dread. When the ulcer is at the cardiac orifice, the pain may come during the swallowing of coarser food; when it is at the lesser curvature, it may not appear until from a few minutes to an hour after eating; when it is near the pylorus, the pain may be still later in appearance (though usually within two hours) and is sometimes relieved by vomiting or by gaseous eructations.

In duodenal ulcer, the time of occurrence of the pain and its relation to the ingestion of food are usually very different from the description just given of the behavior in gastric ulcer, for in duodenal ulcer the pain is prone to occur from two to four hours after eating or in the night (hence sometimes called "hunger pain," "late pain," or "nocturnal pain"), and, moreover, if the ulcer is uncomplicated, the pain is immediately and completely arrested by the ingestion of food, a fact soon learned by the patient who carries biscuits in his pocket in the day time and has a glass of milk at his bedside at night in order that he may quickly secure relief. Thus, the patient with duodenal ulcer has no dread of eating; on the contrary, he usually has a good appetite, is prone to eat freely of all kinds of food, and often looks robust and even overnourished.

Nausea and vomiting are more frequently observed in gastric than in duodenal ulcer, but are characteristic of neither.

Though the pains mentioned have been called "typical" of gastric ulcer and of duodenal ulcer, respectively, and are extremely valuable clinical clues, the fact should not be lost sight of that there is in reality no history that is constant for either gastric or duodenal ulcer, since either may be symptomless, hunger pain may sometimes occur in gastric ulcer, and pains closely resembling "ulcer pains" may be experienced in other conditions (cholecystitis, appendicitis, intra-abdominal adhesions, tabes dorsalis, functional gastrospasms, etc.). Moreover, duodenal ulcer and gastric ulcer may coexist in the same patient with corresponding confusion of the "typical" symptomatology. Periodicity of the pain with seasonal recurrence is much more commonly encountered in duodenal ulcer than in gastric ulcer, though it may sometimes be observed in the latter also.

The necessity of caution in the evaluation of the anamnesis is, therefore, obvious. As a matter of experience, the history only rarely deceives us in the case of duodenal ulcer, whereas in the case of gastric ulcer, the most alert diagnostician will frequently be misled if he relies on subjective symptoms alone. It goes without saying, therefore, that every patient suspected of ulcer should be subjected to a comprehensive diagnostic study, with accumulation of anamnestic, general physical, roentgenologic and clinical chemical data, before judgment is passed on the nature of the conditions existing.

The general physical examination is more helpful in ruling out conditions that may simulate peptic ulcer than in supplying positive indications of ulcer itself. Tenderness at certain pressure points (front and back), evidences of muscular defense in the right upper rectus, and the state of the general nutrition may be of some aid in the recognition of ulcer, but these signs are notoriously unreliable.

Nor dare the study of the stomach contents, of the feces and of the blood be accredited with as much usefulness in the diagnosis of peptic ulcer as many textbooks would lead one to believe. Gastric hyperacidity is usually marked in about three fourths of the cases of duodenal ulcer, whereas in only about one fifth of the cases of gastric ulcer is it exhibited. The acidity conditions, even on fractional analysis, are very variable in both, so much so that one comes, as his experience grows, gradually to rely less, rather than more, on them for diagnostic differentiation. A combination of (1) gastric hypersecretion (gastrosuccorrhea), (2) prolonged emptying time of the stomach, and (3) pylorospasm, the so-called "pyloric syndrome," which can be demonstrated, when it exists, by special examinations of the stomach contents alone, is more or less characteristic of "juxtapyloric ulcer"; but the dangers of passing the stomach tube in patients with either gastric or duodenal ulcer should not be underestimated.

The examination of the feces for occult blood after three days of hemoglobin-free diet is a valuable technical method, but the absence of blood does not exclude ulcer; most ulcer patients that show occult blood in the feces can be made occult blood free by a few days of appropriate medical therapy. An anemia of the secondary type with marked reduction of the hemoglobin content of the blood may give the clue to repeated small hemorrhages from ulcer.

Outspoken hematemesis or melena is strongly suggestive of peptic ulcer but may be due to carcinoma, esophageal varix or hemorrhagic diathesis; even in cholecystitis, in appendicitis, and in splenic anemia, manifest hemorrhage from the gastro-intestinal tract may occur in the absence of ulcer.

The so-called premonitory signs of perforation of an ulcer (feeling of bloating, feeling of intestinal blockage, symptoms of localized peritonitis) should be kept in mind, but experience shows that they only rarely are, in themselves, sufficiently distinctive to serve as prophylactic guides. Too often the excruciating pain and collapse of perforation occur unannounced. The symptoms of "concealed perforation" and of "organ penetration" are difficult of interpretation, certainly without roentgen-ray control.

Roentgenologic studies are, of course, of the utmost importance in confirming and extending the diagnostic data in ulcer. They are dealt with by other speakers in this symposium. But reliance is to be placed on roentgen-ray reports only when they emanate from competent roentgenologists. Every internist has learned to be on his guard against the misleading data supplied by inexpert roentgen-ray observers. Any technician can make plates or roentgenoscopic examinations, but adequate interpretation of what is seen in plates and on the screen is not every man's métier.

THERAPY

General practitioners and consulting internists see ulcers in the earlier stages and more of the milder cases than do the surgeons, whose experience is largely confined to severer cases, later stages, and complications. It is, therefore, easy to understand the difference in the attitude of these two groups with regard to medical therapy and surgical therapy, respectively. As knowledge has grown and as experiences have accumulated, the indications for medical treatment on the one hand and for surgical intervention on the other have become even more precise, and opinions in medical and surgical circles are gradually coming into accord.

All internists now concede that when complications occur that seriously threaten life, surgery should not be delayed. Thus, in cases of perforation (or of threatened perforation), of recurring severe hemorrhage, of organic stenosis, of complicating perigastritis or periduodenitis with adhesions, and of the severer sequelae generally, there can be no question of the necessity of prompt surgical intervention. And in cases in which removal of focal infections combined with well planned and well conducted medical therapy has failed to relieve the symptoms, to prevent frequent recurrences, or to restore a satisfactory state of nutrition, surgical aid should be invoked.

On the other hand, most internists and, I believe, many surgeons favor a fair trial of the more conservative forms of therapy in cases other than those just referred to, and especially in all uncomplicated cases, with the aim (1) of relieving the symptoms, (2) of preventing the progress and of promoting the healing of the ulcer or ulcers present, and (3) of removing as far as possible conditions that might be responsible for the development of new ulcers.

Time will not permit of a discussion of the details of such conservative therapy; only the main principles can be mentioned. The measures to be applied are mainly of a protective nature. Not alone the ulcer should be shielded; the organism as a whole should be guarded from injuries. Hence, diet, physical and psychic rest, and the removal of toxic and infectious influences are the chief means to be employed; foci of infection within the abdomen as well as extra-abdominal foci should receive due consideration.

In planning the dietary, three fundamental features should be borne in mind: (1) the food should be mechanically nonirritating; (2) it should be so chosen and administered as not to increase the hydrochloric acid content of the stomach juice and not to favor hypersecretion, and (3) the food given, while relatively small in volume, should be adequately varied and of a caloric value sufficient to restore and maintain a normal state of nutrition.

Many dietaries have been recommended, but not a few of them deviate from the fundamental requirements just referred to; if used, they should be modified so as to conform to them. Rigid schemes for universal application in ulcer cases are better avoided; the dietary should be individualized to meet each patient's special needs. Any one with a fair knowledge of dietetics should be able to plan a well-balanced diet with no coarse constituents, poor in salt, condiments and extractives, and containing an adequate amount of protein and vitamins, and as much of the calory-rich carbohydrates and fats as may be needed gradually to increase or diminish the body weight to its calculated ideal. Alcohol, tobacco and strong coffee or tea should be interdicted Hypersecretion can be combated by making the meals small, with intervals of two hours between them.

At the beginning of treatment, rest should be enjoined; there should be a short period of complete digestive rest and a longer period of total bodily rest (in bed) with protection from all disturbing psychic influences. But milder cases do not require a prolonged period of absolute rest; indeed, the tendency at present, the result of war experience, is to change to an ambulatory regimen much earlier than was formerly thought permissible. Chronic ulcers are not healed in a month or six weeks, even if a patient remains quietly in bed for that length of time. The abolition of symptoms is by no means synonymous with the healing of the ulcer; symptoms can be made to disappear quickly, but epithelization of the surface of an ulcer and healing in its depths with scarring are very long and tedious processes. It is therefore impracticable to keep peptic ulcer patients at rest until the lesions are healed; but a short period of rest at the beginning of treatment is decidedly advantageous

Drugs have their place in ulcer therapy, but their value has been overestimated and the amounts used have been excessive Particularly is this true of alkalis, the free and reckless use of which may be attended by dangers of intoxication. Remedies for the alleviation of spasm (belladonna, hyoscyamus, papaverin, phenobarbital) may be given in small but frequently repeated doses. Cautious intravenous injection of foreign proteins have recently been highly vaunted for the speedy alleviation of ulcer symptoms, and would seem worthy of further testing. Pain, vomiting and hemorrhage may require special symptomatic treatment for their control, but are usually easily and quickly amenable.

After the symptoms have been relieved and a normal state of nutrition has been restored, the patient should be kept permanently, that is, for the rest of his life, on a protective regimen, the diet, work and recreation being arranged in conformity with this, while the bodily and mental health generally are kept at as high a level as possible. This advice would seem to be valid even for patients who have resorted to surgical intervention. Might not surgical results in cases of peptic ulcer be far better than they are, if, after operation, the patients were always closely supervised and hygienically directed, according to the principles of medical therapy?

Dilatation of the Heart.—Pure hypertrophy of the heart is of rare occurrence, and it does not produce sufficient enlargement of the heart to be recognized by physical examination. Increase in size of the heart is the result of dilatation of the cardiac chambers, a condition in which the heart contains a much larger amount of blood than normal at the end of systole One reads in the older textbooks on pathology of a concentric hypertrophy, that is, an hypertrophy without dilatation of the cavities, but it is doubtful whether this ever occurs In all the cases of hypertrophy of the heart that the student will study in the clinic, the hypertrophy will be combined with dilatation An increase in the unit volume of blood received in diastole and expelled during systole does not cause a sufficient increase in the size of the heart to be recognized clinically (Straub). In violent exercise the systolic output of blood is greatly augmented, and more blood enters the ventricle during each diastole than occurs in any form of valvular heart disease, no matter how severe the valvular defect may be—Pratt, J H, and Bushnell, G E: Physical Diagnosis of Diseases of the Chest, Philadelphia, W B Saunders Company, 1925

GASTRIC AND DUODENAL ROENTGEN-RAY FINDINGS AFTER OPERATION [*]

JAMES T. CASE, M D.
BATTLE CREEK, MICH

My purpose in this communication is to set forth briefly the objectives to be attained by roentgen-ray examination after gastric and duodenal operations, the technic of such examination and some details of the principal findings.

One of the most successful of stomach operations is gastro-enterostomy In the great majority of cases, it gives brilliant results; nevertheless, every physician having occasion to treat or examine a large gastro-intestinal clientele sees a considerable number of gastro-enterostomized persons who complain of more or less serious postoperative disturbance Naturally, only the dissatisfied patients return to the clinician, and the internist who sees a considerable number of this class is apt to feel an unjustified lack of confidence in the operation The foregoing is true, more or less, of all the different forms of operation involving an anastomosis between the stomach and the intestine, as well as the various plastic operations for modification of the pylorus and resection of gastric tumors and gastric and duodenal ulcers

In 1915, before the surgical section of this association, I [1] presented some roentgen-ray studies on patients who had been subjected to various gastric and intestinal operations Prior to that date, the outstanding contributions on this subject were by Cannon and Blake, Guibe,[2] Hartel,[3] Outland, Skinner and Clendening,[4] (1913), Hartmann,[5] Cohn [6] and Barsony [7] (1914). In 1915, Carman and Balfour [8] also presented their classical study on gastrojejunal ulcers, which included very interesting and helpful roentgenologic findings Later, gastroduodenal postoperative roentgen-ray studies have been published by Zollschau,[9] Butsch,[10] Eusterman,[11] Pirie,[12] von Bergmann,[13] Krause,[14] Goetze,[15] Christophe,[16] H. Béclère,[17] Savignac,[18] Hellmer [19] and Moreau and Murdock.[20]

diagnostic study, with accumulation of anamnestic, general physical, roentgenologic and clinical chemical data, before judgment is passed on the nature of the conditions existing.

The general physical examination is more helpful in ruling out conditions that may simulate peptic ulcer than in supplying positive indications of ulcer itself. Tenderness at certain pressure points (front and back), evidences of muscular defense in the right upper rectus, and the state of the general nutrition may be of some aid in the recognition of ulcer, but these signs are notoriously unreliable.

Nor dare the study of the stomach contents, of the feces and of the blood be accredited with as much usefulness in the diagnosis of peptic ulcer as many textbooks would lead one to believe. Gastric hyperacidity is usually marked in about three fourths of the cases of duodenal ulcer, whereas in only about one fifth of the cases of gastric ulcer is it exhibited. The acidity conditions, even on fractional analysis, are very variable in both, so much so that one comes, as his experience grows, gradually to rely less, rather than more, on them for diagnostic differentiation. A combination of (1) gastric hypersecretion (gastrosuccorrhea), (2) prolonged emptying time of the stomach, and (3) pylorospasm, the so-called "pyloric syndrome," which can be demonstrated, when it exists, by special examinations of the stomach contents alone, is more or less characteristic of "juxtapyloric ulcer"; but the dangers of passing the stomach tube in patients with either gastric or duodenal ulcer should not be underestimated.

The examination of the feces for occult blood after three days of hemoglobin-free diet is a valuable technical method, but the absence of blood does not exclude ulcer; most ulcer patients that show occult blood in the feces can be made occult blood free by a few days of appropriate medical therapy. An anemia of the secondary type with marked reduction of the hemoglobin content of the blood may give the clue to repeated small hemorrhages from ulcer.

Outspoken hematemesis or melena is strongly suggestive of peptic ulcer but may be due to carcinoma, esophageal varix or hemorrhagic diathesis; even in cholecystitis, in appendicitis, and in splenic anemia, manifest hemorrhage from the gastro-intestinal tract may occur in the absence of ulcer.

The so-called premonitory signs of perforation of an ulcer (feeling of bloating, feeling of intestinal blockage, symptoms of localized peritonitis) should be kept in mind, but experience shows that they only rarely are, in themselves, sufficiently distinctive to serve as prophylactic guides. Too often the excruciating pain and collapse of perforation occur unannounced. The symptoms of "concealed perforation" and of "organ penetration" are difficult of interpretation, certainly without roentgen-ray control.

Roentgenologic studies are, of course, of the utmost importance in confirming and extending the diagnostic data in ulcer. They are dealt with by other speakers in this symposium. But reliance is to be placed on roentgen-ray reports only when they emanate from competent roentgenologists. Every internist has learned to be on his guard against the misleading data supplied by inexpert roentgen-ray observers. Any technician can make plates or roentgenoscopic examinations, but adequate interpretation of what is seen in plates and on the screen is not every man's métier.

THERAPY

General practitioners and consulting internists see ulcers in the earlier stages and more of the milder cases than do the surgeons, whose experience is largely confined to severer cases, later stages, and complications. It is, therefore, easy to understand the difference in the attitude of these two groups with regard to medical therapy and surgical therapy, respectively. As knowledge has grown and as experiences have accumulated, the indications for medical treatment on the one hand and for surgical intervention on the other have become even more precise, and opinions in medical and surgical circles are gradually coming into accord.

All internists now concede that when complications occur that seriously threaten life, surgery should not be delayed. Thus, in cases of perforation (or of threatened perforation), of recurring severe hemorrhage, of organic stenosis, of complicating perigastritis or periduodenitis with adhesions, and of the severer *sequelae generally, there can be no question of the* necessity of prompt surgical intervention. And in cases in which removal of focal infections combined with well planned and well conducted medical therapy has failed to relieve the symptoms, to prevent frequent recurrences, or to restore a satisfactory state of nutrition, surgical aid should be invoked.

On the other hand, most internists and, I believe, many surgeons favor a fair trial of the more conservative forms of therapy in cases other than those just referred to, and especially in all uncomplicated cases, with the aim (1) of relieving the symptoms, (2) of preventing the progress and of promoting the healing of the ulcer or ulcers present, and (3) of removing as far as possible conditions that might be responsible for the development of new ulcers.

Time will not permit of a discussion of the details of such conservative therapy; only the main principles can be mentioned. The measures to be applied are mainly of a protective nature. Not alone the ulcer should be shielded; the organism as a whole should be guarded from injuries. Hence, diet, physical and psychic rest, and the removal of toxic and infectious influences are the chief means to be employed; foci of infection within the abdomen as well as extra-abdominal foci should receive due consideration.

In planning the dietary, three fundamental features should be borne in mind: (1) the food should be mechanically nonirritating; (2) it should be so chosen and administered as not to increase the hydrochloric acid content of the stomach juice and not to favor hypersecretion, and (3) the food given, while relatively small in volume, should be adequately varied and of a caloric value sufficient to restore and maintain a normal state of nutrition.

Many dietaries have been recommended, but not a few of them deviate from the fundamental requirements just referred to; if used, they should be modified so as to conform to them. Rigid schemes for universal application in ulcer cases are better avoided; the dietary should be individualized to meet each patient's special needs. Any one with a fair knowledge of dietetics should be able to plan a well-balanced diet with no coarse constituents, poor in salt, condiments and extractives, and containing an adequate amount of protein and vitamins, and as much of the calory-rich carbohydrates and fats as may be needed gradually to increase or diminish the body weight to its calculated ideal. Alcohol, tobacco and strong coffee or tea should be interdicted. Hypersecretion can be combated by making the meals small, with intervals of two hours between them.

At the beginning of treatment, rest should be enjoined; there should be a short period of complete digestive rest and a longer period of total bodily rest (in bed) with protection from all disturbing psychic influences. But milder cases do not require a prolonged period of absolute rest; indeed, the tendency at present, the result of war experience, is to change to an ambulatory regimen much earlier than was formerly thought permissible. Chronic ulcers are not healed in a month or six weeks, even if a patient remains quietly in bed for that length of time. The abolition of symptoms is by no means synonymous with the healing of the ulcer; symptoms can be made to disappear quickly, but epithelization of the surface of an ulcer and healing in its depths with scarring are very long and tedious processes. It is therefore impracticable to keep peptic ulcer patients at rest until the lesions are healed; but a short period of rest at the beginning of treatment is decidedly advantageous.

Drugs have their place in ulcer therapy, but their value has been overestimated and the amounts used have been excessive. Particularly is this true of alkalis, the free and reckless use of which may be attended by dangers of intoxication. Remedies for the alleviation of spasm (belladonna, hyoscyamus, papaverin, phenobarbital) may be given in small but frequently repeated doses. Cautious intravenous injection of foreign proteins have recently been highly vaunted for the speedy alleviation of ulcer symptoms, and would seem worthy of further testing. Pain, vomiting and hemorrhage may require special symptomatic treatment for their control, but are usually easily and quickly amenable.

After the symptoms have been relieved and a normal state of nutrition has been restored, the patient should be kept permanently, that is, for the rest of his life, on a protective regimen, the diet, work and recreation being arranged in conformity with this, while the bodily and mental health generally are kept at as high a level as possible. This advice would seem to be valid even for patients who have resorted to surgical intervention. Might not surgical results in cases of peptic ulcer be far better than they are, if, after operation, the patients were always closely supervised and hygienically directed, according to the principles of medical therapy?

Dilatation of the Heart.—Pure hypertrophy of the heart is of rare occurrence, and it does not produce sufficient enlargement of the heart to be recognized by physical examination. Increase in size of the heart is the result of dilatation of the cardiac chambers, a condition in which the heart contains a much larger amount of blood than normal at the end of systole. One reads in the older textbooks on pathology of a concentric hypertrophy, that is, an hypertrophy without dilatation of the cavities; but it is doubtful whether this ever occurs. In all the cases of hypertrophy of the heart that the student will study in the clinic, the hypertrophy will be combined with dilatation. An increase in the unit volume of blood received in diastole and expelled during systole does not cause a sufficient increase in the size of the heart to be recognized clinically (Straub). In violent exercise the systolic output of blood is greatly augmented, and more blood enters the ventricle during each diastole than occurs in any form of valvular heart disease, no matter how severe the valvular defect may be.—Pratt, J. H., and Bushnell, G. E.: Physical Diagnosis of Diseases of the Chest, Philadelphia, W. B. Saunders Company, 1925.

GASTRIC AND DUODENAL ROENTGEN-RAY FINDINGS AFTER OPERATION [*]

JAMES T. CASE, M.D.
BATTLE CREEK, MICH.

My purpose in this communication is to set forth briefly the objectives to be attained by roentgen-ray examination after gastric and duodenal operations, the technic of such examination and some details of the principal findings.

One of the most successful of stomach operations is gastro-enterostomy. In the great majority of cases, it gives brilliant results; nevertheless, every physician having occasion to treat or examine a large gastro-intestinal clientele sees a considerable number of gastro-enterostomized persons who complain of more or less serious postoperative disturbance. Naturally, only the dissatisfied patients return to the clinician, and the internist who sees a considerable number of this class is apt to feel an unjustified lack of confidence in the operation. The foregoing is true, more or less, of all the different forms of operation involving an anastomosis between the stomach and the intestine, as well as the various plastic operations for modification of the pylorus and resection of gastric tumors and gastric and duodenal ulcers.

In 1915, before the surgical section of this association, I [1] presented some roentgen-ray studies on patients who had been subjected to various gastric and intestinal operations. Prior to that date, the outstanding contributions on this subject were by Cannon and Blake, Guibe,[2] Hartel,[3] Outland, Skinner and Clendening,[4] (1913), Hartmann,[5] Cohn [6] and Barsony [7] (1914). In 1915, Carman and Balfour [8] also presented their classical study on gastrojejunal ulcers, which included very interesting and helpful roentgenologic findings. Later, gastroduodenal postoperative roentgen-ray studies have been published by Zollschau,[9] Butsch,[10] Eusterman,[11] Pirie,[12] von Bergmann,[13] Krause,[14] Goetze,[15] Christophe,[16] H. Béclère,[17] Savignac,[18] Hellmer [19] and Moreau and Murdock.[20]

VALUE OF POSTOPERATIVE ROENTGEN-RAY STUDIES

Postoperative studies serve various useful purposes:

(*a*) With the modern facilities for bedside roentgen-ray studies so developed that the making of a postoperative roentgenogram need give the patient no discomfort whatever, a roentgen-ray study may be made immediately after an operation in which untoward symptoms that have to do with the mechanics of the stomach develop.

(*b*) Routine postoperative studies shortly after operation, say on the fifteenth to the twenty-fifth day, afford a valuable check to the surgeon and are useful for research.

(*c*) At any time during the first six months after operation, light on new or persisting symptoms may be afforded.

(*d*) Examinations made long after the operation in patient's doing well from a clinical standpoint aid in determining which are the more useful types of gastric and duodenal operations.

The clinical history and, if possible, the details of the operative procedure should be in the hands of the roentgen-ray examiner. It is just as impossible to base one's diagnosis on the roentgen-ray findings alone in the case that has come to operation as in the one that has not. There is, in fact, in the case in which operation has been performed the additional factor of probable postoperative adhesions to complicate the interpretation of the roentgen-ray findings. At all events, examination of the function of the stomach as seen roentgenologically is only a part of the total clinical examination.

TECHNIC OF THE ROENTGEN-RAY STUDY

The examination should be comprehensive, the patient being studied in the frontal and various oblique positions, both erect and lying. In some cases, the ingenuity of the examiner will be taxed to get the patient into a suitable position to study the anastomotic stoma. Sometimes it will be necessary, by the palpating hand or wooden spoon, to lift up the lower border of the stomach during the screen study. The Trendelenburg position may be helpful in an occasional case. The first part of the opaque meal, consisting of from 2 to 4 ounces (62 to 125 gm.) of barium-water mixture, should be administered while the patient is standing in the vertical fluoroscope. With a small quantity of this type of opaque medium, palpation under the fluoroscopic screen is likely to be more fruitful than with the full meal, the administration of which should be deferred until the fluoroscopic studies are almost completed. Observations in various attitudes in the horizontal position should next be recorded. The fluoroscopic study is the most essential part of a postoperative roentgen-ray investigation, but as many films should be exposed as may be necessary to make permanent record of fluoroscopic findings or to give a better view of fine points of detail. Frequent observations are necessary, preferably once an hour, until the stomach has been emptied. Pirie's results show how valuable may be such a careful and prolonged postoperative fluoroscopic study as an aid in the clinical management of cases after operation.

The examiner should remark on the size of the stomach when filled with the usual meal; the direction of the long axis of the stomach (a line adjoining the cardia with the stoma); the vigor and direction of peristaltic waves; the path chosen by the opaque material in leaving the stomach, whether by pylorus (either spontaneously or under pressure of the palpating hand) or by the new opening; whether any of the material backs into the short-circuited loops; how long it takes the stomach to empty; whether the larger part passes out within the first few minutes, three hours or more being required for the remainder, or whether the emptying is more regularly performed. Are there any niches or pockets that remain filled after most of the meal has passed? What is the relation of points of localized pressure pain to the stoma? Is the stomach as mobile as it should be? Are there any filling defects suggestive of recurrent carcinoma?

For the urgent case studied at once after operation when, if it occurs at all, symptoms of gastric stasis become evident, usually within the first forty-eight hours, I do not hesitate to administer from 10 to 20 gm. of barium sulphate stirred in water, which may be given to the patient in spoonful doses or through a duodenal tube. After from one to two hours, by means of the draw sheet, the patient can be lifted enough to place the roentgen-ray film beneath him, and with a bedside roentgen-ray equipment an anteroposterior roentgenogram of the stomach can be made without removing him from his bed. Thus, within from one to two hours, one may obtain positive evidence for or against acute gastric obstruction.

In my surgical work, all patients for gastric and duodenal operation come to the operating table with a duodenal tube already in place. By leaving off the metal tip, there is rarely any difficulty in passing such a tube through the nose, or if already passed by mouth, it is a simple matter to bring the upper end back through the nose by the aid of a small catheter. This tube, useful for keeping the stomach empty and for lavage when indicated, is also useful for the introduction of the opaque material in those cases in which it seems desirable to make a roentgen-ray study from one to two days immediately after a gastro-duodenal operation. The duodenal tube should be removed as soon as gastric lavage through the tube shows the stomach to be emptying itself.

In the postconvalescent study of patients subjected to the ordinary short-loop posterior gastro-jejunostomy, with rare exceptions, the opaque material begins at once to pass through the stoma even before the stomach is filled. In a series of seventy-two gastro-enterostomies, barium was seen to pass through the stoma in seventy patients, and in one of the remainder, the preoperative subjective symptoms had been entirely relieved and weight gained, although the gastric clearance was still slow. In a series of sixty-five cases, some barium was seen to pass through the pylorus in fifty-two, but in twenty of the fifty-two cases, pressure of the palpating hand was necessary to pass the barium through the pylorus. The proportion passing through the pylorus represented only a fraction of the total meal.

The stoma should lie at or near the lowest point of the stomach when the patient is in the erect position. When the stoma is too high, the stomach empties quickly until the level of the stoma is reached, after which the gastric evacuation is much too slow. In a series of cases in which the gastro-enterostomy opening was made exactly on the greater curvature, the average emptying time of the stomach was practically the same as in an equal number of cases in which the stoma was placed conveniently near the greater curvature but without any special effort to put it exactly on the greater curvature.

Béclère[17] believes that the stoma should be located at the lowest point of the stomach very near the pylorus. The contours of the operative zone should be somewhat retracted, but they should be regular. The evacuation occurs by jets, the total duration of the passage of a bolus, or jet, being about thirty seconds, an interval of about three minutes occurring between jets. His paper is accompanied by roentgenograms illustrating the passage of one of these jets. His observations agree entirely with the work of Cannon and Blake and with the observations that I published ten years ago.

Hartmann and his followers urge the necessity of placing the stoma as near the pylorus as possible.

Goetze sutured small metal beads on the inside of the stomach at the upper and lower end of the anastomosis so that they remained visible for weeks. He was thus able to observe that the anastomosis usually lies higher than was intended even when the surgeon thinks he has made it at the lowest point. He assumes that, in drawing the posterior wall of the stomach forward out of the slit in the mesocolon, the pyloric part frequently remains fixed on account of posterior perigastritis, while the higher part of the body which lies more to the left follows without resistance. If the anastomosis really lies at the lowest point, there is rapid precipitate emptying, and a tendency of the stomach to grow smaller secondarily. When the pylorus has been occluded at operation by any means other than complete division and suture of the stomach, it usually reopens within a few months, sometimes within a few weeks. But even with the pylorus permeable, the great bulk of the barium meal finds its way through the stoma.

Some have declared that the stomach after operation becomes notably smaller than before operation. This is doubtful. In the postoperative examination, evacuation usually begins to occur before the stomach is filled, and this gives the impression of diminished size. Furthermore, since the duodenojejunal angle is more or less fixed, the lower border of the stomach may be held in a higher position than usual when a very short loop of jejunum is employed for the anastomosis, and this adds to the false impression of diminished size of the stomach because the lower border is held at a higher level.

Peristalsis is distinctly less marked than in the nonoperated stomach. Sometimes it is plainly seen in patients who are symptomless. There is no disturbing dilatation of the jejunum below the stoma, and if the gastro-enterostomy is functioning normally, the duodenum is not dilated. Study of the stoma may sometimes reveal adhesions, but its appearance is symmetrical, rarely deformed. There is usually a slight retention of barium in the jejunum just opposite the stoma. This may have to do with the comparative frequency of gastrojejunal ulcer following gastrojejunostomy.

For many years, gastro-enterostomy was looked on as a drainage operation; but Cannon's classic studies on the movement of food after gastro-enterostomy indicate that a purposive control of the new opening is sooner or later established. Goetze holds that fundamental principles in gastric surgery demand that the postoperative form and function will correspond as nearly as possible to those of the normal stomach. In 1915, I declared my belief that in normally functioning cases the passage of material from the stomach occurs very much as in the normal patient who has not been operated on. With the barium-water mixture, the very first swallow of opaque material usually finds its way at once into the jejunum; then there is a certain brief delay after which the passage of food boluses is irregularly intermittent, and the total time required for the clearance of the barium meal averages from three to four and one-half or five hours, depending somewhat on the nature and quantity of the opaque meal.

The average emptying time in sixty gastro-enterostomies that clinically gave perfectly satisfactory results was three hours and forty minutes, a barium meal consisting of 4 ounces (120 c.c.) of barium-water mixture followed by 10 ounces (295 c.c.) of a mixture of barium suspended in buttermilk or warm malted milk being employed. The average emptying time of fifteen perfectly satisfactory cases examined within three weeks of the day of gastro-enterostomy was four hours and twelve minutes. The average emptying time of another series of fifteen satisfactory cases in which operation had been performed more than three years before the postoperative roentgen-ray test was four hours and eight minutes.

Cannon and Blake found that when pyloroplasty had been performed, rapid exit of food from the stomach was prevented by the formation of a rhythmically contracting constriction ring in the duodenum. They believed that this activity replaced in part the function of the pylorus. I have observed evidence of this phenomenon in about one half of the cases in which a Finney or other pyloroplastic sphincter-destroying operation has been done. It is interesting to note that an analogous phenomenon was seen in a fair percentage of cases in which the ordinary gastrojejunostomy has been performed. It is my impression that the surgeon need not fear making the gastro-enterostomy opening too large; the danger is that the opening may prove too small. After all, within reasonable bounds, the size of the gastro-enterostomy opening depends on the caliber of the jejunum below the opening and not on the diameter of the opening itself. Hence, it is better that any error on the part of the surgeon should be in the direction of a larger rather than a smaller opening. In a number of patients clinically well and entirely satisfied with their operation, in whom ordinary gastrojejunostomy has been performed, it has seemed to me clear that a sort of sphincter action is established in the jejunum below the stoma. This was at first interpreted as a spastic contraction of the circular muscle of the jejunum, but in the light of Cannon's studies and many years of personal observation of these cases in the fluoroscopic room, it seems reasonable to conclude that this contraction ring in the jejunum is purposive, serving somewhat as a sphincter. Kocher, many years ago, stated that the gastro-enterostomy developed a sphincter action and actually underwent rhythmic contractions. Later writers have felt that these contractions were due to temporary alterations in the form or angle of the stoma incident to the passage of peristaltic waves in the stomach.

There is no longer any question of an autonomous sphincter capable of coordination. It never completely suffices for active powerful closure even when most favorably situated in the antrum whose stronger musculature, as mentioned by Hartmann, produces an intragastric pressure from four to eight times greater than that obtaining in the body of the stomach. Under pathologic conditions, on the other hand, the new stoma may contract completely and produce total occlusion, if its lumen was not too large in the beginning. But in the latter case, the resistance offered is no longer furnished by the anastomotic ring but by the cross section of the spastically contracted jejunum.

These observations regarding establishment of a sphincteric control at the stoma are strengthened by roentgen-ray studies on patients operated on many years ago. A man in whom, twenty-three years ago, posterior gastro-enterostomy for cicatricial pyloric obstruction was performed, with the use of a button for intestinal anastomosis, recently offered himself for examination although he considered himself in perfect health. At present, the roentgen-ray study shows the stomach, when filled, to be normal in size and shape. In the erect position, the stoma was located vertically below the cardiac orifice. Peristaltic waves were seen on the lesser curvature, commencing in the usual position and passing through to the pylorus. No peristaltic waves were seen on the greater curvature above the stoma, but were slightly in evidence between the stoma and the pylorus. A minute or two elapsed before opaque material began to leave the stomach. Some barium was seen to go through the pylorus, and on manipulation the duodenal bulb filled fairly well. Approximately two-thirds of the material passed through the stoma. There was no dilatation or reverse peristalsis in the duodenum. The stomach required nearly five hours for emptying our standard opaque meal.

De Luna[21] also reported a case in which, twenty-three years before, anterior gastro-enterostomy was performed. The patient had had no gastric or intestinal trouble at any time since. He still complained of the necessity of not eating too much at a time, and on rare occasions, vomited small quantities of bile. Roentgenologic study showed the gastric wall supple, the stoma, situated at the lowest point, functioning in a regular and rhythmic manner. The boluses of food in the upper intestinal loop were distinctly held there a certain length of time.

Christophe[16] has recently reported on the final results in some cases of Hartmann.[5] This surgeon is an advocate of placing the stoma as near as possible to the pylorus with the idea of utilizing the pressure of evacuation of the pyloric antrum, which is from four to eight times greater than in the vertical portion of the stomach. In the cases reported, operation was performed from four to eighteen years ago. He found that the barium hardly reaches the stomach before it begins to leave by the new opening. There is in some instances a situation in which the atonic stomach empties through a wide open orifice through which the barium runs passively. In many cases, but not in all, the rush of barium through the stoma stopped when stomach contractions began, gastric clearance then proceeding by ejaculations more or less rhythmic. It is more logical to admit that the strong contractions of the musculature of the stomach can in certain cases periodically close the opening. Härtel also takes this view. In fact, it seems that the gastric ejaculation precedes by a little the passage of the peristaltic wave.

One can understand easily enough how a complete relaxation of the empty stomach leaves the stoma wide open. The first swallow of barium is gobbled up, and in some instances of marked atonicity (the so-called dumping stomach), the barium continues to rush out through the new opening; but as soon as gastric tonus is resumed and there reappear moderate tonic contractions of the muscular fibers, the borders of the mouth are hugged together. It is quite possible and probable that there is a definite relation between the direction of section of the muscular fibers and the permeability of the stoma. The more or less obliquity of the incision in the stomach wall may explain the apparent differences in size of the anastomotic mouth at the moment of passage of a food bolus. There are, it must be admitted, a certain number of cases in which periodicity of evacuation is not observed and the stoma is open all the time.

Normal cases do not show a deformity of the gastric outline due to the operation of gastro-enterostomy, nor is the gastric mobility seriously modified by the operation. There do not exist incisures or spasms due to the anastomosis.

Summarizing, then, the gastro-enterostomized stomach that is functioning satisfactorily, the patient being symptom free, exhibits the following characteristics: (*a*) normal form of stomach; (*b*) no deformities, serrations, incisures or filling defects due to the operation; (*c*) emptying time exceedingly variable, from one to five hours, more often from three to five hours; (*d*) unless the pylorus has been closed by stenosis or by operation, passage through the pylorus of at least some of the barium; (*e*) passage through the stoma usually by jets more or less rhythmically. Gastro-enterostomy, then, is not by any means simply a drainage operation.

GASTROJEJUNAL ULCER AND GASTROCOLIC FISTULA

The most important pathologic finding in gastro-enterostomized stomachs is gastrojejunal ulcer and its occasional sequel, gastrojejuno-colic fistula.

The one direct sign of a gastrojejunal ulcer is the evidence of an ulcer crater in relation to the stoma. One is able to see this only very rarely. More often there is a deformity about the stoma, narrowing and irregularity of the jejunum, and evidence of fixation at the site of the anastomosis, all of which are in contrast to the lack of deformity and perfect pliability of the jejunal walls and mobility of the stomach at the site of the anastomosis found in normal cases. Indirectly, dilatation of the stomach and duodenum, delay in gastric clearance, and unusual activity of the gastric musculature, manifested either by spasm or by hyperperistalsis, suggest the presence of an anastomotic ulcer. There is a characteristic general excitation of the stomach and upper bowel recognizable by the experienced roentgenologist. Motor irritation may be suggested by: (*a*) extreme, boardlike contractions of the stomach; (*b*) serration of the greater curvature; (*c*) spasm of the new stomach outlet sometimes amounting to a total long continued occlusion of the anastomosis, and (*d*) spastic contractions of the adjacent jejunum, recognizable by the fact that the first bolus of barium that passes is followed immediately by an occlusion that is spastic in nature and may or may not result in a prolonged gastric clearance. In other cases, there is often no disturbance in gastric mobility. The coincidence of a point of pain on pressure with the gastro-enterostomy opening is highly suggestive. When, in addition to other suspicious symptoms, there is pain at the site of the anastomosis that can be localized only by roentgen-ray examination, operation is indicated on account of the suspicion of jejunal ulcer.

Gastrojejuno-colic fistula is a relatively rare complication. There are clinically three principal symptoms: (1) diarrheal stools containing food ingested shortly before the bowel evacuation; (2) vomiting, frequently containing traces of fecal matter, and sometimes accompanied by eructations of fecal odor; (3) rapid cachexia accompanied by the preceding signs. Here roentgenologic study renders great service in proving the gastrocolic communication, either by employing the opaque meal or the enema, or by insufflation, repeated as often as is necessary to observe the following signs:

---

[21] De Luna, C.: Arch. d. mal. de l'app digestif. **12**: *981, 1923.*

1. The passage of opaque material into the left colon immediately after ingestion of the meal, the right colon usually remaining empty.
2. The possibility of causing opaque material from the stomach to pass into the colon, and vice versa, by manual palpation under the fluoroscopic screen.
3. The presence of opaque material in the stomach after the barium enema.

The screen examination should also help us to differentiate between the two greatest causes of gastrocolic fistula—cancer and ulcer of the stomach. Of those methods of study, the enema is the more conclusive, for if the contrasting medium is given by mouth a possible bolus passing into the colon may be disturbed or hidden by filling of the small intestine at the same time.

It is apparent from our postoperative studies that gastrojejunal ulcer occurs more frequently following simple gastro-enterostomy, and especially anterior gastro-enterostomy, than after partial gastrectomies involving resection of the ulcer-bearing zone of the stomach.

RESULTS AFTER GASTRIC RESECTIONS

The immediate postoperative results in all forms of gastro-intestinal anastomosis following partial gastrectomy have been good. In no instance have we failed to find the barium passing readily into the small intestine. Here, in contrast to the case with gastro-enterostomy, the emptying time of the stomach is usually very much reduced, depending somewhat on the proportion of the gastric wall removed at the operation. Of the patients that have come to us years afterward for postoperative study, we have made observations on those subjected to a Polya operation, either postcolic or antecolic, and those who have had a Billroth operation after the first or second method. The patient who returns with severe symptoms after a stomach operation, excluding those who have been operated on for carcinoma, is not the one for whom resection has been performed but much more frequently the one who has had a gastro-enterostomy. I have records of a number of patients perfectly satisfied and clinically well who were subjected to partial gastrectomy several years ago. In a small series of patients operated on by the Polya method for antral ulcers from five to ten years ago, the cardiac end of the stomach was found to be normal, peristaltic waves shallow, and barium starting freely into the small intestine. There was no evidence of dilatation in the upper loops of the small bowel and no irregularities of the stomach around the pyloric end. In spite of the apparent ease with which the material passed into the jejunum, the average emptying time of the stomach was four and one-half hours.

Following a Billroth I operation, there is often precipitate emptying of the stomach. Generally they are steeply oblique, wedge-shaped stomachs with an emptying time of from fifteen minutes to one hour; but longer delays are seen, and it is in these that one observes slight peristaltic waves. This precipitate emptying is sometimes slowed by a narrowness of the anastomotic opening, which is just at the limit of what is permissible.

Billroth II stomachs show rather long shadows hanging well to the left of the spinal column. When the outlet is at the deepest point of the remaining stomach, there is a great tendency to precipitate emptying. There was no noteworthy peristalsis in the cases studied.

ANNULAR RESECTION

After annular resection, there is observed a diminutive stomach usually situated to the left of the spinal column. The pylorus lies in front of or even to the left of the vertebral bodies. That portion of the stomach shadow below the annular suture line is shrunken to the point of being almost nonexistent. The duodenal bulb and the first portion of the duodenum are strongly drawn to the left. In the cases of this type, there has been a midgastric constriction, somewhat serrated, situated on the old line of suture. This constriction is marked by an incisure, deeper on the greater curvature than on the lesser. This deformity is organic and persists in spite of antispasmodics. It is seen from the time the barium enters the stomach and is exaggerated at the moment of the passage of peristaltic waves, the exaggeration being more marked on the greater than on the lesser curvature. There is often a dilatation of the upper sac of the stomach visible on its greater curvature—apparently an excess of gastric wall on the greater curvature of the superior segment. The emptying time of the stomach after annular resection is from three to five hours. The barium collects in the upper segment, but passes so quickly through the lower half that it is difficult to study its walls. The peristaltic waves are shallow but have been seen starting above the field of operation and proceeding to the pylorus on both curvatures.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. KARSNER, CARMAN, BARKER AND CASE

DR. LEWIS G. COLE, New York: Concerning the relative incidence of prepyloric and postpyloric ulcers, it will be more firmly established by roentgen rays than by surgery and necropsies, especially as in roentgen-ray examination the sphincter forms the landmark from which to survey all this region of the bowel. Constitutional and conditional factors concerning the causes and mode of development of peptic ulcers include habitus, diathesis, anomaly, endocrine disharmony, periodicity, acidity, infection, strain, physical and psychic, and others with selective affinities for special tissues. The great number makes it difficult to select the responsible one. Bloating, burning, gas, eructations and constipation, flatulence, are all indications of rumblings in the gastro-intestinal tract. Patients may have hunger without pain, or pain without hunger. There is no history that is typical of either gastric or duodenal ulcer. The statement that "the necessity of caution in evaluation of the anamnesis is therefore obvious" is rhetorically elegant but only mildly emphatic when one considers the facts concerning the value of symptoms. General physical examination is helpful in ruling out certain conditions that simulate ulcers, but the findings are unreliable. We are all very grateful to Dr. Barker for his remarks concerning the misleading reports of inexpert roentgen-ray observers, and we should seek to help our fellow roentgenologists. I wonder whether the percentage of inaccurate diagnoses on gastric ulcers is greater from the source of the inexpert roentgenologist than it is from the inexpert clinician, when the latter's evidence is based entirely on evidence which he does not take from the roentgenologist. I wonder whether the inexperienced roentgenologist would not hit a higher average than even the expert clinician. Dr. Barker says that general practitioners and internists see ulcers in their earliest stages. When, where, and how do they see them? When did they see the last ulcer in its early stage without roentgenogram or without the surgeon's help? No doubt ulcers are readily divided into two groups—surgical and medical; and perhaps from a clinical standpoint all uncomplicated ulcers should first be treated medically. Dr. Barker's conservative, rational and well balanced common sense diet with early ambulatory treatment seems to me the sheet anchor for medical therapy. By a complete and thorough roentgen-ray examination, preferably serial roentgenology, repeated as often as necessary, one can determine the incidence of prepyloric and postpyloric ulcer; he may derive much help in undestanding etiology, and very definite data concerning the pathogenesis, progress or retrogression of the ulcer.

Dr. J. Shelton Horsley, Richmond, Va.: As Dr. Barker said, surgeons and internists are getting closer together, and, from the standpoint of a surgeon, I most heartily endorse the general principles of the treatment of peptic ulcer that he has laid down. The patient always needs medical treatment, at least medical postoperative treatment, in those cases in which operation is done, and undoubtedly many early peptic ulcers are cured by medical treatment alone. The question of the proper technic is vital. Many of the patients treated by a gastro-enterostomy do poorly, as Dr. Case has said. One reason why we do not get more satisfactory statistics is that the gastro-enterostomized stomach is treated as an entity, and the occasion for the gastro-enterostomy is often not considered. It might be done for inoperable cancer, or for a small duodenal ulcer that does not produce any marked spasm. Between these extremes there lie the infiltrating ulcer, the ulcer, the adhesions and stenosis. We should not attempt to twist any one operation to make it fit all the various pathologic gastric conditions. There seems, too, to be a tendency toward very radical surgery in all these ulcers, and that is a swing of the pendulum in the other direction. If a gastro-enterostomy as a routine operation does not cure, then what may we do? Not study the cases carefully from the standpoint of physiology and pathology, but just cut the stomach out and have it over and done with. That seems to me an unscientific attitude if it is taken as a routine measure. There are, of course, other surgical measures, such as pyloroplasty, which have a very definite field. Carlson, in reviewing gastric secretion in *Physiological Reviews*, January, 1923, says that there is no such thing as gastric hyperacidity and that normally there may be 0.5 per cent. of hydrochloric acid. He thinks that gastric juice has been too much glorified. Great variations in gastric juice may occur without materially affecting the health. The specific hormone gastrin, which Edkins is supposed to have discovered about twenty years ago, is now discredited by Carlson and others. But there is something in food that excites a secretion of gastric juice. It is not solely mechanical because sand, while causing a mucous secretion, does not produce gastric juice. A spasm that causes obstruction makes the food stay in contact with the stomach longer than normally. Hyperperistalsis overcomes the obstruction for a while, but after the hyperperistalsis has exhausted itself still some food is retained, and the presence of this food excites an excessive amount of gastric juice. What would you do if there was an ulcer in the rectum just above the sphincter which caused a spastic contraction and pain and dammed back fecal contents? You would give physiologic rest by stretching or dividing the sphincter, and cauterize or excise the ulcer. So we can in many cases divide the sphincter and the pyloric canal by an incision, excise the ulcer and relieve the spasm. Of course, all foci of infection should be removed. Where there is recurrence of an ulcer after pyloroplasty or when the ulcer is gastric and even moderately extensive, a partial gastrectomy should be done. But I think that if I had a small duodenal ulcer I would rather have a milder operation with a restoration of normal physiologic conditions and take a slight chance on a more radical operation later on, than to have the radical gastrectomy done at first.

Dr. W. H. Stewart, New York: I should like to issue a word of warning as to depending on bismuth in water or even in buttermilk as indicating the time of emptying after gastro-enterostomy. I have had one or two cases in which the patient manifested symptoms of a reclosure of the stoma, and with the ordinary bismuth in water or bismuth in buttermilk, the time of emptying was about three and a half hours, which we considered practically normal. Still, the symptoms continued. The surgeon found that the stoma had contracted down to a very marked extent and reproduced some of the old symptoms. From that time on we have made our tests with meal. As Dr. Vici said some years ago, when surgery came in all bets were off, and I do not know of anything that it applies to so well as it does to the gastro-enterostomy stoma, and I do not believe that anybody can recognize ulceration, a marginal ulcer in much more than 10 or 15 per cent. I hope I do not misunderstand Dr. Case when he said that in normal gastro-enterostomies there was a normal contour. I have examined many gastro-enterostomies and found that the surgical procedure almost always produces a deformity. It produces a puckering, a deformity that is very difficult to differentiate from the ulceration. Another point one has to bear in mind in estimating the emptying time of a gastro-enterostomy is that when the surgeon operates, the patient is lying on his back. When the patient is placed in an erect position, there is a valvelike action from the stomach falling forward, and there is a kinking of the jejunum in such a way that a marked obstruction is produced. I have seen at least three cases of that character in which by holding the stomach up the stoma was relieved of its obstruction.

Dr. I. O. Palefski, New York: I listened to the several papers of this symposium with a great deal of interest, particularly to the paper by Dr. Barker. He presented his subject from a general but practical point of view. What pleased me particularly is his emphasis on the importance of the after-care following the initial medical treatment of ulcer; for it should never be forgotten that the results of any of the procedures in vogue depend on the subsequent enforcement of dietetic restrictions for at least two or three years or even longer. As to the relative merits between the clinical and roentgen-ray findings I cannot agree with Dr. Cole who, in his discussion, attempts to put a damper on the value of clinical examinations. Those, like myself, who employ both clinical and roentgen-ray examinations in almost every case presenting for diagnosis, know from experience that both types of examinations are necessary for a correct diagnosis in the average patient. It is not uncommon to find instances in which the roentgen-ray findings mislead the diagnosis. In duodenal ulcer as well as in diseases of the gallbladder, the clinical findings are indispensable, while in gastric conditions the roentgen-ray findings are more important. It is impossible to accept the results of several roentgenologists as a standard. Of late, a large number of men of limited experience entered this field, and it is here that roentgenology suffers considerably.

Dr. Seale Harris, Birmingham, Ala.: As to the pathogenesis of ulcer, we hear a great deal about the focal infections, and unquestionably they play a very important part; but the recent work of expert observers seems to show that there is something far back of that which lowers resistance of the gastro-intestinal tract, the stomach and duodenum to infection, and those men think that our present diet of white bread, white rice and white sugar, a very excessive carbohydrate diet, has something to do with lowering resistance to these bacterial organisms, for they can find a place in which to thrive. As to the anamnesis in ulcer and to the early diagnosis of ulcer: The Mayo statistics show that ulcers had existed in their patients over a period of about nine years before they came to the Mayo Clinic. Dr. Finney's and Dr. Friedenwald's statistics show that theirs existed about ten years. A study of our patients that came to us for medical treatment showed that they existed about five years, and unquestionably the ulcer should be regarded as a very chronic condition. If we will study our cases, we shall find that long before the patient had the pain, there was nausea, vomiting, vague gastric disturbances of a periodic character.

One thing in the history of ulcers should be considered, and that is the patients who complained of indigestion and vague discomfort of various kinds that came on two and three and four times a year, passing off only to recur again. Periodicity is the important thing in ulcers. As to diet, it is thoroughly unscientific to attempt to make an ulcer diet fit every patient. We should make the condition of the patient, his age, his size, weight and all those things have their proper consideration, as well as the nutritional needs of the patient in making out the ulcer patient's diet, and I am convinced that instead of the high protein diet that most of these routine ulcer diets contain, averaging from 120 to 150 gm. of protein a day, which these patients are given and taught to live on for the rest of their lives, a protein diet of about 60 or 75 gm. is enough for the body to eat, the relatively high fat diet and low carbohydrate diet, and a diet that is righ in vitamins that may be given with the idea of building up resistance to these infections.

Dr. A. E. Barclay, Manchester, England: One point Dr. Carman did not bring out as to the radiographic and actual size of the ulcer. The large craters that we see radiographically are not necessarily the same size as those which the surgeon removes. The ulcer is usually much smaller than we expect. This is due, I believe, to the heaping up of the mucous membrane around the ulcer. My first lesson was an ulcer which I thought was probably about half an inch in diameter, and when the surgeon brought it down to me after operation, it was little more than an eighth of an inch in diameter. The site of the stoma may vary from time to time. On one occasion I told the surgeon that he had placed his stoma too high, and this he denied categorically. I then took it into my head to observe a number of these stomas from day to day, and found that the stoma can move more than an appreciable distance from the lowest point upward on the lesser curvature; i. e., one day the position appears to be good, while on another occasion it appears to be far too high. What the meaning of this is I do not know. Perhaps Dr. Case will tell me. Dr. Carman had some very nice pictures illustrating palpation, a subject on which we are in full agreement as to its value. He showed the heavy shadow of a gloved hand lying in the middle of the illuminated field. But I do not think Dr. Carman does palpate that way. I know I do not myself. The screen should be limited down to a very small field, and the palpating hand should never be within the illuminated area, for there is more than an inch of margin between the edge of the illuminated area and the organ that is being palpated.

Dr. Lewellys F. Barker, Baltimore: The stress laid on predisposition by both Dr. Karsner and Dr. Harris deserves attention. In this connection, the recent reports of the existence of areas of capillary inferiority would seem to be of especial interest and it is just possible that a vascular inferiority in some of these ulcer patients may be the basis of predisposition. What has been said by Drs. Carman, Case and Cole has shown very clearly how important roentgenologic examinations are for the control of clinical work; they aid in diagnosis, and in following the cases after operation they are most useful for the determination of the success or the nonsuccess of the surgical intervention. Some reference was made to the number of mistakes made by clinicians in contrast with those made by roentgenologists. Of course, I had reference rather to mere technicians who are not expert roentgenologists. It is quite true, of course, that an inexpert clinician can make equally bad mistakes. The internist and the general practitioner of today, in his study of gastro-intestinal disturbances, does not, however, limit his study to the anamnesis and the physical examination, but includes also roentgenologic reports. In other words, the clinician has become more or less protected from making mistakes because he wisely associates with him, in his studies, workers in special domains. Dr. Horsley has emphasized the fact that all cases should be treated medically and some of them should be treated surgically. I believe that that is true. The uncomplicated cases certainly deserve a fair trial of medical treatment before operation is resorted to. An operator will secure better results, too, if his patient has been given a preliminary period of medical therapy, and, certainly, after operation, the same precautions that characterize the medical therapy should be observed in all cases. Cures undoubtedly follow medical therapy and surgical therapy, but they are perhaps not quite so numerous as either the medical man or the surgeon is prone to think. We often see an abatement of symptoms or a disappearance of symptoms and a restitution of apparently normal function, but in many instances the ulcer remains unhealed. It is well known that even after operation for ulcer, especially after gastro-enterostomy, the necessity of secondary laparotomy often arises. I have also been impressed with the difficulty patients experience in accommodating themselves to a gastro-enterostomy. I have known many physicians who have gone through gastro-enterostomy operations; they have told me that it took them a long time "to adapt themselves" to the gastro-enterostomy. In case I had to undergo, myself, an operation for ulcer, the kind of operation I should want done would depend on two things: (1) the surgeon who was to perform it, and (2) the local conditions found at operation. If I could choose an expert surgeon, I should leave matters entirely to his judgment; but if I had (because of some emergency) to submit to operation by a surgeon of limited experience, I should want him to do as little as possible "to let me get by." An expert surgeon would, of course, choose the particular operation that he thought would not only relieve the immediate situation but also give me the best chances of permanent freedom from symptoms. Thus, when a severe chronic gastritis is present in association with ulcer, an extensive gastrectomy with removal of the diseased mucous membrane might often be preferable to a gastro-enterostomy.

Dr. James T. Case, Battle Creek, Mich.: Dr. Stewart spoke about the proper type of meal to test the time it takes the stomach to empty. My feeling is that it matters not a great deal what type of meal one uses, provided the same kind is used year after year and it becomes a standard for him. It is not possible for different men to compare the emptying time of the stomach under different conditions, but one man can compare various cases of different types under the conditions under which he works. As for the variation in position of stoma suggested by Dr. Barclay, that is a very interesting suggestion to me and one that I shall study. It had not occurred to me before. I want to call attention to a paper by Dr. A. H. Pirie which appeared a couple of years ago regarding the value of postoperative roentgen-ray studies in aiding one to accommodate oneself to gastro-enterostomy. I refer to it in my paper but had not time to read it. One important question I did not bring up at all in my paper. What is the significance of a persisting deformity of the duodenum following an operation? We hear a good deal about the disappearance of ulcer roentgen-ray signs in the stomach as a proof that the medical treatment of gastric or duodenal ulcer has cured the ulcer, and there are appearing in the literature publications, including publications of roentgenograms, where these roentgenograms are being used to prove that the ulcer had been cured, because in the pretreatment roentgenogram there was a crater and in the later roentgenograms there was not a crater. What about the duodenum? We consider a persisting deformity of the duodenum as one of the characteristic signs of ulcer, but I find it very common also in the duodenum after operation, even years after operation when the patient has no symptoms at all of duodenal ulcer. Some of these on which I have reported are patients who live somewhere near me who have very kindly come in to submit to restudy just so that I could get some data. I do not know how to explain why in apparently cured cases the duodenal ulcer deformity persists long after operation. I hope some future writer will tell us that.

Plague Prevention.—Once plague infection is present in a given city or community, the fight against the disease resolves itself into a fight against the rat or other rodent concerned in its spread. In pneumonic outbreaks the human cases, of course, must be separated promptly from the noninfected portion of the population.—*Pub. Health Rep.* **40**:53 (Jan.) 1925.

MEAT INSPECTION AS A PUBLIC HEALTH MEASURE *

W. H. LIPMAN, M.D.
CHICAGO

The last decade has greatly enriched the science of nutrition, but two achievements stand out most prominently. They are the discovery of vitamins and the proof that not all proteins are of equal nutritive value; that some, particularly most vegetable proteins, are incomplete, while most animal proteins are complete in that they contain the components necessary for growth, repair and replacement. A number of diseases whose etiology was heretofore unknown have been definitely proved to be caused by lack of vitamins, and of late, considerable evidence has been brought forth to prove that resistance to disease, particularly infection, and even reproduction, may be dependent on vitamins and the quality of proteins, or both.

These facts have collectively been called "the newer knowledge of nutrition," and they prove that there is more to food than calories. The proper selection of foods both in quality and in quantity is not merely an individual problem but a public health question of great magnitude. The last decade also brought forth new ideas regarding the hygiene of food and the relation of food to disease. The older teachings that food per se can cause disease after it is assimilated has been largely if not entirely discarded. Many diseases, particularly the various forms of so-called rheumatism, were for a long time thought to be caused by foods and were therefore treated dietetically, but are now known to be caused by infection.

Food poisoning, looked on for a long time as due to intoxication with products of food cleavage, either bacterial or chemical, has now been proved to depend on contamination of food with bacteria and ingestion of specific toxins produced by the bacteria, as in botulism, or of the bacteria themselves, as in the paratyphoid group.

Just as the newer knowledge of the nutritive principles of food has made the selection of proper food a matter of public health concern, so have the newer conceptions of food intoxications or, as some refer to call them, food infections, added greater importance to food hygiene.

Mohler and Eichhorn, in their introduction to "Meat Hygiene," express themselves as follows:

> Regulation of the diet or hygiene has for its purpose the retaining and strengthening of the human or animal organism by increasing the internal resistance and by preventing any noxious effects. In doing this it is necessary in the first place to consider the nourishment of the organism. Inasmuch as meat constitutes the principal foodstuff for the human body, the regulation of the diet of man must also extend to meat products. And since recently there has been considerable attention paid to the latter from a hygienic standpoint, justification is had for the use of the words "meat hygiene," by which it is understood that part of the regimen which concerns the procurement of wholesome meat foods for man, their value to public health as well as the dangers which threaten the consumers of diseased or unsound meats.

The term "meat inspection" in this country practically always refers to inspection conducted by the federal Department of Agriculture under the meat inspection law passed by Congress in 1906. Under this act, the Secretary of Agriculture has the power to formulate regulations governing the antemortem and postmortem inspection of food animals; to prescribe sanitary requirements for the manufacture of meat products and proper and truthful branding and labeling. The law also gives the secretary the power to eliminate from the food supply all those carcasses and parts and meat products that are found in any way objectionable for human food and to destroy them.

It is to be remembered, however, that this law applies only to meats and meat products that enter into interstate or foreign commerce. It has no jurisdiction over meats that are sold and consumed in the state in which the animals are slaughtered. At present, something over 60 per cent. of the meats consumed in this country are manufactured in establishments operating under federal inspection. The remaining 40 per cent. of the meat receives little or no inspection because, while there are a number of state and municipal inspection laws, they are not thoroughly enforced. The fact that only one-half the meats consumed in this country receive adequate inspection can at once be seen to constitute an important problem of public health, but this will be referred to later.

It is not necessary here to go into the detail of the technic of meat inspection as conducted by the federal Department of Agriculture. It suffices to say that the technic is based on modern etiology and pathology of animal and human disease and the principles of sanitary science. All parts, organs and the important lymphatic glands are examined by palpation and incision. That it is thorough is at once proved by the fact that for the fiscal year ending June 30, 1924, of 79,966,913 animals given antemortem inspection, 4,228 were condemned, and of 79,814,060 given postmortem inspection, 342,539 animals were condemned and 1,355,394 parts were condemned. These condemnations were made because of thirty-five different causes, chief among which is tuberculosis, which was responsible for approximately one-half the condemnations. These condemned carcasses and parts were treated under the regulations in such a manner that none of the resulting products could under any circumstances be used for edible purposes. The removal of such enormous quantities of meats from the food supply of the country unquestionably constitutes a great sanitary achievement.

The elimination of undesirable and unwholesome food is only a part of the inspection. The conditions under which slaughter is conducted, and the manufacture of meat products, are as thoroughly under the supervision of the federal government and are as minutely controlled as is the postmortem examination. The equipment used, materials, etc., and even the clothing of the employees must comply with specifications of the regulations, and when at any time in the process of preparation or packing the animal or part becomes contaminated or in some way unwholesome, it is condemned.

The removal of objectionable meats either by antemortem or by postmortem inspection is not the only benefit public health obtains through meat inspection. There is another benefit, by some considered of equal importance to the actual withdrawal of objectionable meats. I stated before that tuberculosis causes approximately one half of all condemnations of carcasses and parts on account of disease; in other words, tuberculosis causes as much condemnation as the thirty-four other diseases combined. There is, perhaps, no better way of discovering the localities infected with

---

* Read before the Section on Preventive and Industrial Medicine and Public Health at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

bovine tuberculosis than meat inspection. When tuberculosis is found during meat inspection, the origin of the animal can usually be traced and in that way either governmental or other agencies notify the producer so that measures can be taken to eradicate it. The discovery of tuberculosis in animals during postmortem examination has been a great stimulus to eradication work against bovine tuberculosis, chief among which is the antituberculosis work of the United States Department of Agriculture. The antituberculosis work is as important as, if not more important than, meat inspection itself.

Tuberculosis is a ubiquitous disease and we are, perhaps, exposed to it everywhere and at all times; but it is generally conceded that milk from tuberculous cattle is one of the most fertile sources of infection of human beings, particularly children. It is believed in some quarters that all tuberculosis is acquired from milk in childhood and later changed to the human form. Tuberculosis eradication as stimulated by meat inspection has been greatly instrumental in diminishing contamination of the milk supply with tuberculosis, first, by the discovery of the location of tuberculosis herds, and, secondly, by the education of cattle producers to the value of the tuberculin test. In fact, meat inspection by the discovery of tuberculosis in cattle has undoubtedly advanced the movement for pasteurization of milk. Ditewig, said, in 1915:

> That the meat inspection service is the most effective existing agency for collecting on a broad scale data absolutely necessary to the success of any extensive program for the eradication of certain diseases from the food herds of the country can readily be shown.

The elimination of tuberculosis from dairy herds is more important from the standpoint of preventing tuberculosis than the destruction of meat from tuberculous cattle because, while infection of milk is an acknowledged etiologic factor in the spread of tuberculosis, infection with meat is practically unknown because muscle meat is rarely, if ever, affected with tuberculosis.

I stated before that the meat inspection law exercised jurisdiction over those meats and meat products which are shipped out of the state and exported, and that it has no jurisdiction over meats of animals killed and consumed locally, and for that reason only approximately 60 per cent. of the meats consumed in this country are inspected. We saw how efficient the inspection is by the searching and elimination of a large number of carcasses and parts. It is reasonable to assume that the meats prepared in noninspected establishments come from animals affected with the same conditions, at least to the same degree as are animals that are at present inspected, and it follows then that 40 per cent. of the meat consumed in this country is more or less objectionable. The necessity of providing some means of inspecting this quantity of meats is therefore at once apparent. The installation of some form of inspection of the uninspected meats and the supervision of the conditions under which they are prepared is an important problem of public health today.

Meanwhile, it is paramount as a public health measure that the consumer be acquainted with meat inspection—its extent, function and sanitary benefit. A great deal is being accomplished today by scientific writers, by magazines, by the press, by public health organizations and health departments, state and municipal, in teaching the public the selection of a well balanced diet; but the public has not been equally well informed in the hygiene of food. The consumer ought to be told how to select food on the wholesomeness and purity of which he can confidently rely. In order to select meats that have been inspected and found sound and been prepared under sanitary conditions, all the consumer needs to do is to insist on meats that bear the stamp of the United States Department of Agriculture, reading "U. S. Inspected and Passed." This stamp shows that the meat comes from a sound and healthy animal and was found fit for human food, that it was prepared under sanitary conditions, and that nothing of an injurious nature was used. Furthermore, it signifies that the contents of the container are exactly as the label reads, no more nor less. In addition to the knowledge on the nutritional value and hygiene of food, the public ought to be informed on the safe methods of preparing and keeping food in the home. From the standpoint of preventing food intoxication or infection, it is just as important that the housewife be informed of the proper methods of preserving food, either for a short period by refrigeration or for a longer time by heat, as it is to know how to buy hygienically prepared food.

ABSTRACT OF DISCUSSION

DR. THOMAS CASTOR, Philadelphia: Dr. Lipman has very completely outlined the necessity of meat inspection as a public health measure and has shown the thoroughness of the federal inspection service, which covers 60 per cent. of the meat supply, so I would like to emphasize the necessity of inspecting the other 40 per cent. by calling attention to a common practice of sorting out unsound or diseased animals at the stock yards or country shipping points and slaughtering them locally where no inspector will see them to pass on their fitness for food. Most of the states in this country have no system of state inspection or have so inadequate a force that they can only look after the worst places and clean up or eliminate the pest holes. This also holds good with the ordinary city inspection; so in view of these conditions it appears that the only way ever to secure thoroughly satisfactory meat inspection is to supplement the federal service by establishing municipal or community slaughtering plants where all of the slaughtering would be conducted, excepting only that performed under federal supervision, as thus a satisfactory and efficient service could be performed by a reasonable sized force of inspectors, because it is doubtful whether the ordinary city can ever supply sufficient funds to maintain enough inspectors to supervise properly the slaughtering at the considerable number of small, widely separated killing plants that are usually found operating in most cities. Unfortunately, many cities and especially small towns pursue an opposite policy and prohibit all slaughtering within the corporate limits, thus depriving these plants of all the advantages of city water and sewerage systems and force the slaughtering houses into rural districts where they are beyond all jurisdiction of the local health officials, thus leaving the butchers to do about as they see fit both as to sanitation and as to the handling of diseased carcasses, whereas if they were required to remain within the town limits they could be forced to keep clean and to handle their products in a proper sanitary manner. When establishing a local meat inspection service, the federal regulations can be used as a guide so far as practicable, and a veterinary inspector having had federal experience should be secured if possible, as these men have gone through a thorough drilling in the inspection work and are, I believe, less likely to be influenced by personal or political pressure.

DR. GEORGE M. KOBER, Washington, D. C.: In view of the fact that the inspection now covers only about 60 per cent. and until inspection becomes more universal, it seems to me at least desirable to raise our voices in favor of cooking all meat products. The same principle applies to milk, so far as pasteurization to a certain point is absolutely essential for the destruction of infectious germs. This much we can all do. In our present state of knowledge, nothing short of general pasteurization will confer immunity from milk-borne epidemics. Typhoid epidemics have been traced to consumption of even certified milk. I enunciated that principle fifteen years ago and I have had no reason to change my mind.

Dr. W. H. Lipman, Chicago: There are two important points to consider from the standpoint of the consumer. First, how to secure inspection on meats that are at present uninspected; second, how can the consumer tell that he is getting inspected meats? Dr. Castor referred to the "little purple stamp" that is placed on carcasses and passed by the government to show that the animal has been inspected and found fit for food. If the consumer will insist on meats that have this stamp, he can be sure that he is getting sound and wholesome food.

EPIDEMIC ENCEPHALITIS

A COMMON ETIOLOGIC FACTOR, AND ITS IMPORTANCE IN PREVENTION *

WILLIAM BROWNING, M.D.
Professor of Neurology, Long Island College Hospital
BROOKLYN

Aside from the question of infection there are few suggestions regarding the cause of epidemic (lethargic) encephalitis. An overliability to contract the disease is shown by certain classes, such as males (though not in all statistics), pregnant women, physicians, persons of foreign birth, and especially recent sufferers from influenza. Typhus, measles, mumps, pneumonia and scarlatina have also been noted in the histories, as have parturition, sepsis and accidents or operations particularly about the head. There has also been some question whether poliomyelitis or herpes and epidemic encephalitis might not be closely related. The upshot of all this is that any exhausting infection or occurrence can evidently play a contributory rôle.

My purpose in this paper is to point out a coordinate and more constant factor. This is to the effect that the victims are recruited from those who at the time have become exhausted by prolonged or excessive tire and especially by lack of needed rest. The one common element is loss of sleep. In most instances there has been a burning of the candle at both ends (overtire and underrest).

Many agencies of allied character doubtless can cooperate, such as toxemias, drug habits, bad air, anxiety and shock. Depressed mental states are a common cause of insomnia, and naturally contribute, though insomnia and enforced loss of sleep are not identical. Sexual excesses can do the same. This factor is of practical importance whether epidemic encephalitis is caused by a specific virus or not.

Some years since, a report from the Northwest noted that physical depletion, and especially loss of sleep, were frequent antecedents. Bassoe made similar observations. English reports figure overwork and a possible breakdown of immunity as predisposing causes.

Instances of like purport can be picked up in various publications. In general, however, it may be said that the antecedent history in these cases has received slight attention. While, therefore, there may be little radically new in these observations, scant account has been taken of the like, nor has their significance been duly appraised.

The matter attracted my notice more from an old habit of giving special attention to the amount of sleep usually secured—a field in which few attempt to gather exact information.

As only cases in which the diagnosis was clear are included, details need not burden the paper, beyond the statement of the factor in question.

In the early days of the outbreak this side of the subject was less scrutinized. Later cases, however, in sufficient number can now be listed to have significance.

The great problem is to work out the relevant items. Difficulty in so doing is doubtless the reason why the matter has not been better recognized. As yet, and until methods can be systematized, it is a time-consuming process, requiring the personal attention of the physician. Useful tips on obscure and nocturnal habits of the human can sometimes be obtained from social experts. In some cases the job is easy if attention is given the matter, but in many instances to secure the needed information it is necessary to make a determined "drive" backed by confident assurance that the facts exist. As the particulars in question are rarely twice alike the skill of a detective can find full play. Cases that have existed a long time are impossible to work out, or yield only to elaborate delving. General statements cannot be accepted, as these patients are always sure they have had plenty of sleep. Such night-habitués are often very secretive. At any rate, the items desired refer to lines of conduct about which the patient is not proud, or not in condition to state. Knowledge of the patient's life for a period before the onset may have to be extracted by bits, and then pieced together, before the clue is apparent.

To quiz or cajole, josh or jolly, may not succeed or need to be continued until some one gives the facts. The presence of strangers or of an entourage does not facilitate disclosures.

In most institutional and chronic cases, therefore, it is impracticable to get the required data. I long since gave up trying to do so as a routine in hospital work, and had to wait for enough patients in private practice. This report is based on twenty-eight such cases, including two in physicians. Several are given in brief to illustrate types and in part show the trouble encountered in eliciting this phase in the histories.

Case 1.—A chauffeur, aged 18, seen in February, 1923, though his case was acute and he was confined to the bed, was able to deny strenuously all excesses and deprivations. Both parents also positively confirmed his story of orderly living. But on the side, an uncle stated that the patient had catered to a fast crowd of youths, carried them to all hours of the night, caroused with them, frequented night joints, and been out until 3 and 4 a. m. six nights a week on an average.

Case 2.—A man, aged 55, seen in June, 1924, was troubled first about the middle of February. "He seemed to get run down a while before this came"; in fact, he had been tired out and "nervous" all the previous winter. No cause for this condition or for his attack could be discovered by the most diligent inquiry of the patient or his wife. He was "a home body," was never out evenings, had no worries, and lived an ideal existence, aside from one or two hours a day in the subway. It seemed impossible to dent the story of perfect living at any point, or to disclose any changed conditions. Here was apparently a case that must remain unsolved. The only other morbidity was a chronic systolic bruit at the mitral valve. However, conversation later with a son disclosed the

---

* Read before the Section on Nervous and Mental Diseases at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

fact of a new radio the previous October, and the patient's heedless absorption in it. "He sat up all hours of the night" with it the whole winter.

CASE 3.—An electrician, aged 31, seen in January, 1925, first gave the duration of his trouble as one and a half years. From much questioning, however, it appeared that he was in a distant hospital with it for more than six months in 1922-1923. Further inquiry disclosed an acute attack in January, 1920, from which he remained weak, "extremely nervous" and sleepy. It was finally traced further back. He had been in the American Expeditionary Forces more than two years, in part at the front. The winter of 1918-1919 in Paris he had on his own showing only from six to six and a half hours' rest a night. Then in the spring he had an attack of the influenza, with a week in bed, followed by a chronic state of excessive sleepiness. Whether the influenza or not, it was evidently the onset of the encephalitis.

CASE 4.—A Russian, aged 51, of large frame, a job painter and decorator, had had left sacro-iliac trouble three years before and was relieved by Dr. Rushmore, the orthopedist, by whom he was referred to us. The onset was somewhat insidious. He had had pain in the left foot at times during the past year, and an occasional "shake" in that foot when on a ladder, with two acute upsets. The lethargic sequel was more pronounced the six weeks before examination. All shortcomings were persistently denied. No clue was discoverable, beyond pyorrhea. However, by the next morning he was so anxious to get home to a town in Jersey, that a little emphasis brought out the story. He was known locally as "the hardest worker in the country." During the active major part of the year he retired at from 10:30 to 11, and rose at 5. He worked from 6 a. m. to 7:30 p. m., less a brief stop for lunch. Minor taxes on his rest period were: a radio every evening, an automobile ride with his family many evenings, movies once a month, as fireman out two nights a month, nocturia every two or three nights and snoring regularly. Hence, besides being an inordinately hard worker for thirteen hours a day, he allowed only from six to six and a half hours a night for rest.

CASE 5.—A boy, aged 18, seen in February, 1923, with acute trouble of twelve days' duration, lived in Brooklyn, but attended college in Manhattan. He was a bright student, necessitating work on his studies until after midnight. He rose at 6:45 to get a snatched breakfast and be at his class in time. This reduced his sleep allowance to at most six and a half hours a night. There was the further evil element of two hours daily spent in the wretched air of the subway at the time when it was crowded. Besides these things he had just been through the midwinter examinations, evidently the last straw.

CASE 6.—A broker, aged 26, was in coma when first seen in January, 1921. He was a man of large mold, but with an old aortic regurgitation. The trouble began the month before. He had been "overworked for some time." He lived out of town, requiring an hour each way in transit. He regularly remained until late in town sporting. He had only four or five hours of sleep nightly for the previous two or three months.

CASE 7.—Mrs. D., aged 25, seen last December, had a subacute attack beginning a month before. She had been a public school teacher for some years. She had been married six months. Previously she had had no household duties. She now cared for her apartment, and got some meals, besides continuing her teaching at a distance. Moreover, most of the evenings she had been out, socially, not getting home before midnight. She rose by 6:45 a. m. Though of excellent physique, her strength had been waning for some time under this load of work and shortness of rest (barely six and a half hours a night). Then came the acute symptoms.

CASE 8.—A youth, aged 17, seen in January, 1921, was of good physique, but growing fast. The attack began a week before. Besides regular day work he attended a business school twice a week, not reaching home till 10:30 p. m. One other night a week he was at the regiment until after midnight. One night a week he bowled until after midnight. Two nights a week he stayed late with his girl. This left at most only one free night a week. It was far too strenuous a life for a youth who had not completed his growth.

CASE 9.—A man, aged 26, of Italian stock, seen in February, 1925, was a twin of sturdy physique. He was unmarried, and never had been a sexualist. Previous to epidemic encephalitis six years before, he had been a clerk. He rose at 6 a. m. and reached home at 8, 9 or 10 at night, with supper after. Saturdays he worked until midnight or 1 a. m. and also Sunday morning. He went to the movies once a week after his work. Twice a week he stayed at a friend's home until 10:30. He went to a dance one or two nights a week. He had a phonograph going when home. Then half the nights he read in bed until 2 a. m. Even at that he slept poorly, thus losing some of the remaining time. Hence, besides working twelve hours a day, he netted on an average less than five and a half hours sleep a night.

CASE 10.—A man, aged 21, seen in April, 1925, a sales manager, had epidemic encephalitis in the summer of 1921. He felt "sort of weakening spasms" in his legs prior to that, and every stride he made was an effort." The sequels were worse since recent illness in the family. Previous to the onset he rose at 8, was at business by 9, and not home until midnight, and Saturdays not until 1:30 a. m. He always ate supper after getting home. He then read one or two hours. He also spent two hours a day in the subway. There were a few other minor interferences with sleep. Hence, besides long hours of work, and time in the crowded subway, he had an average of barely six hours a day for sleep.

CASE 11.—A vigorous man, aged 23, seen in April, 1924, had his first attack four years before. He "stayed out with the boys" at least one night a week. Then a couple of days before the onset, he was up for forty-four hours at a stretch, working at urgent business plans.

A close counterpart of this case is Case 3 of Houda,[1] in which a man, aged 30, "had worked for forty-eight hours without stop, just previous to onset."

These two cases are so nearly identical and so special in type as almost to constitute experimental proof of the part that lack of sleep plays in this trouble.

CASE 12.—A man, aged 38, seen in April, 1923, had worked very hard as a tailor up to an acute attack a year before, sewing regularly from 4 a. m. until midnight.

CASE 13.—A man, aged 26, seen in 1923, had risen at 4:30 a. m. and worked until 5:30 p. m. for six weeks before the onset of his trouble. At that time he slept only six hours a day.

CASE 14.—A bank clerk, aged 25, had had epidemic encephalitis three years before. He had long been an erotic. He smoked twenty-five cigarets a day. One hour daily was spent in the subway. He rose at 7 a. m. and was at business until 7 or 8 p. m. Then seven nights a week he spent at the chess club until midnight. After that, two or three nights a week, he went to a restaurant. At best he was not in bed until 12:30. He was slow getting asleep, and was a dreamer. Hence, he averaged less than six and a half hours' rest a night.

FREQUENCY AMONG PHYSICIANS

That physicians have a special liability to epidemic encephalitis has been remarked by various observers. This has also been apparent in Brooklyn. I. S. Wechsler, in 1921, found it "almost sixteen times as frequent as among average population."

At the present day we do not to any like extent see physicians affected by the diseases with which they have to deal, unless occasionally in laboratory work. There is consequently a natural inclination to attribute this to infection from cases seen in practice; but before doing so it is well to see whether the facts substantiate the suspicion. Several of my medical friends have been killed by automobiles—also an undue proportion —yet no one thinks of this as a bacterial infection.

---

[1] Houda, E. O.: Northwest Med. **20**: 182 (July) 1921.

If we presume that medical men contract the disease from their brief association with such patients, then the families of such affected colleagues, exposed to it at all stages as they are, ought in turn to be scourged. Yet practically it never spreads to any member of their households. Nor would a single case signify much, in view of the added care. We can therefore be sure that the frequency of this trouble among physicians is due to some other cause; and close scrutiny of the individual case commonly discloses the reason for susceptibility.[2]

THE NORMAL AMOUNT OF SLEEP

In estimating the normal amount of sleep, it is possible to introduce an element of mathematical exactness. Certain standards are required for comparison, chiefly regarding sleep.

So far as concerns the present discussion, it is sufficient to know that a large share of the public of whatever age needs at least eight hours of rest daily. Those persons requiring the most are presumably the ones who break soonest on curtailment. The amount a patient previously secured has to be reckoned up as exactly as possible, if the relation to epidemic encephalitis is to be calculated.

In the cases in which the sleep allowance was figured with some definiteness (eighteen out of twenty-eight), the amount in each was well under seven hours, usually six and a half or less. In the other ten cases the facts were similar but were not determined with the same exactness.

The sleep requirement of individuals differs, but only within moderate limits. When the total is cut down to seven hours for any length of time the average person is taking risks. Some appear to tolerate it, but many then evidently become sensitized. And any further reduction or temporary bad break makes the candidate eligible for various ailments including the sleeps.

COMMENT

The cases given, with many more at hand, indicate that we have here a causative factor that is at least common. The cases include both acute and chronic forms in males and females from 15 to 56 years of age at onset. Regarding the uniformity of occurrence, the most direct evidence to be cited is the fact that my last fourteen consecutive private cases are included in this report. These cases embrace all the eligible patients seen last year and this, and show what can be found by closer attention.

Circulation.—Chronic valvular leaks (two cases), low blood pressure and suboxidation naturally accentuate the effect of tire, and are overfrequent in the histories.

Syphilis.—To avoid any question of its possible relation, all cases with any suspicion of syphilis, past or present, or with positive Wassermann reactions, were excluded.

Study and Examinations.—The increase in number and complexity of subjects imposed on the student class, with the sequent limitation of rest and sleep, affects most of the younger element in the community. There is also a great multiplication of present-day examinations. Insomnia and other morbid tendencies are favored. Midwinter examinations with us mature a seasonal crop of epidemic encephalitis (two out of twenty-eight in this series).

In Children.—Bramwell, in a review, concludes that epidemic encephalitis "is very uncommon or at least seldom recognized in childhood." From the few cases seen, educational excesses as just noted are prominent in the histories of patients with epidemic encephalitis before the teens. My associate, Dr. O. C. Perkins, finds that these young victims are of the mentally active class. Parents are not always aware of children's need of longer sleep, or permit undue abbreviations.

Cases Before School Age.—These cases may need separate study. A couple of points are to be noted. Both serous and tuberculous meningitis at this age have often proved difficult to distinguish from epidemic encephalitis. Sundell[3] says, "Of the twenty-four hours of the day, the new-born infant sleeps for twenty-two, the baby of 6 months for eighteen, and the child of a year for fourteen.

Suggestive is the mention in the English report[4] of the "case of a young child who had recently obtained two 'firsts' at a baby show," which certainly must have disturbed its rest.

Several cases have been reported in which nursing infants appear to have taken it in some way from affected mothers, suggesting a modified form of development.

Causative Trends of Modern Life.—Are there features of recent development in our mode of living that in this sense might contribute? Many can be mentioned, such as the phonograph (now less in evidence), telephones, movies, the radio after midnight, automobiles, various Volstead effects, subways and tunnels in large centers, clubs and lodges, cross-word puzzles and other innovations. Improvements in illumination favor night life, in part at the expense of rest. So many of the changes in common activities involve abridgement of rest. Collectively, they furnish a large background when added to older customs. In populous centers all these evils are massed, affording a plausible explanation of the urban excess.

Not to be forgotten are the recent prophets who delude many with the idea that little sleep is necessary.

What corresponding malconditions are active in other countries can be left to their investigators.

A Preliminary Period.—This does not refer to the common "prodromal stage of from one to ten days" with grippal symptoms, but to forerunners of a break, premonitory warnings extending back from a month to a year or more before the acute stage. A suggestion of this was noted in six cases of this series, and is recorded in three of Tilney and Howe's[5] cases. Wimmer[6] enlarges on this point.

These manifestations are largely such as follow sleep deprivation, and are what might be expected when such an etiologic factor is in play. It does not prove or disprove infection, though it makes less imperative the view that it is a specific distemper. Occasionally these signs mass in a kind of preliminary outbreak, as remarked in the 1922 English report.

A study of these antecedents might afford means of recognizing impending trouble, and so help to ward off attacks. Tracing back the history would parallel the method of the present study, and probably meet with less obstruction.

Relation of Sequelae and Relapses.—In the after-phase as well as in the inception, this factor can play a rôle. When nominal recovery occurs it follows a variable period of disability. The patient then either feels the pressure of financial necessity or has an accumulated craving for former diversion. It is not unusual for such persons to remark that they are "going to have a good fling" to make up. Inhibition is still weak, and they drop back into careless living. Other evils doubtless cooperate.

---

[2] When the paper was read, a physician who had suffered from epidemic encephalitis offered his experience in full corroboration.

[6] Wimmer, A.: Chronic Epidemic Encephalitis, 1924.

An Aid in Diagnosis.—The principle proves at times of value in diagnosis. Uncertain cases are not rare. When there is any question, this element becomes an essential part of the history. Per contra, inability to uncover such a factor has repeatedly led to further and decisive study.

If experimenters gave attention to suitably exhausting their animals, they might score more definite knowledge of the modus of the ailment.

Susceptible Classes.—We can now glance back at the groups that show a special tendency to develop epidemic encephalitis and see how they comport with this form of etiology.

Men, more than women, tend to follow irregular living, and with us are more numerous in night occupations. Nurses afford a similar record to physicians.

Immigrants average a more strenuous existence, often including night work. This is accentuated when they have to learn a new language.

Pregnancy and parturition bring greatly increased demands on the individual, as also do infections and operations. Neurotic antecedents, as in several of Wimmer's cases, are naturally contributory.

That the vigorous and hardy fall to the count is to be expected, as they are more reckless in health matters than are those who are compelled to conserve their energies.

The susceptible persons prove to be those subjected to special strain, leaving no great margin for primary lack of resistance.

Personal Prophylaxis.—While there is no wholly satisfactory method of treating epidemic encephalitis, in the matter of prevention we have more chance of success. On the basis described I have no hesitancy either in advising the anxious how to avoid it, or in assuring them of safety if they follow proper living. Mild and incipient cases yield well to this plan. It might not be amiss to reinstall the curfew and the fine old habit of seasonable retiring. Individuals can take care of themselves in most cases without waiting for outside protection.

Infections, pregnancies, operations and infancy may still call for extra care.

It is often gratifying to note the prompt heed paid by those intact to this warning. Many a fond parent evinces a cheerful alacrity in applying the new brake. However, advising the afflicted requires so-called moral support or any other kind available.

54 Lefferts Place.

ABSTRACT OF DISCUSSION

DR. EDWIN G. ZABRISKIE, New York: Dr. Browning has almost started something that may create a reaction against further infringement of our personal liberties, but I sure that the warning he has conveyed to us today is of extreme importance. What centers or what parts of the brain are most exhausted by the attacks of fatigue that he has discussed today I do not know that anybody is prepared to say; but I, at least, feel the extreme importance of his warning in the connection of fatigue with especially an existing infection of some sort and the development of epidemic encephalitis.

THE EXCRETION OF NEUTRAL RED INTO THE HUMAN STOMACH *

ASHER WINKELSTEIN, M.D.
AND
JOSEPH M. MARCUS, M.D.
NEW YORK

Following the introduction of phenolsulphonephthalein as a test of renal function, the analogous use of dyestuffs to test the function of other organs has been attempted. For instance, phenoltetrachlorphthalein, indigocarmin and methylene blue have proved of some value as liver function tests. On account of the ease with which gastric contents may be recovered, and the fact that certain dyestuffs are readily excreted into the stomach, chromoscopy has also recently been applied to the study of the secretory function of the stomach.

Fuld, in 1908,[1] had observed that neutral red was excreted by the gastric mucosa. Finkelstein,[2] using a Pawlow pouch in dogs, found that the neutral red was excreted in the gastric juice in large quantities and that fluorescin and methylene blue were excreted only in traces, while eosin, indigocarmin, phenolsulphonephthalein, congo red, acridin red and phenoltetrachlorphthalein did not appear in the stomach after subcutaneous administration. Saxl and Scherf [3] reinvestigated the excretion of dyestuffs in the stomach of human beings, rats and rabbits. Glaessner and Wittgenstein [4] selected neutral red to study the secretory function of the human stomach. The findings of these observers with reference to the use of the dye as a test of gastric function are conflicting. Saxl and Scherf deny its value, while Glaessner and Wittgenstein find it very valuable. The latter assert that the excretion in the fasting stomach of neutral red follows closely the gastric acidity; i. e., in the normal, the dye appears in from eleven to fifteen minutes; in anacidity, the dye is not excreted; in hypoacidity, it appears in from twenty to sixty minutes, and in hyperacidity, in from seven to eight minutes. Recently Carnot and Gaehlinger [5] repeated this work and agree with the findings, saying, "In general there seems to be a correlation between the free acidity and the time of the elimination of the neutral red."

In view of the comparative novelty of the subject and the small but conflicting literature, it seemed important to make further studies. As a preliminary investigation, a series of forty-six unselected, ambulatory patients in the gastro-intestinal division of the outpatient department were studied as follows: The patients presented themselves with a fasting stomach; the Rehfuss tube was passed, and 2 c.c. of a 1 per cent. solution of neutral red (Ehrlich's neutral red was freshly dissolved in distilled water and boiled) was injected intramuscularly in the gluteal region. The gastric contents were aspirated every two minutes until the dye appeared as a definite pink discoloration. If no dye appeared, the aspiration was continued for two hours. Rehfuss, Ewald, alcohol and meat extract test meals were employed to confirm the acidity figures, particularly in the patients with achlorhydria. The observations are recorded in the accompanying table.

COMMENT

In the thirty-six cases in which the dye appeared, the average excretion time was twenty-two minutes. There does not seem to be a close correspondence, when free hydrochloric acid is present, between the degree of the acidity and the time of excretion. In general, however, the patients with hyperacidity excreted the dye earlier; eleven patients with hyperacidity averaged seventeen minutes (of these, seven had duodenal ulcer). The subacidity cases, contrary to expectation, gave a normal average—twenty-one minutes in seven cases. Thirteen patients with normal acidity averaged twenty-one minutes. The excretion of the dye was observed in twelve cases of true achylia gastrica; i. e., there was a persistent absence of free acid and ferments In three cases it appeared in sixty-five, ninety and ninety minutes, respectively. In the other nine, it did not appear in two hours. A study of the table with reference to the disease reveals that nine patients suffering from duodenal ulcer excreted the dye in the average time of thirteen minutes, and one in thirty minutes; two patients with gastric ulcer in twenty-three minutes; nine patients with chronic disease of the gallbladder, in seventeen minutes; and two patients with cholecystitis and achylia gastrica showed no excretion.

Results of Observations

Patient	Disease	Free Hydrochloric Acid	Total Acidity	Dye Excretion in Minutes
1	Achylia gastrica	0	12	65
2	Gastric neurosis	38		25
3	Ulcerative colitis	40		45
4	Achylia gastrica	0	15	90
5	Gastric neurosis	30	40	20
6	Cholecystitis	30	50	15
7	Constipation	40	60	15
8	Constipation	20		14
9	Gastric ulcer	18	30	22
10	Gastric ulcer	40	50	25
11	Ulcerative colitis	35	52	18
12	Duodenal ulcer	50	80	15
13	Duodenal ulcer	20	40	30
14	Gallstones	45	55	16
15	Duodenal ulcer	60	78	16
16	Gallstones	50	70	16
17	Gallstones	22	36	16
18	Pulmonary tuberculosis	9	33	18
19	Duodenal ulcer	9	21	16
20	Gallstones; achylia gastrica	0	10	No excretion
21	Ulcerative colitis	28	42	12
22	Achylia gastrica	0	10	No excretion
23	Achylia gastrica	0	10	No excretion
24	Pernicious anemia; achylia gastrica; syphilis	0	18	No excretion
25	Gastric neurosis	31	64	27
26	Duodenal ulcer	70	80	12
27	Gallstones ?.	0	14(Fasting)	12
		0	6(Ewald)	Present
		25	40(Rehfuss)	12
28	Gastric neurosis	8	18	46
29	Syphilis	23	..	23
30	Gallstones	20	30	25
31	Achylia gastrica	0	10	90
32	Constipation	30	38	47
33	Duodenal ulcer	20	30	13
34	Gallstones	20	40	15
35	Achylia gastrica	0	10	No excretion
36	Achylia gastrica	0	12	No excretion
37	Achylia gastrica; mucous colitis	0	15	No excretion
38	Duodenal ulcer	41	61	12
39	Gallstones	5	9	16
40	Duodenal ulcer	16	32	16
41	Duodenal ulcer	52	69	12
42	Gastric neurosis	42	65	15
43	Duodenal ulcer	62	74	10
44	Achylia gastrica	0	24	No excretion
45	Constipation	8	26	14
46	Syphilis; duodenal ulcer	18	25	15

A few facts seem to be brought out by this preliminary study. Apparently, in certain irritable conditions in or near the stomach, such as hyperacidity, duodenal ulcer and disease of the gallbladder, the time of the appearance of the dye is somewhat hastened. However, the variation in the excretion time of the dye is so little, and the correspondence of this variation to the disease present is so inconstant that the test appears to have little, if any, diagnostic value. The failure of the dye to be excreted before at least an hour, if at all, in the cases of true achylia gastrica seems more important and of some value in the study of disturbances of the secretory function of the stomach.

For example, in a case of cholelithiasis, the ordinary methods of study disclosed an achlorhydria both in the fasting contents and after an Ewald test meal. The dye, however, appeared in twelve minutes. A confirmatory Rehfuss test meal revealed 25 degrees of free hydrochloric acid. This case suggests the possible use of the dye to distinguish true from false achylia gastrica.

This question, as well as the excretion of the dye in patients with pernicious anemia, gastric carcinoma, achlorhydria and heterochylia, and in partial gastrectomy, is now being investigated. A study of the excretion of the dye as influenced not only by the normal physiologic stimuli, but also by pharmacologic agents, such as pilocarpin and histamin, is also planned.

SUMMARY

1. The excretion of neutral red into the stomach was investigated in forty-six cases.

2. Patients with normal or subnormal free hydrochloric acid figures excrete the dye in a fairly constant average time of twenty-one minutes.

3. In hyperacidity, the time of the appearance of the dye is hastened to seventeen minutes. Patients with duodenal ulcer or gallbladder disease, with or without hyperacidity, often show a similar figure.

4. In achylia gastrica, the excretion time is greatly prolonged to an hour or more. In most cases the dye does not appear in the stomach.

5. These preliminary observations suggest that the test may prove of value, in addition to the usual methods, in the study of the secretory function of the stomach, particularly in the various forms of achlorhydria and achylia gastrica.

Clinical Notes, Suggestions and New Instruments

ANGINA PECTORIS IN A YOUTH OF EIGHTEEN

S Chaille Jamison, M D, and George H Hauser, M.D., New Orleans

Senior Physician and Pathologist, Respectively, Mercy Hospital

History.—M S, a boy, aged 18, white, was admitted to the medical service of Mercy Hospital, March 12, 1925, at 6 p. m, complaining of agonizing pain over the whole surface of the chest and the epigastrium This pain was not referred to the arms or to any other part of the body; it was constant, though it waxed and waned in intensity. He had suffered in this manner throughout the day, though not so intensely. There had been nothing unusual in his habits, diet, health or exercise to account either to himself or to his family for the occurrence of this seizure; he had never had a previous attack During the few days preceding, there had been no symptoms of ill health, and this attack was ushered in with no symptoms except the pain.

March 3, the patient had been admitted to the surgical clinic of Mercy Hospital because of pain in the right lower quadrant of the abdomen A tentative diagnosis of chronic appendicitis was made by the surgeon in charge, Dr. E. A. Ficklen, but operation was not advised at the time, as the signs and symptoms did not warrant a positive diagnosis This attack is said to have lasted only a few hours. The boy's mother said that her son had enjoyed splendid health in the past; that he went in for strenuous athletics and heavy physical work, which did not seem to be limited by undue fatigue or breathlessness. She did not remember that he had ever had a sickness, and he had been particularly free of the usual diseases of childhood. She was positive that he had never had scarlet fever, diphtheria, tonsillitis, rheumatism or chorea. There was no history of venereal disease. The father had an aneurysm, of which he died at about 40. The mother had bronchial asthma, and congenital miosis of both pupils, but circulatory disease could not be demonstrated. Her blood was negative to the Wassermann test. Other members of the family were said to be in good health, though accurate details could not be obtained.

Physical Examination.—The young man was of the Alpine type, well developed and well nourished. He sat up in bed, but was bent forward, as one in great pain. His face was flushed and covered with sweat; his expression was anxious. The temperature was normal; the pulse full and regular, beating 100 times a minute. The blood pressure was 120, systolic, and 80, diastolic. The apex beat of the heart was located in the fifth interspace, inside the nipple line; the impulse was regular, not diffused or heaving, and there were no thrills. Percussion revealed no cardiac enlargement. Auscultation found the heart sounds regular and clear, and there were no murmurs. Examination of the lungs revealed no abnormalities (a particularly careful examination was made for dulness and râles at the bases). The examination of the abdomen was negative, except for moderate rigidity in the epigastric region. The genitals appeared normal. The urine contained no albumin, sugar or casts. The patella reflexes were present and equal. The pupils were miotic, and did not react to light or to distance (the state of the pupil was said by the mother to be congenital, and was identical with her own). The teeth were in good condition, and the tonsils were not enlarged or inflamed.

Course.—The patient was given one-half grain (0.03 gm.) of morphin by needle, without much relief; this was repeated in a few hours, with only transient relief. The application of ice caps had no effect. Nitroglycerin was not given, nor was amyl nitrite. There was vomiting of a frothy mucous fluid on several occasions. At no time did the pulse become rapid or irregular, and cyanosis did not develop. About 3 o'clock on the morning of March 13, at the height of a severe paroxysm of pain, the patient suddenly died. Prior to death, the diagnosis of angina pectoris was not considered on account of the patient's age.

Necropsy Findings.—At necropsy, the heart was found to weigh 240 gm. The coronary arteries were tortuous and rigid. The myocardium was light brown and of firm consistency. In the interventricular septum, the anterior wall of the left ventricle and the papillary muscle of the left ventricle were irregular areas, varying in size from about 0.5 to 1 cm., which were pale and sclerotic (healed infarcts). The endocardium showed a few small plaques of sclerosis about the base of the tricuspid valve. The right auricle was dilated. The coronary arteries, when opened, showed numerous yellow and gray areas of sclerosis throughout. Near the origin of the right anterior coronary artery was found a large excrescence (organized thrombus), which had almost occluded its lumen; this thrombus showed marked calcareous infiltration. The valves were normal. Microscopically, all the blood vessels showed proliferative endarteritis. Many of the smaller vessels were completely occluded, while the larger ones were atheromatous, with hyaline degeneration and calcareous infiltration. There were focal areas of cloudy and fatty degeneration, and diffuse and localized connective tissue increase (fibrosis and scar formation) throughout the myocardium.

The omentum was found attached by fairly recent adhesions to a small area over the outer third of the appendix, which measured 6.5 cm. in length, was somewhat thickened and showed near the tip a small injected area about the size of a pea. The lumen was almost obliterated by scar tissue. Microscopically there was found subacute and chronic exudative over chronic proliferative (obliterative) appendicitis.

The liver weighed 1,500 gm.; it was enlarged and was brownish gray, with white striations of scar tissue over the surface. The cut surface was of a mahogany color with congestion of the central veins and some increase of connective tissue. Microscopically there was marked congestion (central), slight connective tissue increase (intralobular), fatty and granular degeneration, and an area of acute exudative (suppurative) inflammation (focal abscess).

Nothing of note was demonstrated in the other organs of the body.

SUMMARY

The organs presented an acute (toxic) inflammation, with a small (microscopic) abscess of the liver, secondary to an infection of the appendix, which at the time of death was in a subacute stage. The sudden death was the result, not of the foregoing infection (which, however, may have been contributory) but of the disease of the vascular system of the heart itself, as described above. The changes noted in the vessels of the heart and also in many of the smaller vessels of the other organs were characterized by primary changes in the intima, with marked proliferation of the endothelium. This character of lesion is the result of a diffusible toxin acting directly through the circulation. The absence of perivascular round cell infiltration in any of the vessel walls or elsewhere or other gross or microscopic evidence of syphilis in the organs rules out syphilis as the etiologic factor. Likewise is the absence of any Aschoff bodies in the heart against a rheumatic etiology.

It seems possible that the injurious agent (toxin) responsible for the vascular changes came from the appendix during its acute and chronic stages of inflammation.

COMMENT

True angina pectoris in a person under the age of 20 is very rare. Houchard[1] quotes Gauthier's report of its occurrence in four patients between the years of 10 and 20, proved at necropsy, and also Walter Maxon's necropsy of a child of 11, whose coronary arteries showed sclerosis. Powell[2] reports no cases under the age of 20, but quotes Dreschfeld's report of a boy of 12, who had the symptoms of angina pectoris and who died suddenly in an attack, but no reference is made to a necropsy of this case. The more modern textbooks and systems of medicine make no reference to cases occurring in the young, and confine themselves to the statement that the disease is rare under 40.

It is interesting that there is no evidence of syphilis in this case, and also that there is no disease of the aorta. As the necropsy in this case was performed at an age before the arterial changes of later life could come on and confuse the pathologic picture, it seems to lend strong support to the prevalent idea that angina pectoris is due to changes in the coronary arteries, and, to a certain extent, to refute the theory that syphilis and aortitis play a necessary part in the production of this syndrome. It seems that, in this case, the plausible idea is that the cardiac changes were the result of a focal infection, the original focus being the appendix.

Management of Delinquent Children.—Of the 879 supervised institutions in New York State, twenty are conducted for delinquent children, while several receive only truants or those with improper guardianship. This does not take into consideration the various orphanages, many of which accept delinquent or neglected children under special conditions, or of the mentally defective delinquents in the several state schools for the feebleminded. Of the group of twenty just mentioned, three are controlled exclusively by the state, seven are maintained by the Roman Catholic Church, four are nonsectarian, two are Jewish, one Protestant, two episcopalian, and one is municipal in management and is under the local board of education. The scope of these institutions is becoming increasingly delimited to the care of the truant child. Approximately 6,000 children are cared for in this manner, less than a third of whom are in state institutions.—Branham, V. C.: *State Hosp. Quart.* **10**:*611 (Aug.) 1925.*

THE DIARRHEAS OF INFANTS

Although the manifestations of the diarrheas of infancy have long been recognized in medical practice and can in most instances be treated with success, the pathogenesis or etiology of such alimentary disturbances remains the subject of uncertainty and debate. For frank bacillary dysentery there is, of course, evidence to incriminate special intestinal invaders; yet the harm that they initiate can be described better in general terms than in specific references to disarranged gastro-intestinal functions. Lack of the "physiologic antiseptic" of the alimentary tract—the gastric juice—or reduced acidity of this secretion has in particular been incriminated in the past. Davison's[1] recent observations at the Johns Hopkins Hospital showed practically no difference in the reaction or cultures of the gastric contents of normal infants and of those convalescent from diarrhea. Streptococci and gram-negative cocci, which are mouth organisms, were more often found, as might be expected, in gastric specimens containing saliva; colon bacilli were more frequent in those contaminated by duodenal regurgitations.

The use of diets containing some form of lactic acid milk has become popular in recent years in the treatment of digestive disturbances of infancy. It seems undoubted that such diets increase the gastric acidity. Davison[1] is unwilling to admit, however, that the acidity, per se, destroys the bacteria present and thus explains the beneficial effects of lactic acid milk feeding. He noted that the reaction of the gastric contents has no apparent relation to the frequency with which various micro-organisms were found in the stomach. Consequently, the suggestion is advanced that the soured milk diets, even though they do not actually kill bacteria after ingestion, may constitute a poor culture medium; so that, as a result, bacterial growth does not flourish.

With respect to the duodenal conditions also, a revision of opinion is ventured. Duodenal cultures were found sterile more frequently in infants whose gastric acidity ranged from p_H 5.1 to 5.7 than in those in which it was p_H 3.6 to 4.4. The reaction of the gastric contents in the cases studied by Davison[2] did not have any apparent relation to the amount of duodenal amylase and trypsin. In the digestive disturbances of infants, especially in diarrhea and to a lesser extent in bacillary dysentery, he found the activity of these enzymes decreased while the hydrogen ion concentration of the duodenal contents and the number of colon bacilli in the duodenum were increased. These "unorthodox" findings call for a new interpretation of the pathologic physiology of the diarrheas. Davison proposes the following sequence of factors to explain the actual happenings in the diarrhea: (1) a primary cause, which still remains undetermined but which may be different in individual cases and include external heat, fever, infections and overfeeding with an undesirable diet; (2) a reduction in the activities of the duodenal enzymes as the result of the primary factor; (3) consequent accumulation of undigested and unabsorbed food residues; (4) invasion of these by organisms of the colon group from the cecum and large intestine, and (5) the decomposition of this food material by the micro-organisms with formation of irritating products that accelerate peristalsis. If such a view is even in part correct, it is evident that the problem of infant diarrhea cannot be envisaged from a single angle.

ARCHIVES OF PATHOLOGY

At the last annual session of the American Medical Association, held in Atlantic City in May, a resolution was introduced into the House of Delegates by the delegate for the Section on Pathology and Physiology, urging the establishment by the Board of Trustees of a periodical which would be representative of pathology and allied sciences in this field. At the meeting of the Board of Trustees held in Chicago in September, such a journal was definitely constituted, to be published by the press of the American Medical Association, along the same plan as the other special periodicals now issued, including the *Archives of Internal Medicine*, the *American Journal of Diseases of Children*, the *Archives of Neurology and Psychiatry*, the *Archives of Dermatology and Syphilology*, the *Archives of Surgery* and the *Archives of Otolaryngology*. It may safely be said that these journals have earned high repute in their fields not only as the leading periodicals in the specialties they represent but also for the manner in which they have advanced the progress of medical knowledge through affording investigators suitable mediums for the expression and interchange of opinion. Since the first of these periodicals, the *Archives of Internal Medicine*, was established, in 1908, the Board of Trustees has been constantly besieged by representatives of various departments of medicine to add to the list. It was these considerations, no doubt, that moved the Board of Trustees to give favorable consideration to the newest member of the group—the *Archives of Pathology and Laboratory Medicine*.

---

[1] Davison, W. C.: Gastric Analyses in Normal Infants and in Those Convalescent from Diarrhea, Am. J. Dis. Child. **30**: 23 (July) 1925.

[2] Davison, W. C.: The Duodenal Contents of Infants in Health, and During and Following Diarrhea, Am. J. Dis. Child. **29**: 743 (June) 1925.

As many readers are no doubt aware, several periodicals devoted to pathology are already available both in this country and abroad. However, it was the belief of the representatives of the Section on Pathology and Physiology, of the Board of Trustees and of the editorial staff of the Association that none of these periodicals are representative of all of American pathology, and that there exists opportunity for the development of a complete journal along a scale similar to that of the other special journals.

The Board of Trustees selected as the first editorial board: Dr. Ludvig Hektoen, Chicago, local editor and chairman of the board; Dr. James Ewing, New York; Dr. W. G. MacCallum, Baltimore; Dr. William Ophüls, San Francisco; Dr. Alfred Stengel, Philadelphia, and Dr. S. B. Wolbach, Boston. This editorial board, working with the editorial staff of the Association, proposes to issue a periodical which will contain original articles in the field of pathology and laboratory investigation, abstracts of current literature on pathology, the transactions of important pathologic societies, news of those working in the field of pathology, a department of medicolegal pathology, reviews of new books on pathology, and monthly reviews of the present state of our knowledge of such topics as heredity, constitution and disease, lymphogranulomatosis, cancer, allergy, nephritis and nephrosis, and postmortem methods. A special section also will be devoted to new technical methods used in the laboratory and in the postmortem room, and, indeed, to all of those procedures which have been classified under the somewhat colloquial term, "laboratory medicine."

The growth of scientific medicine has resulted, not in a departure from the fundamental investigations of anatomic changes within the human body during and subsequent to disease, as was perhaps expected by some, but, indeed, in an intensification of the belief that a knowledge of pathology is absolutely fundamental to successful diagnosis and treatment in every field of medicine. Virchow, it has been pointed out, realized that pathology embodies both the anatomy and the physiology of the abnormal organ. German investigators, however, concentrated their attention on morbid anatomy, and Great Britain and France up to fairly recent times practically limited pathology to anatomic findings in the postmortem room. The modern experimental conception of pathology, as pointed out by Flexner, has developed a type of pathologist who is at the same time investigator and teacher in the school of medicine and pathologist to the hospital in intimate contact with the diagnosis and treatment of disease. Indeed, the modern medical school is likely to be built around the pathologic unit as the very heart of the institution. In this situation, when pathology as a science is beginning to come wholly into its own, it is well that American physicians should have from the first an authentic, independent organ ready to serve for the advancement of knowledge.[1]

THE NEWER GASTRIC PHYSIOLOGY

When Beaumont began his pioneer observations on Alexis St. Martin, the human carrier of a gastric fistula, he was familiar with studies on the functions of the stomach by several eminent predecessors and contemporaries. One might suppose, therefore, that after all the intervening years the behavior of the gastric mechanisms would have been well established. Despite this, however, there have been reversals of opinion as well as important increments of knowledge regarding the working of the abdominal organ in which the alimentary processes are initiated. Scarcely a detail of the story has not been challenged or denied at one time or another. From the standpoint of clinical physiology, this is unfortunate. The problems of gastro-enterology have often become confused because of the "instability" of the information that has been brought to bear on some of them. The history of the study of gastric physiology would furnish striking illustrations of the impediment that dogmatic assertions supported by the authority of a prominent person may introduce into the development of dependable knowledge.

Caution, a critical attitude and intellectual courage—the indispensable attributes of a real scientist—are nowhere called for more insistently than in the contemplation of the causes of gastric secretion and motility. Ivy,[2] newly appointed professor of physiology at the Northwestern University Medical School, has discussed some of the recently accumulated evidence that points to the desirability of reorganization of our knowledge in this field. He believes that gastric secretion can be divided into three phases with reference to cause: 1. The cephalic phase, caused by reflexes through the cerebrum (psychic) and by reflexes through the thalamus, midbrain and medulla, excited by the sight, taste and smell of food in the presence of appetite. 2. The gastric phase, caused by mechanical distention of the stomach and by the action on or by way of the gastric mucosa of substances in the food. 3. The intestinal phase, caused by the action on or by way of the intestinal mucosa of substances in the food or resulting de novo from digestion.

[1] The Archives of Pathology and Laboratory Medicine, to be published monthly by the American Medical Association, 535 North Dearborn Street, Chicago; first issue, January, 1926; subscription price, $6 annually.

[2] Ivy, A. C.: Contributions to the Physiology of the Stomach, IX, The Causes of Gastric Secretion: Their Practical Significance and the Mechanisms Concerned, J. A. M. A. **85**: 877 (Sept. 19) 1925.

The existence of true psychic secretion has long been recognized. The fact that decerebrate animals will secrete gastric juice after excitation that proceeds from the head region is new and shows that other than solely cerebral reflexes are concerned therein. The recent reestablishment of the validity of Beaumont's observations on the effectiveness of mechanical factors as stimuli for gastric secretion has already been referred to in The Journal.[3] Ivy has indicated how this may be related to the clinical pathology of the hypernormal secretion that is associated with pylorospasm or pyloric stenosis. The retention of food in the stomach tends, through mechanical stimulation of the mucosa, to augment the gastric phase of secretion. The intestinal phase also is augmented because the chyme is more completely hydrolyzed, as the result of its retention in the stomach, so that when it is ejected into the duodenum it is more readily and rapidly digested. This more rapid digestion in the intestine means an increase in the concentration of secretagogues acting on or by way of the intestinal mucosa.

The beautiful demonstration that a sequestered and transplanted gastric pouch will secrete an acid juice through the influence of foods in the alimentary tract reinforces the belief that a humoral mechanism, as well as a nervous one, is concerned in the secretory act. This seems to be true whether or not there is some specific secretagogue or "gastrin" concerned as a hormone for the secretion or whether the provocative substances that act through the blood stream are merely ordinary food components. From a practical standpoint it is noteworthy that meat is the only food thus far studied containing a substance that stimulates on contact with the gastric mucosa.

THE COLORATION OF SUBDURAL BLOOD CLOTS

The much debated problem of the extrahepatic formation of bile pigment, to which reference has repeatedly been made in The Journal,[4] has found its solution in the positive demonstration that the liver is not essential to the production of bilirubin. Perhaps the most convincing evidence has been furnished by Mann's experiments at the Mayo Clinic, wherein it was observed that in the urine, blood plasma and fat of totally dehepatized dogs a yellow pigment appears which gives a positive reaction to all the accepted chemical tests for bilirubin. More recently, Mann, Sheard and Bollman[5] have made the evidence for the identity of the yellow pigment even more convincing. They have determined the curve of light transmission of the pigment and compared the curves obtained with the bilirubin in the plasma of a control dog having the common bile duct obstructed and gallbladder excised, with the curve produced by bilirubin removed from the gallbladder of the dehepatized animals at the time of operation. The general character of all the curves was the same. This would seem to be final evidence, as the physiologists contend, that the pigment which develops in the dehepatized animal is bilirubin, and that extrahepatic formation of bile pigment is possible. Rich likewise has lately corroborated the observation that the intra-abdominal organs are not necessary for the formation of bilirubin; consequently there can be little if any doubt that the liver must be considered to some extent as an excretory organ for this pigment.

These findings with respect to the extrahepatic genesis of bilirubin give a new significance to a phenomenon that has attracted neurologic surgeons in connection with chronic subdural hematoma. Cushing[6] has drawn attention to the peculiar greenish appearance often noted on the dural surface of the partly organized blood clot. The unusual color may sometimes be recognized through the semitranslucent dura. Though a discoloration of the dura of some sort is commonly observed in these cases, it is variously described.

Although there are as yet no records of discriminating tests of these greenish surfaced clots, Berglund of the Harvard Medical School is reported to have examined the dark, greenish fluids obtained from some of the intracranial tumor cysts, and demonstrated that the color is due to biliverdin. There is a likelihood, therefore, that the unusual colors of the subdural hematomas are attributable to an extrahepatic formation of biliary pigments. The demonstration of such products, notably under the designation of hematoidin, which may occur in crystal masses in old blood clots, has a long, familiar history. Cushing points out, however, that apparently it is only on the surface of the subdural hematomas that a sufficient amount of bile pigment is deposited to produce the deep icteric color under consideration. Present-day students of the subject have regarded the transformation of hemoglobin into biliary pigment as a function of the endothelial clusters widely distributed in the body, of which the Kupffer type is the best known. These represent the so-called reticulo-endothelial system. Following this suggestion, Cushing believes it safe to assume that the mesothelial cells of the leptomeninges are in their action similar to if not identical with the cells of the reticulo-endothelial apparatus as it has been described by pathologists in other parts of the body, more particularly in the liver and spleen; and as a part of this apparatus that they possess among other properties the ability to transform hemoglobin into bilirubin and biliverdin. These subproducts, indeed, become so heavily deposited on the surface of a long standing subdural hematoma as to give it an unmistakable icteric color. On the other hand, Cushing assumes, when the clot has been removed the subpial surface of the compressed brain will usually be found to have the yellowish color commonly observed in old cerebral extravasations of any sort, owing, as Virchow long ago showed, to the presence of hematoidin crystals.

Current Comment

PIGMENTED MOLES

Among the most important and most difficult aspects of a practitioner's work are such little lesions as the nevi. Frequently the physician must decide whether or not a pigmented mole is malignant or benign; and if benign, whether or not it is likely to assume malignancy. The melanin forming cells, specific in their function, are called melanoblasts. These melanoblasts are able to produce pigment and to give rise to other cells of their own nature. They lie in the basal cell layer of the rete malpighii and can produce pigment in response to any adequate stimulus. The production of a nevus involves the departure of these cells from their original epithelial nature and their migration into the corium. This phenomenon may occur anywhere in the body but is found more often on the face and neck, perhaps because of the likelihood there of irritation. Since the cells, after migration, are still capable of producing melanin, they may, after a period of slow growth, become quiescent, or they may undergo malignant change. In those nevi which remain benign, the regression that takes place is a fibrosis. This does not mean, however, that all benign moles will remain macular, become less noticeable and fade in color. Some of them may become warty, nodular and mamillated. The size or contour of the nevus, then, is not in itself an indication of safety or of danger. A complete study of melanomas [1] has just been issued as a monograph, forming a single issue of a foreign periodical. Dr. James W. Dawson there indicates the significant signs in a mole that is undergoing malignant change. Increased vascularity and pigmentation, or superficial ulceration with periods of bleeding and subjective symptoms, are signals of warning. A history of trauma or mechanical irritation is usually obtained in such cases and is not to be taken lightly. Such history and signs justify wide extirpation, and a microscopic study of the tissue removed will show pigmentation and proliferation beyond the area in which pigmentation can be detected by the naked eye. If the extirpation is not sufficiently wide, not only has pathologic tissue been left in situ, but also more harm than good may have been done by opening channels of metastasis into subepidermal layers or into the lymphatic nodes of adjacent regions. Should the lymph nodes be involved, Pringle advises "excision of the tumor, with a good zone of healthy skin around it and a somewhat larger zone of the underlying deep fascia, up to and including the nearest anatomical group of glands at least; and all that is removed should be, in one continuous strip as far as possible."

LOWERED BASAL METABOLISM AND THE PULSE

The existence of a proportionality between the pulse rate and the level of metabolism has been recognized for some time. It has been suggested that the pulse rate multiplied by the pulse pressure may be an even better indicator of the metabolic level than the rate alone. We must emphasize the fact, Du Bois [1] writes, that the pulse rate is a symptom of major importance and should be studied frequently when the patient is at complete rest. Only a rash clinician disregards its warnings. Despite the cogent demonstration that in such diseases as exophthalmic goiter, leukemia and myxedema the basal metabolism and pulse rate go hand in hand, it must be recognized also that the rate of the heart beat is easily influenced by extraneous factors, especially the emotions. The presence of bile salts in the circulation is a chemical influence in the direction of bradycardia. Enlargement of the heart, such as attends certain infections, also affects its rate. It has long been observed that the febrile periods of certain acute infections are sometimes succeeded by a postinfectious period of slow pulse. Schick and Cohen [2] of the Mount Sinai Hospital in New York have just demonstrated that this is also attended with a low metabolism, and is due to the latter rather than to some special factor, such as stimulation of the vagus that inhibits the heart. Schick and Cohen believe that the lowered postinfectious metabolism is caused by a more or less generalized cellular damage which, at times, hits the endocrine glands especially. Only toxic cases seem to have the lowered type of metabolism. The union of laboratory and clinical facts thus demonstrates the "interrelated trinity of pulse, temperature and metabolism, to which we can add respiration."

OUTPUT OF THE HEART IN HEART DISEASE

In a recent issue of The Journal,[3] in which attention was directed to some new and outstanding features of the circulation, reference was made to Henderson and Haggard's estimate that the blood stream pumped by the heart is about twice as large as was formerly supposed. An excellent heart stroke volume along with an augmented pulse rate provides for an effective oxygen supply even in periods of vigorous demand such as muscular exercise occasions. The quickened circulation furnishes a volume of blood so large in relation to the oxygen consumption of the body that the oxygen content of the venous blood

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Society News.—Dr. Harry Spiro addressed the San Francisco County Medical Society, October 14, on "Modern Diagnosis and Treatment of Heart Disease," and Dr. Ernst Gehrels on "Gastric Surgery." The October number of *California and Western Medicine* publishes a list of about two pages of the names of physicians, and the subjects on which they have volunteered to speak in the extension service of the state medical society.

Gertrude Steele, Naturopath, Wanted for Manslaughter.—The *Police Bulletin*, Oct. 13, 1925, from Los Angeles, reports that Gertrude Steele, "Naturopath," under indictment for manslaughter, is "wanted." In February, 1920, THE JOURNAL recorded that Gertrude Steele had been charged with manslaughter following the death of a "patient" who died in the process of being "beautified." THE JOURNAL in April, 1921, reported that the same woman had had her license revoked by the board of medical examiners. In the issue of Nov. 1, 1924, THE JOURNAL recorded a warning issued by Dr. Charles B. Pinkham, executive officer of the state board of medical examiners, against Gertrude Steele, in which it was stated that although the woman's license had been revoked in 1921, she was still operating. THE JOURNAL for Nov. 29, 1924, stated that Gertrude Steele had been indicted but had not been apprehended, and it was said she had gone to Canada. It was recorded further that a suit for $5,000 against Mrs. Steele had been filed by another victim who claimed to have been permanently disfigured, and a judgment for nearly $3,000 against Mrs. Steele had been given another victim, also alleged to have been permanently disfigured. In February of this year THE JOURNAL recorded that Gertrude Steele had been located in Oberhausen, Germany. The files show that this notorious quack has for years advertised in the Los Angeles *Times*, advertisements appearing as late as January, 1924.

COLORADO

Society News.—The Colorado State Medical Society, at its fifty-fifth annual session at Colorado Springs, conducted an historical exhibit in addition to commercial and scientific exhibits; subjects were assigned to certain counties. According to the president-elect, Dr. George A. Boyd, Colorado Springs, this is the first attempt at an historical exhibit by a state society.

DELAWARE

County Society Prosecutes Chiropractor.—Following the institution of a suit brought by Chiropractor O. M. Heimark against a patient for nonpayment of a bill, the Kent County Medical Society engaged the services of an attorney to prosecute Heimark for practicing medicine without a license, and the state medical society at its annual meeting adopted a resolution approving the Kent County Medical Society's action and offering any financial aid that may be necessary.

State Medical Election.—At the annual meeting of the Medical Society of Delaware, Wilmington, October 13-14, Drs. Olin S. Allen and Richard C. Beebe were nominated vice presidents; Dr. William O. LaMotte, secretary, and Samuel C. Rumford, treasurer. The new president is Dr. John B. Derrickson, Frederica. The nominating committee selected the following names to be submitted to the governor for his selection of two members of the medical examining board: Drs. Henry W. Briggs, William Wertenbaker, Harold L. Springer, George F. Jones, Joseph S. McDaniel, Joseph Bringhurst, Luther S. Conwell, Jerome D. Niles, Joseph W. Bastian and Joseph K. Frame. The next annual meeting will be in Dover in October, 1926.

DISTRICT OF COLUMBIA

Washington's Negro Health Problem.—A special meeting of the directors of the Washington Tuberculosis Association was held in October to consider the death rate among negroes from tuberculosis, which in the last five years has averaged almost five times as high a rate as that of the white population. Among those in attendance were Dr. George M. Kober, president; Dr. Joseph A. Murphy, chief sanitary inspector of the public schools; Dr. Frederick C. Smith, representing the U. S. Public Health Service and Dr. Harvey W. Wiley, formerly chief chemist, U. S. Department of Agriculture. It was shown that there was a rapid decline in the colored tuberculosis death rate in the period 1915-1920, but that from 1920 to 1925 there had been no decline. Plans are being made now to examine and follow up every child entering the schools, to extend the nutrition clinics up to the eighth grade in the public schools, to supply help for more of the open window classes, to renew efforts to establish a sanatorium for tuberculous children, and to extend the plan of educating and examining adult workers in industry.

GEORGIA

Hospital News.—The new $275,000 hospital at Fort Benning, Columbus, has been opened. It has a capacity of 102 beds.——The Central of Georgia Railway will build a sixty-bed hospital for employees at Savannah under the supervision of Dr. Craig Barrow.

State Board Election.—At a meeting of the state board of medical examiners at the Piedmont Hotel, Atlanta, October 13, Dr. Clarence M. Paine, Atlanta, was elected vice president; the other officers were reelected; Dr. Jarrett W. Palmer, Ailey, is president, and Dr. Charles T. Nolan, Marietta, secretary-treasurer.

ILLINOIS

Unlicensed Chiropractors.—Five chiropractors were tried in circuit court at Benton, recently, on charges of illegal practice; they were, it is reported, Howard C. Gott and Arthur Coleman, Christopher; Thomas E. Shaw, Benton, and Thomas Heaney and Margaret C. Heaney, Zeigler.

Personal.—Dr. Clyde H. Cable, South Bend, Ind., has been appointed superintendent of the McDonough County Tuberculosis Sanatorium at Bushnell.——Dr. Victor H. Bassett, health officer of Savannah, Ga., has been appointed health officer of the Quincy public health district, Quincy.——Dr. Emil A. Edlen, city physician of Moline, has been elected president of the Moline Public Hospital staff, Dr. Henry S. Bennett, vice president, and Dr. Florence E. Bollaert, secretary.

Cancer Now in Second Place.—The state department of health reports in *Illinois Health News* that there were thirteen diseases, which caused at least 1,000 deaths, in Illinois in 1924. As in the previous year, heart disease was first, but it showed no increase during 1924, and the rate dropped slightly Cancer, however, moved from fourth place in 1923 to second place among the leading causes of death, partly the result, it is said, of the sharp decline last year in deaths from pneumonia. In 1902, cancer was the cause of 2,542 deaths in Illinois and last year of 6,960, the rates per hundred thousand population being fifty-one and 101, respectively. Violence has become one of the chief mortality problems in Illinois, it was third on the list. Violence, including accidents of all kinds, suicide and homicide, caused 6,867 deaths, and more than 55 per cent. of the victims were between 25 and 50 years of age; nearly one out of every five deaths among people in the state between these ages was due to violence, and the automobile is the chief factor; next, accidental falls, and then railroads. Suicides increased from 886 in 1923 to 1,012, and murders from 709 to 821. Chronic nephritis moved up from fifth to fourth place, and cerebral hemorrhage up to fifth. Pneumonia dropped from second to sixth place (not significant, since it varies so much from year to year), and tuberculosis dropped from sixth to seventh place. About 80 per cent. of the deaths from heart disease were among people more than 50 years of age, and about 75 per cent. of them were more than 60 years of age. Deaths from diabetes were fewer by 128 than in the year before.

Chicago

Hospital News.—A $2,500,000 addition to Cook County Hospital is being planned.——The social service department of the woman's board of St. Luke's Hospital will give its third annual charity ball in the Gold Room at the Congress Hotel, November 13.

Liquor Permits Revoked.—It is reported that the liquor permits of Dr. Samuel S. Epstein, 803 Roosevelt Road, Chicago, and Dr. Roy Griffy, Oblong, Ill., and those of the Raynor Pharmacal Company, 140 West Van Buren Street, and returned to the heart is surprisingly little below that of the freshly oxygenated arterial supply. In cardiac disease, however, this efficiency may break down, the inefficiency of the circulation showing itself by the increase in arteriovenous oxygen difference above the normal value. Henderson and Haggard[4] found this to be due, in a few patients studied by them, to the smaller "stroke volumes," as they describe the fraction of a liter of blood that each ventricle discharges in one beat. As the pulse rate is generally increased in cases of heart failure, it appears reasonable to infer that the oft noted slowing of the circulation is due to a greater relative decrease in the output per beat. In the evidence collected by Rabinowitch[5] at the Montreal General Hospital, marked and consistent differences were noted between the values in the normal persons and the pathologic cases of various heart lesions, associated with heart failure. Thus the average ventricular output of blood per beat in ten normal persons at rest and without any clinical signs of heart failure was 85.3 c.c., with maximal and minimal values of 99.5 and 70.1 c.c., respectively. In heart failure the figures ranged from 13.6 to 46.2 c.c., with an average output—if these data can properly be averaged—of 27 c.c. One can therefore well understand why such patients are "out of breath" from a degree of physical exertion, and demand for oxygen, that in normal persons involves no considerable decrease of the partial pressure in the tissues.

Association News

REDUCTION OF MEDICAL TAXES

Representatives of Association Appear Before Ways and Means Committee

At a hearing before the Committee on Ways and Means of the House of Representatives held at Washington, October 21, a presentation of reasons was made for the reduction of the existing war tax on physicians under the Harrison Narcotic Law. The American Medical Association was represented at the hearing by Dr. Charles W. Richardson, Washington, D. C., member of the Board of Trustees, and by Dr. William C. Woodward, Chicago, executive secretary, Bureau of Legal Medicine and Legislation.

Dr. Richardson pointed out to the committee that prior to the war the federal tax or fee paid by physicians for a license under the Harrison Narcotic Law was one dollar. He said that the medical profession of the country gladly accepted the increased war tax of three dollars and that the profession did everything in its power to make the law effective. He said that, as many of the war taxes are being removed, this increased tax against physicians should now in justice be restored to the rate existing prior to the war.

Dr. Woodward stated that it is clearly a question of whether Congress will or will not reduce a war tax; that the present rate of three dollars was effected by the Revenue Act of 1918 along with other increases; that these other increases have, to a large extent, been removed or reduced.

"For a number of years," said Dr. Woodward, "the tax derived from physicians under the narcotic act was nearly a half million dollars greater than the expenses of enforcing the act. Obviously, that was as it should be if one were dealing with a measure intending to raise revenue. Recently, however, the plea was made that inasmuch as approximately half a million dollars a year was being collected under the law, therefore the appropriation should be increased so as to permit the use of the entire amount for enforcing the law. That argument was accepted and an increased appropriation of half a million dollars was made. So it is not fair to take the cost of enforcing the law and fix the tax on that basis."

Representative W. R. Green, chairman of the committee, made the significant remark, "I suppose you are inclined to think that in any event the burden of enforcing the law ought to be on the whole public and not on the medical profession." The remark of Chairman Green may be regarded as the crux of this proposed tax reduction. The enforcement of the law is clearly an expense which should be borne by the public generally and not by the medical profession alone. Under no conditions can it be claimed that the enforcement of a general federal statute should be paid for exclusively by any class or any profession.

Drs. Richardson and Woodward also presented two proposed amendments to the existing federal income tax law: first, authority to deduct expenses incurred in attending meetings of scientific and professional organizations; and second, expenses of postgraduate study.

Dr. Richardson stated that, in the revenue acts of 1921 and 1924, exemptions are permitted to all trades, industries and mercantile organizations that send their representatives to various parts of the country. Dr. Woodward argued that the medical profession should be entitled to the same privilege, which has been denied to physicians under rulings of the Commissioner of Internal Revenue. The extent to which physicians are members of medical organizations and attend their meetings was shown by Dr. Woodward. He stated that inquiries were addressed to ninety-eight medical organizations, and seventy-seven of these reported their membership. The total membership of these seventy-seven medical organizations was 177,219. He stated that the estimated cost of attendance was $1,718,000. On a 4 per cent. basis the tax amounted to $68,726, which is a very conservative estimate of the federal taxes paid by the medical profession under this particular section of the law because of the adverse rulings of the Commissioner of Internal Revenue.

The Committee on Ways and Means will continue to hold hearings for a considerable time, and will then go into executive session for the purpose of drafting the new federal tax bill to be considered at the December session of Congress.

THE DALLAS SESSION

Plans for the Scientific Exhibit

The Committee on Scientific Exhibit calls attention to the fact that those who expect to exhibit at the Dallas session should begin making arrangements sooner than usual, as it will occur the middle of April. Plans for the Scientific Exhibit and Motion Picture Theater Program are under way; as soon as the details have been formulated, further announcement will be made in THE JOURNAL. The circular letter and application blank for the Scientific Exhibit, 1926, will be sent out in about six weeks. Any who desire to receive these should send their names and addresses to Director, Scientific Exhibit, American Medical Association, 535 North Dearborn Street, Chicago, Illinois.

Physician and Social Service Worker.—The physician is in charge of the patient; it is his responsibility to diagnose the disease and to prescribe treatment. He is the head of the unit organized for the benefit of the patient; the social worker is a part of his unit. Working with the physician, fitting her specific qualities into the plan of action, her work reaches its greatest usefulness to the patient. Working alone, touching the physician only casually, she cannot function to the best advantage. It is therefore highly important that for the exercise of her primary duty "to further restoration and maintenance of health" she work under the immediate direction of the physician. It is equally important that the physician outline the principles for the social worker to follow.—*Hosp. Social Service* **12**:137 (Sept.) 1925.

Liquor Permits Revoked.—It is reported that the liquor permits of Dr. Samuel S. Epstein, 803 Roosevelt Road, Chicago, and Dr. Roy Griffy, Oblong, Ill., and those of the Raynor Pharmacal Company, 140 West Van Buren Street, and the Blaine Manor Pharmacy, 4833 North Talman Avenue, were revoked, October 26, by the prohibition director.

Lectures for Nurses.—The Chicago Tuberculosis Institute's annual lectures for nurses began October 21; lectures will be given in various sections of the city until December 16; among the lecturers will be Dr. Daniel P. MacMillan, director of child study of the board of education; Dr. Ethan Allen Gray, medical director of the Chicago Fresh Air Hospital; Dr. Hiram H. Bay of the Chicago Tuberculosis Institute; Dr. Max Biesenthal; Dr. John M. Dodson of the American Medical Association; Dr. Walter W. Hamburger; Dr. Harrold A. Bachmann and Dr. John Leonard Manning.

Resolution on Free Medical Service.—The council of the Chicago Medical Society, at a meeting, October 13, adopted a resolution concerning free medical service, a copy of which will be forwarded to all hospitals and social agencies and health departments in the city. The council held that the Chicago Medical Society should take the initiative in defining medical charity and approved free medical service to all persons who receive charity of any other kind or description. The council, however, views with alarm the tendency of hospitals, social agencies and health departments to pauperize the public by giving free service to those who can afford to pay even a part of the usual fee, and concluded that members of the Chicago Medical Society who aid such institutions in pauperizing the public may be brought before the ethical relations committee.

Personal.—Dr. Frank R. Guido won second place in Part I in September, 1923, and first place in Part II in February, 1925, it is reported, in the National Board of Medical Examiners examination. Dr. Guido took the first two years of his medical course at Loyola University School of Medicine, and the other years at Rush Medical College.——Dr. Daniel P. MacMillan, director of the Child Study Bureau and examiner of teachers, Chicago Board of Education, addressed a meeting of physicians, October 23, at the Logan Square Masonic Temple, preparatory to the coming health pageant to be conducted under the auspices of the Northwest Branch of the Chicago Medical Society. His subject was "Uncared for, Handicapped Children."——Dr. Charles F. Read, formerly superintendent of the Chicago State Hospital, has been appointed head of the department of nervous and mental diseases, Loyola University Medical School.——Dr. Paul R. Cannon has been appointed assistant professor in pathology at the University of Chicago.——Dr. Karl A. Meyer has been appointed to a professorship of clinical surgery at the University of Illinois.

INDIANA

Hospital News.—The City Hospital, Indianapolis, has let the contract for the construction of a $234,000 surgical unit. ——The new $750,000 wing of St. Margaret's Hospital, Hammond, having a capacity of 325 beds, has been dedicated.——The commissioners of Miami County have agreed to take over and operate the Miami County Hospital, Peru, as a county institution.

Society News.—Elmer V. McCollum, Ph.D., professor of biochemistry, Johns Hopkins University School of Hygiene and Public Health, Baltimore, addressed the Marion County Medical Society, Indianapolis, October 13, following a dinner in his honor.——Dr. Edward C. Kendall, head of the chemical division of the Mayo Foundation for Medical Education and Research of the University of Minnesota, Minneapolis, addressed the Indianapolis section of the American Chemical Society, October 9, on "The Chemistry of the Thyroid Gland and Its Relation to Oxidation."——Dr. John L. Tierney, St. Louis, addressed the Seventh District Medical Society, Martinsville, October 28, on "A Consideration of Cardiovascular Renal Diseases."

IOWA

Society News.—Dr. Paul A. O'Leary of the Mayo Clinic, Rochester, Minn., addressed a joint meeting of the Scott and Rock Island County medical societies at Davenport, October 6, on "The Treatment of Syphilis," illustrated by lantern slides.——Among the speakers at the state conference on social work, Iowa City, October 23, were Dr. William A. Evans, Chicago; Dr. Fred M. Smith of the University of Iowa Medical Faculty; Dr. Matthew U. Chesire, Marshalltown, and Dr. Don M. Griswold, state health commissioner. ——Dr. Thomas F. Beveridge, Muscatine, has been elected president of the Southeastern Iowa Medical Society; Dr. John P. Mathias, Mediapolis, vice president, and Dr. Daniel F. Huston, Burlington, secretary.

KENTUCKY

Hospital News.—The Ashland General Hospital, Ashland, has been taken over by the Baptist Church.——Elmwood, Lexington, which has been operated as a sanatorium by Dr. Charles A. Nevitt, has been tendered to the U. S. Public Health Service for use as a trachoma hospital and will be purchased, according to *Hospital Management*, for that purpose in January.

Funds for Crippled Children.—The Kentucky Society for Crippled Children is conducting a campaign to raise $36,000. This society was organized about three years ago and largely through its influence the legislature created a Crippled Children Commission last year and appropriated $10,000 a year for two years. This sum has been found inadequate for the amount of work to be done. Last summer in twelve clinics for crippled children in various parts of the state, about 800 children were examined, and after treatment in hospitals more than 100 of them have been restored.

Policy of State Journal.—The council of the Kentucky State Medical Association reported to the House of Delegates at the annual meeting in Louisville that the net balance, September 1, was $4,996.07 as compared with $1,667.67 on the same date last year. The income from the *Kentucky Medical Journal* was $7,477.22 and the expense of its production $6,660.07. The policy of the state journal for many years has been to publish all papers read at county medical societies. The council recommended that this custom be continued at whatever cost but that the house of delegates determine whether the state journal should publish only such material as the council would select.

LOUISIANA

Hearings for Failure to Report Narcotics.—About twenty-seven physicians and nine druggists were summoned to appear before the state board of health, October 13, to explain their failure to report instances in which they are alleged to have prescribed narcotics. The hearings were in executive session, in accordance with provisions of the state laws.

Mosquito Control Conference.—At the Tri-State Conference on Mosquito Control, New Orleans, October 14, a permanent committee was appointed charged with making a survey of the mosquito situation in Alabama, Mississippi and Louisiana, and Mayor Kennedy of Biloxi was elected chairman. The cost of the survey will be borne by the coast towns and cities. There were about 100 representatives present at the conference, as well as members of the state board of health of Louisiana.

Personal.—Dr. Earl Z. Browne, an assistant professor, Tulane University of Louisiana School of Medicine, has resigned to take up medical missionary work in Mexico.——William A. Danner, secretary of the American Mission to Lepers, has sailed, according to the *Times-Picayune*, on a tour round the world to enlist the cooperation of governments in a general campaign to eradicate leprosy.——Dr. Paul J. Gelpi, Jr., has been elected president of the visiting staff of Charity Hospital, New Orleans; Dr. Jerome E. Landry, vice president, and Dr. Lucien A. Ledoux, secretary-treasurer.

Milk Ordinance Disapproved by State Board.—The milk ordinance of New Orleans, which is to become effective, Jan. 1, 1926, was disapproved at the quarterly meeting of the state board of health, October 12, the bacterial standard having been considered insufficient. The ordinance provides for the bacterial count of 100,000 for Grade A raw milk and permits a maximum count of 1,000,000 for Grade C raw milk and 500,000 for Grade C pasteurized milk. The state board tentatively adopted at this meeting a regulation requiring a bacterial count of 10,000 for certified milk, 50,000 for special raw milk, and 20,000 for special pasteurized milk. This measure will be tried out for two months, when the board will finally pass on it. The assistant state attorney general has held that cities cannot adopt health measures that conflict with the state sanitary code. They may adopt an ordinance more strict than state requirements but none that require less.

MARYLAND

Medical and Chirurgical Faculty Meeting.—The semiannual meeting of this society will be at Frederick, November 3-4. Dr. George H. Riggs, president, Frederick County Medical Society, will give the address of welcome at a dinner at the Francis Scott Key Hotel, and the response will be delivered by the president of the faculty, Dr. Lewellys F. Barker, Baltimore. Among the speakers at the scientific session will be Dr. Adolf Meyer, director, Henry Phipps Psychiatric Clinic, Baltimore; Dr. Guy L. Hunner, Johns Hopkins Hospital; Dr. Elmer C. Kefauver, county health officer of Frederick County, and Drs. John E. Legge and George Linthicum, Baltimore.

MASSACHUSETTS

Appointments at Tufts College Medical School.—Dr. Charles F. Painter has been appointed head of the department of the history of medicine at Tufts College Medical School, and Dr. Mark H. Rogers, head of the department of orthopedic surgery. This school opened, September 16, with a freshman class of 146 chosen from more than 600 applicants for admission. The total registration was 490. Dr. James S. Stone, president of the Massachusetts Medical Society, gave an address at the reception given by the faculty to the freshman class, September 28.

Dr. Cushing Lectures in Edinburgh.—Dr. Harvey Cushing, professor of surgery, Harvard University Medical School, Boston, delivered the Cameron-Prize Lectures at the University of Edinburgh the week of October 18, his subjects being: (1) "The Third Circulation"; (2) "The Glandula Pituitaria as We Now Know It," and (3) "Intracranial Tumors and the Surgeon." Among others who have delivered the Cameron-Prize Lectures were Monsieur Pasteur, 1889; Sir Joseph Lister, 1890; Professor Behring, 1895; Major David Bruce, R. A. M. C., 1899; Patrick Manson, 1901; Sir Ronald Ross, 1902; Professor Finsen, 1904; Dr. Simon Flexner, 1911; Paul Ehrlich, 1914; J. J. B. V. Bordet, 1921, and Prof. John J. R. Macleod, 1923.

Society News.—Dr. Francis D. Donoghue, medical adviser, Industrial Accident Board, State House, Boston, addressed the clinical staff of the Boston Dispensary, October 20, on "Industrial Accident and Health Activities."——Dr. John J. Moorhead, professor and director of traumatic surgery, New York Post-Graduate Medical School and Hospital, New York, addressed the Berkshire District Medical Society at Pittsfield on "Treatment of Some Minor Injuries."——Dr. Harlan L. Paine entertained the Worcester District Medical Society at the Grafton State Hospital, North Grafton, October 14. Allan W. Rowe, Ph.D., addressed the society on "Differential Diagnosis of Endocrine Disorders from an Objective Standpoint."——Dr. Edward O'Keefe addressed the North Shore Medical Fraternity at Lynn, October 20, on "Eczema in Infants and Its Dietary Treatment."

MICHIGAN

Tuberculosis Survey.—A section of the city of Detroit was selected a year ago in which to apply all the known reputable means of fighting tuberculosis. The experiment was suggested by the Framingham, Mass., survey, and the Detroit Community Fund appropriated $25,000 for the work last year and will appropriate a like sum for the coming year. There are 101 cases of tuberculosis in this district of the city, exclusive of those under the care of private physicians. Fifty of these cases were discovered by the survey in persons who did not know they had tuberculosis. There are now 578 persons in connection with this work under supervision, and a full-time physician will be assigned, November 1. Dr. Burt R. Shurly, Dr. Fred M. Meader and Henry F. Vaughan, D.P.H., are members of the committee directing the experiment. The object of the investigation, the *Bulletin of the Wayne County Medical Society* says, is to learn just what part a man's health, a man's job and a man's recreation has to do with tuberculosis, and then attempt to make correction.

MINNESOTA

Malignant Smallpox Epidemic Ends.—The secretary of the state board of health recently reported that there had not been a case of malignant smallpox in the state for a month; he attributed this to the state-wide vaccination campaign brought on by the epidemic of smallpox, in which from January, 1924, to September, 1925, there were more than 4,000 cases and 503 deaths; of these, 1,936 were of the malignant type and among them 492 deaths.

Society News.—Dr. Charles Eugene Riggs addressed the Minnesota Academy of Medicine, Minneapolis, October 21, at the Town and Country Club on "The Dynamics of Personality."——Albert P. Mathews, Ph.D., professor and head of the department of biochemistry, University of Cincinnati College of Medicine, addressed the Minneapolis District Dental Society, October 21, on "The Calcium Metabolism of the Body."——Dr. Herman G. Franzen addressed the Hennepin County Medical Society, October 21, on "The Clinical Aspect of Superficial Tumors."

MISSOURI

Hospital for Negro Children.—Mr. William Volker and Mr. Frank C. Niles, Kansas City, have donated $65,000 to erect an addition to the Wheatley-Provident Hospital for ill and crippled negro children. The Wheatley-Provident Hospital, which has been in operation since March, 1922, through a gift of Mr. Niles, is conducted largely in connection with the Children's Mercy Hospital. The staff of the new hospital for negro children probably will be negro physicians.

Society News.—The Jackson County Medical Society, Kansas City, held a symposium on diabetes mellitus, October 20; the speakers were Drs. Russell L. Haden, Frederick C. Narr, Ralph H. Major, Benjamin L. Myers, Joseph S. Lichtenberg, Paul M. Krall and Donald R. Black.——Dr. Frankwood E. Williams, medical director, National Committee for Mental Hygiene, lectured in Kansas City, October 23, on "Mental Hygiene and the Day's Work."——Charles-Edward A. Winslow, D.P.H., Yale University, addressed the St. Louis Medical Society, October 20, on "Social Hygiene: A Program for Community Health." Dr. James M. Ball, Jr., will address the society, November 3, on "Resurrection Days: An Historical Epitome of Certain Events in Old English Medicine."——Dr. Jonas Curtis Lyter, St. Louis, will address the Kansas City Academy of Medicine, November 27, on "Experimental and Clinical Aspects of Certain Lung Conditions."

NEW YORK

Hospital News.—Work has been started on a new $250,000 preventorium for children on the grounds of the Nassau County Sanatorium, Farmingdale, N. Y. When completed it will accommodate seventy children.——A completely equipped health center for mothers and children was opened at Fulton, Oswego County, October 9, which will be conducted by a committee representing the Fulton Academy of Medicine, the Fulton Health Department and the local child welfare association.

Society News.—Dr. Frank D. Jennings addressed the Society of the County of Queens, September 29, on "Graduate Medical Instruction," and Dr. Walter J. Highman on "Common Sense in the Management of Syphilis."——Dr. Nathan B. Van Etten, president of the Medical Society of the State of New York, addressed the eighty-first regular meeting of the Associated Physicians of Long Island, October 13.——Dr. Ignatius L. Stein assumed the duties of president of the Long Island City Medical Society at the meeting, October 8; Dr. William J. Lavelle was elected vice president, and Dr. Mandel H. Weinstein, secretary-treasurer, reelected.

New York City

Personal.—Dr. Wendell C. Phillips, New York, president-elect of the American Medical Association, addressed the students' assembly at the Medical College of Virginia, Richmond, October 15.——Dr. John R. Whisenant has been appointed urologist to the Tarrytown Hospital.——Dr. Pierre Janet, Paris, France, was the guest of the Neurological Section of the New York Academy of Medicine and the New York Neurological Society at a tea given in his honor at the academy, October 23.

Gifts to Columbia University.—The president of Columbia University announced, October 11, the receipt of gifts of more than $111,000 to the university, among which were $15,000 from the Borden Company for research in food chemistry and nutrition, $15,000 from the Commonwealth Fund for the psychiatric clinic, and other gifts from the Commonwealth Fund for the maintenance of two fellowships for British students, and to meet the expense of certain researches conducted by the university. There was a gift of $2,500 from Edward D. Faulkner, to be applied toward the cost of research in the department of surgery, and $2,000 from the Eli Lilly Company, Indianapolis, to be applied toward the "pernicious anemia fund" in the department of pathology.

Society News.—Dr. Emil Goetsch addressed the Flatbush Medical Society, October 9, on "The Treatment of Diseases of the Thyroid."——Dr. Joseph C. Bloodgood, Baltimore, will address the Clinical Society of the Hospital for Joint Diseases, October 27, on "The Diagnosis and Treatment of

Lesions of Bone in the Earliest Stages with Special Relation to Biopsy (lantern slide demonstration).——John H. Northrop, Ph.D., of the Rockefeller Institute for Medical Research will deliver the second Harvey Lecture at the New York Academy of Medicine, November 14, 8:30, on "Pepsin and Trypsin."——Dr. Herman Goodman will address the American Society of Medical History, October 30, on "The Historical Aspects of Radium."——Dr. John Shelton Horsley, Richmond, Va., addressed the Medical Society of the County of Kings, Brooklyn, October 20, on "Relation of the Physiology of the Stomach to Gastric Surgery"; Dr. Tasker Howard, on "The Pathologic Physiologic of the Kidney," and Charles Frankenberger, "Our Library—Its Literature and How to Consult It."——Dr. Edward S. Welles, Saranac Lake, will address the society, November 6, on "The Surgical Arrest and Cure of Pulmonary Tuberculosis."

NORTH CAROLINA

Personal.—Dr. Lewis P. McBrayer, Southern Pines, has been elected president of the Southern Tuberculosis Association to succeed Dr. Henry Boswell, Jr., Sanatorium, Miss. ——Dr. Thomas E. Tucker, Dothan, Ala., has been elected health officer of Edgecomb County for the unexpired term of Dr. John S. Hooker, who resigned to resume practice at Farmville.

Millions for New Medical School.—The will of Mr. James B. Duke, who died October 10, provides for a bequest of $10,000,000 to the Duke endowment, in addition to the original endowment of more than $40,000,000 bestowed a few month ago (The Journal, Dec. 20, 1924, p. 2027). The will provides also that the trustees shall expend not to exceed $4,000,000 of the additional bequest in erecting and equipping at the Duke University, Durham, buildings suitable for a medical school, hospital and nurses' home.

OHIO

Hospital Superintendent Appointed.—Dr. Chester C. Kirk, professor of nervous and mental diseases, University of Arkansas School of Medicine, Little Rock, has been appointed superintendent of the State Institution for Feeble-Minded at Orient. Dr. Kirk formerly was assistant superintendent of the Toledo Hospital, Toledo, and of the Arkansas State Hospital for Nervous Diseases, Little Rock.

Midwifery in Cincinnati.—Only twenty-two midwives are known to the registrar of vital statistics in the city of Cincinnati, and the *Cincinnati Sanitary Bulletin* says that the birth records indicate that eleven have been inactive during the last three years. The remaining eleven midwives attended 247 cases in 1924, or a little less than 3 per cent. of the 8,817 births. Of these eleven midwives six are from Germany, two from Russia, one from Italy, one from Austria and one is native born. All of them but two are more than 50 years of age and have been in practice at least fifteen years. They all hold licenses issued by the Ohio State Board of Medical Registration.

Health Commissioners Conference.—At the sixth annual health commissioners conference, Columbus, recently, a day was devoted to the discussion of milk supplies and recent milk-borne epidemics in Ohio; other sessions considered child health programs; the business standpoint of public health administration; public health publicity and preventoriums. Among the speakers were Dr. Allen W. Freeman; Dr. Charles H. Miner, state health commissioner of Pennsylvania; Dr. Clarence D. Selby, president of the Ohio State Medical Association; Louis I. Dublin, Ph.D., Metropolitan Life Insurance Company, New York; Dr. William T. Henshaw, state commissioner of health of West Virginia; Dr. Arthur T. McCormack, state commissioner of health of Kentucky; Dr. John A. Ferrell, director of the International Health Board, and Surg. Leslie L. Lumsden, U. S. Public Health Service.

PENNSYLVANIA

Hospital News.—The University of Pennsylvania recently sold the Medico-Chirurgical Hospital buildings, Philadelphia, to J. Walter Rosenberg for $800,000.

Personal.—Dr. Charles H. Keene, director of public education in the Pennsylvania Department of Public Education, has resigned to accept the professorship of hygiene and director of physical education at the University of Buffalo.

Society News.—Dr. Theodore Diller addressed the Pittsburgh Academy of Medicine, October 27, on (*a*) "The Meaning of the Term 'Mentally Ill' in the Pennsylvania Law"; (*b*) "The Knowledge of Right and Wrong as the Test of Insanity in Murder Cases"; Dr. Forrest L. Schumacher gave a lantern slide demonstration of roentgen-ray plates (by invitation).

State Medical Election.—At the recent annual meeting, in Harrisburg, of the Medical Society of the State of Pennsylvania, Dr. Ira G. Shoemaker was installed as president; Dr. Harry W. Albertson, Scranton, was made president-elect; Drs. Clarence R. Phillips, Harrisburg, Edgar S. Buyers, Norristown, William E. Delaney, Williamsport, and Thomas L. Williams, Mount Carmel, vice presidents; Dr. Walter F. Donaldson, Pittsburgh, secretary, reelected; Dr. Christian B. Longenecker, Philadelphia, assistant secretary, relected, and Dr. John B. Lowman, Johnstown, treasurer, reelected. The next annual meeting will be in Philadelphia.

Pennsylvania Heart Association.—The first annual meeting of the Pennsylvania Heart Association was held, October 7, at Harrisburg, during the annual meeting of the Pennsylvania State Medical Society. Officers elected for the ensuing year were Dr. Joseph Sailer, Philadelphia, president; Drs. James D. Heard, Pittsburgh, John B. McAlister, Harrisburg, Francis J. Dever, Bethlehem, and Edward W. Bixby, Wilkes-Barre, vice presidents; Dr. John D. McLean, Philadelphia, secretary, and Dr. William S. Bertolet, Reading, treasurer. The Pennsylvania Heart Association was formed to promote the prevention and relief of heart disease throughout the state. There are now two heart associations in Pennsylvania—the Philadelphia Heart Association and the Harrisburg Heart Association—and there are thirty-six clinics throughout the state: Philadelphia, twenty-four; Bethlehem, one; York, one; Clearfield, one; Chester, one; Allentown, one; Johnstown, one, and Pittsburgh, six.

Philadelphia

Society News.—Dr. Nathaniel W. Winkelman addressed the Philadelphia Neurological Society, October 23, on "The Newer Staining Methods as Applied to Neuropathology," and Dr. Milton C. Borman on "Carbon Monoxid Poisoning: A Case Showing Mental and Neurologic Changes with Recovery."——At the October meeting of the Academy of Stomatology Dr. Elmer I. McKesson, Toledo, Ohio, held a clinic at the Pennsylvania Hospital. There were other clinics by the members of the dental profession at Evans Institute, and papers were read in the afternoon and evening at the Adelphia Hotel.—Among others, Dr. Stuart Mudd addressed the Physiological Society, Philadelphia, October 19, on "Electrokinetic Behavior of Mammalian Serous Membranes." ——The November meeting of the Obstetrical Society of Philadelphia will be a joint meeting with the Philadelphia Pediatric Society, November 10.

OREGON

Personal.—The dean of the University of Oregon Medical School, Portland, announces that Mr. Ralph Couch has been appointed secretary of the medical school to succeed Mr. Charles N. Reynolds, who goes to Stanford University as an instructor.

Society News.—The eight-story Medical Arts Building, at Tenth and Taylor streets, Portland, will be ready for occupancy in November; it is reported that more than half of the offices has been leased. The building is for the use of physicians and dentists.

Military Committee Recommendation.—The military committee of the Oregon State Medical Society, at the recent annual meeting at Medford, recommended that each county society and each component society of the state set aside one regular meeting each year as a Medicomilitary Night in order that the means of preventing disease and caring for the sick as practiced in the army may be given to the profession in general.

TENNESSEE

New Health Units.—The county courts of Dyer and Weakley counties have voted in favor of establishing full-time county health units. The Dyer County unit will be established, Jan. 1, 1926.

Personal.—Dr. Alfred B. DeLoach, Memphis, has been reappointed a member of the state board of medical examiners.——Dr. Herbert Acuff, Knoxville, was reelected president of the Tennessee Antituberculosis Association at the annual meeting, October 14.

Society News.—The Memphis Urological Society appointed a special committee recently to consult with the Memphis hospitals regarding the installation of equipment for urologic work, which reported to the society that no hospital in the city at present accepting private patients has a cystoscopic room with the equipment that one would reasonably expect to find in a modern institution. The committee also recommended certain things which each hospital should provide for carrying on urologic work. The report was signed by Drs. Thomas D. Moore and Marcus G. Spingarn.——Dr. Thomas N. Coppedge will address the Memphis and Shelby County Medical Society, November 3, on "Pott's Fracture and Its Treatment." Dr. William R. Blue addressed the society, October 20, on "Diabetes in Children."——At a joint meeting of the Southern Tuberculosis and Southern Sanatorium Associations, Memphis, October 14-16, Dr. Alfred Henry, Indianapolis, spoke on "The Follow-Up Work in Treatment of Ex-Sanatorium Patients"; Dr. John Stewart, Booneville, Ark., "The Sanatorium's Opportunity as a Teaching Agency," and Dr. James A. Price, Oakville, "Ways and Means of Securing Early Cases." There was a barbecue at the Oakville Sanatorium Friday and a general invitation extended to the public meeting that evening to hear the report of Dr. Haven Emerson on the Hospital and Health Survey of Memphis and Shelby County.——The Tri-State Medical Association will meet in Memphis, January 26-28, 1926.

TEXAS

Charges Against Ten Chiropractors.—Charges were filed, October 6, in Dallas County courts against ten chiropractors of Dallas who, it was reported, violated the state medical practice act in that they publicly professed to be physicians and surgeons and offered to treat disease without having first obtained a license from an authorized state board of medical examiners.

VERMONT

State Medical Election.—The Vermont State Medical Society announces that the officers for 1926-1927 are Dr. Edward A. Tobin, Bennington, president; Dr. Thomas S. Brown, Burlington, vice president; Dr. William G. Ricker, St. Johnsbury, secretary; Dr. David Marvin, Essex Junction, treasurer; delegate to the American Medical Association, Dr. Ricker; alternate, Dr. Clarence H. Beecher, Burlington.

VIRGINIA

State Medical Election.—At the annual meeting of the Medical Society of Virginia, Richmond, October 13-16, Dr. William L. Harris, Norfolk, was elected president; Drs. Thomas D. Jones, Richmond, George J. Tompkins, Lynchburg, and Alexander M. Showalter, Christiansburg, vice presidents, and Miss Agnes V. Edwards, Richmond, secretary-treasurer.

Dr. Knott Succeeds Dr. Levy.—Dr. Arthur D. Knott has accepted the position of acting professor of preventive medicine at the Medical College of Virginia, Richmond, to take the place of Dr. Ernest C. Levy, who is on indefinite leave of absence. Dr. Knott received his degree of Doctor of Public Health from Johns Hopkins University and for several years was in charge of public health work in Accomac County. Dr. Robert P. Cooke, who has been connected with the Army Remount Station at Front Royal, will succeed Dr. Knott in Accomac County.

Personal.—Dr. Charles H. Moncure has been elected health officer of Orange.——Dr. William H. Parker has resigned as a member of the school board of Richmond, having moved from the district from which he was appointed.——Dr. Joseph A. McGuire, Norton, has been appointed a member of the state board of health for the unexpired term of the late Dr. Henry M. Miles.——D. B. Lepper, health officer of the Isle of Wight County, has been transferred to Sussex Court House in charge of health work in that county, and Dr. Goldsborough Foard McGinnis will have charge in Isle of Wight County.

Pediatrics at the University of Virginia.—A new clinic building has been opened at the University of Virginia Hospital, Charlottesville. A General Child Welfare Clinic will be conducted, for which funds have been secured through the Commonwealth Fund, New York, from private contributions, and the women of the University Hospital League. The aim will be to study child health, first, in the vicinity of the university and to extend the work, ultimately reaching the mountain people in the western part of the state. There will be trained public health pediatric nurses, student nurses and medical students employed in the clinic building and out in the field. Funds for the first three years' work are in hand. The work is under the direction of Dr. Lawrence T. Royster assisted by Dr. William W. Waddell, Jr.

CANADA

Sir Henry Gray Resigns.—According to the *British Medical Journal*, Sir Henry Gray has resigned as surgeon-in-chief of the Royal Victoria Hospital, Montreal, and as lecturer in clinical surgery at McGill University; when appointed to these positions two years ago, he was surgeon to the Aberdeen Royal Infirmary and previous to that was consulting surgeon with the British army in France.

GENERAL

Personal.—Dr. H. Allasys, Antwerp, Belgium, and Dr. Chompret, St. Louis Hospital, Paris, secretary and president, respectively, of the International Stomatological Association, were elected honorary members of the American Stomatological Association at the meeting in New York, October 15. It was due to the efforts of Allasys and Chompret that the American Stomatological Association received recognition on the occasion of the recent visit to Europe of the American Stomatological Committee.

New Name for Inter-State Postgraduate Assembly.—Dr. Carl Larsen, St. Paul, was elected president-elect of the Inter-State Postgraduate Assembly at the annual convention in St. Paul, October 16. Drs. William J. Mayo and Charles H. Mayo, Rochester, Minn., remain as presidents of clinics, and Dr. William B. Peck, Freeport, Ill., as managing director of the assembly, which hereafter will be known as the Inter-state Postgraduate Association of North America instead of the Inter-State Postgraduate Assembly of America.

Diseases Under Investigation.—The Hospital of the Rockefeller Institute for Medical Research, New York, announces the diseases that are under investigation at that institution at present. Physicians may communicate with the hospital by telephone or personal application to the resident physician concerning the admission of patients suffering from (1) nephritis; (2) chickenpox; (3) acute pulmonary infections, including acute lobar pneumonia; (4) rheumatic fever, and (5) cardiac diseases. Patients suitable for these studies will be admitted to the extent of the hospital facilities.

Permits for Tax-Free Alcohol.—Physicians who have permits to procure tax-free alcohol issued prior to August 31, and who desire to carry over tax-free alcohol secured during the present year, must file applications for renewal permits on or before December 31 with the Collector of Internal Revenue having jurisdiction. Tax-free alcohol may be withdrawn for the use of any scientific university or college of learning, any laboratory for use exclusively in scientific research, and for use in any hospital or sanatorium. New bonds are not required with renewal applications when the bonds previously filed are sufficient to cover the needs of the applicants, and the security they afford has not been impaired in any way.

American Hospital Association.—The twenty-seventh annual convention of the American Hospital Association was held in Louisville, Ky., October 19-24. There were more than 2,000 delegates in attendance and about 3,000 other persons interested in hospitals. The association has established a personnel bureau to assist hospitals in securing qualified personnel, and has adopted a set of standards for outpatient departments of hospitals; a set of principles governing the admission to membership; established a legislative reference bureau, and adopted a curriculum for the university training of hospital executives. "Essentials in a Hospital Approved for Interns," prepared by the Council on Medical Education and Hospitals of the American Medical Association, was accepted as governing the intern, or fifth, year in medicine. As to what practitioners shall be allowed to use the hospital, the association ruled that "the members of the staff and all physicians granted the privileges of the hospital should be reputable practitioners of medicine who hold the degree of Doctor of Medicine and of unquestioned moral and professional integrity. A hospital admitting any of the so-called cults to practice under the corporate name of the hospital is not admissible to membership." The association voted to purchase a building at 18-22 East Division Street, Chicago, and the headquarters will move to the new location, June 30, 1926.

Southern Medical Association.—The nineteenth annual meeting of this association will be at Dallas, Texas, November 9-12. There will be all day clinics at the leading hospitals the first day and in the evening the first general session, at which the presidential address and the orations in medicine and surgery will be given. Three prominent surgeons will deliver addresses at the second general session, Tuesday evening. The section meetings will begin Tuesday morning. Following the general session, Tuesday evening, will be the president's reception and grand ball. There will be a golf tournament, and special trophies as well as the *Washington Post* trophy, which is offered each year, will be awarded. The meetings will be in the First Baptist Church; the hotel headquarters will be at the Adolphus Hotel. The Texas State Pediatric Society will hold an all day clinical meeting at Stoneleigh Court, November 9. Among many other scientific features will be a symposium on cancer, November 11, at a joint session of the sections on surgery and pathology, and a symposium on diabetes, November 12, at a joint session of the sections on medicine and pathology. The Southern States Association of Railway Surgeons, an auxiliary organization, will conduct a symposium on fractures, November 10, at a joint session of the sections on bone and joint surgery. The National Malaria Committee will meet, November 10-11. Among others, Dr. Oliver S. Ormsby will address the section on dermatology and syphilology, November 9, on "Anaphylaxis and Allergy in Dermatology."

Institutions Devoted to Cancer Research.—The director of the American Society for the Control of Cancer notes that the following research institutions, among others, are adding to the scientific knowledge as to the cause, prevention and cure of cancer: Institute of Cancer Research of Columbia University; the State Institute for the Study of Malignant Disease at Buffalo; the Cancer Commission of Harvard University; the Imperial Cancer Research Fund of England, and hospital and research organizations such as the Collis P. Huntington Memorial Hospital, Boston; the Memorial Hospital, the New York Skin and Cancer Hospital and the New York City Cancer Institute, in New York City; the Barnard Free Skin and Cancer Hospital, St. Louis; the Albert Steiner Ward for Cancer and Allied Diseases, Atlanta; the George Chase Christian Hospital and Clinic, University of Minnesota, Minneapolis; the American Oncologic Hospital, Philadelphia; the Pennsylvania Cancer Commission; the Middlesex Hospital in England, and others. In addition, there is the American Association for Cancer Research, established in 1907, with a membership of 148, whose researches are published in the *Journal of Cancer Research*, and the American Society for the Control of Cancer, established twelve years ago, to carry on a campaign of education as a means of using the existing knowledge of cancer to the fullest extent; about 25,000 volunteer workers engage during the year in this educational work of instructing the public by lectures, newspapers, radio and other means of publicity. The society's headquarters are at 370 Seventh Avenue, New York, where inquiries on all aspects of cancer will be answered.

Society News.—At the recent annual meeting of the American Academy of Ophthalmology and Otolaryngology, Chicago, Dr. Edward C. Ellett, Memphis, Tenn., was installed as president; Dr. Ross H. Skillern, Philadelphia, was made president-elect; Drs. Austin A. Hayden, Chicago, William C. Finnoff, Denver, and George L. Tobey, Jr., Boston, vice presidents; Dr. Luther G. Peter, Philadelphia, secretary, and Dr. Secord H. Large, Cleveland, treasurer. The next meeting will be at Colorado Springs, September, 1926.——Dr. Walter G. Alexander, Orange, N. J., was installed as president of the National Medical Association at the recent annual meeting in Chicago, and Dr. Carl G. Roberts, Chicago, made president-elect; Dr. Joseph J. France, Portsmouth, Va., J. H. Terrell, D.D.S., West Palm Beach, Fla., and J. A. McFall, Phar.D., Charleston, S. C., vice presidents; Dr. Clyde Donnell, Durham, N. C., general secretary, and Dr. J. R. Levy, Florence, S. C., treasurer. The next annual meeting will be at Philadelphia, August 24-27, 1926.——At the fifty-fourth annual meeting of the American Public Health Association, St. Louis, October 19-20, Charles-Edward A. Winslow, Dr.P.H., professor of public health and hygiene, Yale University School of Medicine, New Haven, Conn., was elected president; Drs. John A. Amyot, Ottawa, Canada, Max C. Starkloff, St. Louis, and Albert J. Chesley, Minneapolis, vice presidents, and Louis I. Dublin, Ph.D., New York, treasurer. The next meeting will be in Buffalo.——The American Congress of Internal Medicine will be held at Detroit and Ann Arbor, Feb. 22-26, 1926. There will be clinics, addresses and demonstrations at Detroit on all of these days, and clinics, addresses and demonstrations at the University of Michigan, Ann Arbor, February 25. The hotel headquarters will be at the Book-Cadillac, Detroit. Information may be obtained from Dr. Frank Smithies, Secretary-General, 1002 North Dearborn Street, Chicago.——Dr. Frank H. Walke, Shreveport, La., was elected president of the American Association of Railway Surgeons at the recent annual meeting in Chicago, October 21-23; Drs. Don W. Deal, Springfield, Ill., Ebenezer P. Clapper, Waynoka, Okla., and Prince E. Sawyer, Sioux City, Iowa, vice presidents; Dr Frederick G. Dyas, Chicago, treasurer (reelected), and Dr. Louis J. Mitchell, Chicago, secretary-editor (reelected).

FOREIGN

Foundation of Banti Prize by Argentine Physicians.—The *Policlinico* states that the sum of 50,000 liras has been presented to the medical faculty at Florence by physicians in Argentina to found the Guido Banti prize. The income from the endowment is to be awarded for the best original Italian work on pathologic anatomy.

New Hospitals in Tokyo.—The city of Tokyo, Japan, has decided to construct six new hospitals at a total cost of 5,380,000 yen, one of which will be for the exclusive treatment of laborers and others living in the slum districts. The first of this group will be constructed in Azabu, the second in Okubo, a suburb of Tokyo, both of which and three others will be finished by the end of 1926. The buildings will be of reinforced concrete, three stories high.

Personal.—A chair of epidemiology has been created at the Collège de France at Paris and Prof. H. Vincent appointed to it. This is regarded as a national honor for Dr. Vincent, who was médecin inspecteur général of the French army until his retirement on reaching the age limit.——Professor Jude of the military medical school at Paris has been appointed to the chair of nervous and mental diseases in the new Syrian medical school at Damascus. The dean of this school, Dr. Riza Said, and nearly all the other members of the faculty studied medicine in France.——The medals awarded to Profs. Heitz-Boyer, Pasteur Vallery-Radot and Mathé, Paris, by the Cuban Academy of Sciences were presented to them recently by Prof. M. Fernández, president of the academy, at a banquet at the Paris-Latin America Club.——Dr. G. F. Fuse, professor of anatomy, Tohoku Imperial Medical College, Sendai, has been appointed dean to succeed Dr. K. Awoki.——Dr. T. Satow, health officer in the Home Department, was the Japanese delegate to the International Malaria Conference at Rome in October.——Dr. Alfred Kassel was given the Croix de Guerre recently in appreciation of his evacuation of the wounded under heavy fire in the Morocco campaign. He is the first Morocco physician to be given a decoration.——Dr. Ammerling, who is one of a group of 100 Czechoslovakian physicians on a tour of western Europe, spoke at the Collège de France, Paris, on "Purkinje, the Founder of Czech Medicine."——Dr. Rouhet has been a leader in physical training in France for forty years, and the community of Roquebrunė recently placed a commemorative tablet on his residence. He was given at the same time a plaque presented by the World Federation for Physical Training, and the gold medal of the French Société d'encouragement à l'amélioration de la race." His training of the educated stallion Germinal attracted attention several years ago.

CORRECTION

"New Home for New York Academy of Medicine."—In The Journal, October 17, appeared a statement relative to the new home of the New York Academy of Medicine, saying that its public medical library is the only one in New York. Mr. Charles Frankenberger, librarian of the Medical Society of the County of Kings, writes that this statement is erroneous. Since its consolidation in 1898, New York City has comprised the five boroughs of Manhattan, Brooklyn, Bronx, Queens and Richmond. The Library of the New York Academy of Medicine is not the only public medical library in New York. It is the only public medical library in the Borough of Manhattan. But in the Borough of Brooklyn is the Library of the Medical Society of Kings. This library, established in 1844, is the only public medical library in Brooklyn and on Long Island. It contains 100,000 volumes and receives regularly 1,080 current periodical publications. In size it ranks as the fourth largest medical library in the United States, exclusive of the Surgeon General's Office in Washington. It is housed in a modern library building, owned and maintained by the county society; is open daily and on two evenings each week to the medical and allied professions and to the public for reference, and is in charge of a trained staff of workers.

Government Services

U. S. Public Health Service

P. A. Surg. Marion R. King has been relieved from duty at Hongkong and assigned to the Hygienic Laboratory, Washington, D. C.——Asst. Surg. R. L. Lawrence has been assigned to duty at Manila.——Surg. George W. McCoy has been directed to proceed from St. Louis to Oklahoma City to inspect a laboratory which has applied for a license to manufacture and sell vaccine.

Examination for Public Health Service

Surgeon General Cumming announces that examinations will be held, December 7, in Washington, D. C., Chicago, New Orleans and San Francisco for entrance into the regular corps of the U. S. Public Health Service. Candidates must be not less than 23 nor more than 32 years of age, graduates from a reputable medical college and have had one year's hospital experience or two years in professional practice. There will be oral, written, physical and clinical examinations before a board of medical officers. Permission to take the examination is obtained by addressing the Surgeon General, U. S. Public Health Service, Washington, D. C.

Meeting of Council of Veterans' Bureau

President Coolidge is in favor of establishing in the Veterans' Bureau a medical corps with the same rank, pay and allowances now granted to medical officers in the army and navy, according to an announcement by Frank C. Hines, director of the Veterans' Bureau, at a recent meeting of the medical council of the bureau. General Hines stated that the bureau would request that legislation establishing such a corps be proposed at the next session of Congress. Other speakers at the council meeting included Dr. Ray Lyman Wilbur of Leland Stanford University, chairman of the council, and Dr. E. O. Crossman, medical director of the Veterans' Bureau. Dr. Crossman informed the council of the *Medical Bulletin*, a publication of the bureau started in July, which he said was proving of much value. Medical supervisors, he said, are standardizing both administration and treatment in the Veterans' Bureau hospitals.

Graduation of Field Officers at Carlisle

Graduation exercises were held at the Medical Field Service School, Carlisle Barracks, Pa., October 13, for the class of officers of the medical department, National Guard and Reserve, who completed the field officers' course in this school. The commandant, Lieut.-Col. Charles R. Reynolds, M. C., presented the DeVries medal, which is given to the officer attaining the highest standing in the class, to Lieut.-Col. Roy M. Fortier, Medical Reserve. Lieut.-Col. Joseph C. DeVries, the donor of this medal, is a graduate of the course for national guard and reserve officers of this school. The McCamant medal, given for the highest standing in military hygiene, was presented by Major M. C. Stayer, M. C., director of the department of hygiene, to Major Harold E. Eggers, Medical Reserve. Col. Thomas J. McCamant, Medical Reserve, the donor of the medal, is also a graduate of this school. Diplomas were presented to the following officers:

Col. James E. Daniel, Medical Reserve, Greenville, S. C.
Col. David C. Hilton, M. C., Nebraska National Guard, Lincoln, Neb.
Col. Edward M. Iland, M. C., Pennsylvania National Guard, Coraopolis, Pa.
Col. James H. Ullrich, Medical Reserve, Baltimore.
Lieut.-Col. William G. Noe, Medical Reserve, New York.
Lieut.-Col. Henry W. Cattell, Medical Reserve, Washington, D. C.
Lieut.-Col. Erin E. Epting, Medical Reserve, Anderson, S. C.
Lieut.-Col. Roy M. Fortier, Medical Reserve, Santa Ana, Calif.
Lieut.-Col. William B. Lewis, Medical Reserve, Denver.
Lieut.-Col. Walter F. Schmaltz, Medical Reserve, Dallas, Texas.
Major Harold E. Eggers, Medical Reserve, Omaha.
Major Ralph G. Cressman, Medical Reserve, Hastings, Neb.
Major John F. West, Medical Reserve, Belvidere, Ill.
Major David E. Smallhorst, Medical Reserve, El Paso, Texas.
Major Bernard A. Gallagher, Vet. Reserve, Washington, D. C.
Major Carl W. Lupo, Medical Reserve, Vienna, Ga.
Major Lorenzo O. Smith, M. C., Kentucky National Guard, Harlan, Ky.
Major Ray R. Knight, Medical Reserve, Minneapolis.
Capt. Leland O. Carey, M. C., Iowa National Guard, Des Moines, Iowa.
Capt. Karl H. Metz, Dental Reserve, White Plains, New York.
Capt. William H. Thaler, M. C., Missouri National Guard, St. Louis.
Capt. Henry A. Jasme, V. C., Georgia National Guard, Savannah, Ga.

Imperial Social Hygiene Congress

A largely attended congress has been held under the auspices of the British Social Hygiene Council in one of the halls of the British Empire Exhibition at Wembley. It was opened by Mr. L. S. Amery, secretary of state for the colonies, who reviewed the problem of venereal diseases in various parts of the empire. He considered that, under the conditions of modern science, there were no diseases which were more susceptible of being dealt with and cured, if only public opinion was strong enough. Over great parts of the empire the difficulty had been ignorance, indifference and fatalism. At home and in the self-governing dominions, concealment had made it very difficult to deal with the problem, but there had been an enormous change for the better.

VENEREAL DISEASES IN THE SERVICES

Surgeon-Commander T. B. Shaw said that the figures for 1922, in the navy, the latest available, showed that the case ratio per thousand men had fallen from 113 in 1921 to 103.9, and the ratio per thousand sick daily had fallen from 8 to 7.2. A fall in incidence had occurred in all stations except Africa, where the number of cases per thousand was 176.7, as compared with 157.6 in 1921. Although in the China station a considerable fall had taken place, the incidence, 282.3, was still much higher than in any other. The loss to the service from these diseases was, therefore, still very heavy. In the years preceding the Great War, there had been a steady decline in the incidence, but since 1915 venereal diseases had shown a steady increase, associated, no doubt, with a general increase in promiscuous sexual intercourse following a general laxity in sexual relations. He was convinced that promiscuity would continue for some people in spite of all efforts to the contrary. The only hope of eventual extermination of these diseases lay in the wider application of means of disinfection immediately after intercourse. His experience showed that when prophylactic measures were properly used, there was little or no risk of contracting the disease.

Major F. C. Lambkin said that in the army the great advances made in connection with the subject of social influences, especially temperance, played a great part in producing improvement. During the last twenty years, excluding the war period, the incidence of venereal diseases in the army at home steadily declined. In 1904, the admissions were at the rate of 55.8 per thousand men, and in 1922, 25.9. The admissions in garrisons abroad had always been high, owing partly to the lack of provision for regular exercise, partly to the laxity of treatment in small scattered units. In the area of occupation on the Rhine and in Turkey, the problem was difficult; in Cologne alone it was computed that there were 6.000 prostitutes. He emphatically declared, contrary to the view held by some, that the army did not condone or encourage sexual irregularities but did its best to make the conditions for the soldier as alert and invigorating as possible. There should be some organized attempt at prevention by medical means, such as the packet in use in the navy.

Race Problems

At the annual Church Congress, just held, great attention was given to a problem of much wider bearing than the religious one, which of course was mainly in view; namely, the future relation of the white and the colored races. The

Great War has stimulated certain tendencies already existing. In the East the gospel of self-determination has been everywhere eagerly received by the colored races. To the resentment of the colored man at his position of inferiority, and to his determination that the democratic ideals of the Allies should be of universal application, there has been added the belief that the moral basis of Eastern life is in many ways higher and nobler than that of the West. The war has done more than anything else to rouse the people of India to a sense of nationhood and to an intense desire to have more control of their affairs. In opening a discussion on the subject, Lord Willingdon said that there was only one solution to the problem. The white races must realize the necessity of treating all colored men in a spirit of absolute equality, and give up the attitude of color superiority. Providence had long years ago placed the white man in the position of a trustee, whose wards, the colored men, were rapidly growing up. The white man no longer dominated them even for their own good. At best he could tactfully guide them past particular dangers. He had now to meet on terms of absolute equality those whom he had previously regarded as inferiors.

Mr. J. H. Oldham said that perhaps the most fundamental cause of friction and conflict between races was not so much racial as economic. The exclusive immigration policies of the United States and the British dominions, which had produced tension between Western and Oriental peoples, were due, in part at least, to the fear that the standards of living might be affected by the admission of cheap labor. The relations between the white and the black races were largely influenced by the fact that the whites were almost everywhere the employers and the blacks the employed. The problem was essentially economic, though made more difficult by racial differences. In the case of the Eastern races, differences of civilization, which in turn depended on historical experiences, complicated the question. The race problem, to the minds of the colored peoples, resolved itself largely into a claim for equality. The sting of the exclusion of oriental immigration from Western countries lay not so much in the fact of restriction as in discrimination. Many voices called today in all sorts of ways for a solid white front against the colored races. But a solid white front meant a solid yellow front, a solid black front and so on, which in turn meant war. The only way to avoid this disaster was to put the claims of humanity and justice higher than those of race, and in this the lead should be given by the Christian churches.

Ultraviolet Rays for Monkeys

Light therapy has attained a considerable vogue in this country and its use has now been extended to animals. Now that the autumnal fogs are cutting off the sunlight a new departure in the care of monkeys, which is being carried out at the Zoological Gardens, London, has been advanced a stage farther by providing two batteries of powerful electric light in quartz globes, which do not shut off the ultraviolet rays. One battery of three lights is in the open air under a veranda roof; the other is inside the monkey house, placed above the highest perches, with a reflector which throws down the beams, but which is protected from the monkeys by wire netting. At present the monkeys are given an exposure of only a quarter of an hour at a time, once or twice a day, according to the weather. When the light was first turned on, it was interesting to see how the African monkeys and the little American marmosets discovered it at once. They rushed toward the light and sat immediately under it, stretching their limbs and turning themselves round and round, so as to expose their bodies thoroughly to the radiant light and heat. In the case of the lion house also, a move has been made in the direction of more light. The area of the roof lights is being more than doubled, and instead of ordinary glass, "vita-glass," which is transparent to the ultraviolet rays, is being fitted.

Alcoholism as an International Problem

The eleventh Norman Kerr memorial lecture was delivered before the Society for the Study of Inebriety by Dr. R. Hercod, director of the International Bureau against Alcoholism, Lausanne, Switzerland, who took for his subject, "Alcoholism, an International Problem." He said that the question of the supply of alcoholic beverages had become a very important international problem from the economic point of view. The widespread ramifications of the traffic in alcohol and its increasing production had produced a tendency of the liquor trade in a country not only to oppose what was done there to diminish the use of alcohol, but also to try to introduce alcoholic beverages into countries where their use was hitherto unknown. Africa was now suffering from a veritable scourge of alcoholism, the outcome of the introduction of European civilization. The same might be said of Moslem countries. Referring to American prohibition, he said that it was a great pity that the authorities of the United States, who, it might be said, were experimenting for the benefit of the whole world, had not thought of organizing a systematic and continuous investigation with regard to the facts of prohibition. With the help of trained investigators and a few hundred thousand dollars, it would have been possible to constitute a good documentation, before which all would have had to incline, on the subject of prohibition. This would have been of the greatest benefit to every country engaged in the fight. Those who were engaged in the fight should aim at creating such public opinion that principles which were ripe for adoption, but not yet recognized, might be introduced into a future code of international law. The facts concerning alcohol could be taught with fruitful results through the means of schools and colleges.

Lead Poisoning Resulting from the Manufacture of Storage Batteries

Balsac, Lafont and Feil recently published in the *Bulletin médical* the results of an inquiry made to complete their previous investigation of occupational morbidity among workmen employed in the manufacture of accumulators. They found that lead poisoning in workmen so engaged is frequent. They examined fifty workers, two women and forty-eight men. Of the latter, nineteen were Frenchmen and twenty-nine were Moroccans. Only two of the workers were under 20 years of age, while eight were past 40. The stigmas of lead poisoning and of preliminary stages, which the authors studied particularly, are: urticaria, basophilic stippling of red blood cells, nucleated red blood cells, Teleski's sign (extensors of the wrist too weak to raise the hand above an angle of 45 degrees when the forearm is extended), and finally lead colic. For the nineteen Frenchmen and two French women, the findings were: urticaria or wheals, 8 (38 per cent.); red blood cells with granulations, 15 (71 per cent.); nucleated red blood cells, 0; sign of the extensors, 7 (33 per cent.); lead colic, 9 (43 per cent.). For the twenty-nine Moroccans the findings were: wheals, 21 (72 per cent.); red blood cells with granulations, 23 (80 per cent.); nucleated red blood cells, 22 (79 per cent.); sign of the extensors, 14 (49 per cent.); lead colic, 3 (11 per cent.).

It will be seen that workmen employed in the manufacture of accumulators present a very high percentage of stigmas and symptoms of lead poisoning—much higher, namely, than is found in other lead industries. That the stigmas and symptoms (aside from the lead colic) were more frequent in the Moroccans than in the Frenchmen is presumably because the latter were better able to understand and adopt proper prophylactic measures. The stigmas of lead poisoning are found most frequently among the spreaders and mixers, and this class of workmen should therefore receive special medical supervision. This is compulsory in accumulator factories, as well as in other establishments using large quantities of lead.

Social Workers in Factories

During the war, a group of women established a school to train other women as social workers in factory communities, since the factory manager and directors are too much absorbed in the direction of affairs for such matters. Now many heads of industry see that social supervision has a definite influence on the output of the factory. The social worker guarantees good order and discipline, proper management of the milk-distributing station, the consultation service for nursing mothers, the crèches, the day nursery, the canteen, the rest room, and other enterprises accepted or introduced by the factory management, the value of which depend on the way they are managed. Prepared by her studies in the school for nurses and by long service in the hospital, the social worker cooperates with the medical service in the crusade against infant mortality, tuberculosis, syphilis, cancer and occupational diseases. She visits the families of the women employees, learns their aspirations, assists them socially and trains them in hygiene and right ways of living in general. In former days, the wife of the factory owner did some of this work, but with the growth of the great industries new needs and new problems require better methods. Thus today the charity of olden times has been replaced by a form of social service which endeavors not only to do works of mercy and kindness but also to take a just and comprehensive view of the situation that surrounds factory women and to preserve them in health and strength; and in this way to contribute toward a stronger and healthier stock in the future.

The social worker is familiar with the resources of public and private aid: the legal provisions concerning large families, lying-in women and nursing women, and sees to it that those in her charge get the benefits of these provisions. Her moral influence is great, and the social worker knows also how to make herself beloved.

The training school for these social workers is located in Paris, 43 Rue Pernety (XIV). It is growing steadily under the direction of Dr. Armand-Delille assisted by two women vice presidents and a committee on instruction. The management is as solicitous as to the general character and moral worth of the students as it is in regard to their formal training. Of sixty-seven applicants for admission, only ten were accepted. The school finds places for its graduates, and they are paid by the industries or administrations that employ them. Their initial salary is 8,400 francs.

The careful selection of applicants and the judicious placing of graduates explain the unanimous satisfaction expressed by the establishments that have employed these social workers. There are now 177 social workers in factories and like positions. One of the most distinguished founded the service that provides compensation to injured workmen of the Paris region. Another is a licentiate in law and is administering the affairs of a woman's work colony. Another is in charge of a mutual aid society composed of the employees of one of the large tailoring establishments of Paris. A worker employed by Michelin superintends the hiring of new employees. In a report, she has pointed out how the social worker can assure the recruiting of an efficient, reliable force and good production. One large railway company (La compagnie des chemins de fer d'Orléans) employs eight workers.

Center for Research on Human Growth and Constitution

Prof. Nicola Pende, rector of the University of Bari, has accepted the chair of clinical medicine at the University of Genoa, where he has founded a new study center or institute. The new institute will take over the guardianship of the growth and the individual constitutional betterment of children and youths from the beginning of school age up to the commencement of military service, at which time physical development is practically completed. Professor Pende induced Senator Gentile, the preceding minister of public instruction, to decree that one of the medical schools should establish a center of research on the morphology, physiology and pathology of physical and mental development in the schools. As the outcome of that decree, we have now the new institute in Genoa. Another decree regulates state aid for mothers during the early childhood of offspring. With these decrees and the recent legislative measures on physical education, the state plans to correct abnormalities of physical and mental development which are wont to appear during the first years of life, and which, if diagnosed in time, are susceptible of great betterment.

The institute planned by Professor Pende will apply to the youth of the land those measures needed to strengthen weak points in their constitutions and to combat disease tendencies, with a resulting maximal benefit to society. The institute will also constitute a center of information in regard to the qualities and capacities of young persons. Herein the state (and likewise large industrialists) will be given better opportunities for selection of persons to fill difficult positions, as in the aviation or the colonial service.

Visit of Foreign Physicians to the Italian Climatic Resorts

One hundred and sixty foreign physicians are participating in a study tour of the climatic resorts and the mineral springs of Italy. The trip was organized by the Ente Nazionale Industrie Turistiche and is conducted by Professor Ruata. During the last few days the physicians have visited San Remo, Ospedaletti Ligure, Bordighera, Nervi, Rapallo and San Margherita Ligure, where they were most cordially received by the sanitarians and the local authorities. The further itinerary will include Viareggio, Leghorn, Montecatini, Bagni di Chianciano, Fiuggi and Rome. The natural beauties, the therapeutic equipment and the sanitary organization of the health resorts visited made a favorable impression on our welcome guests.

The Title of Medical Specialist

The national government proposes to regulate the use of the title of medical specialist and the corresponding professional practice. This problem has occupied Italian sanitarians for a good many years and for a number of months has been the subject of lively discussion in the medical press. The president of the Federazione degli ordini dei medici, at the request of the bureau of public health, has set forth criteria that might be temporarily adopted until the medical faculties could establish state examinations admitting to the title of medical specialist. According to the federation, the practice of the various specialties should be allowed, at present, to the following: department heads of university medical faculties; department chiefs in large hospitals, and those who, for a period of five years, have been known as practicing specialists. Although the latter would require the endorsement of the council of the medical organizations of which they are members before they would be recognized, certain medical organizations refused to approve the proposals of the federation on the ground that they were too liberal. They asserted that medical and legal agencies desired the title of specialist reserved for those who truly possess a profound knowledge of a branch of medicine. It was also held requisite for securing the title of specialist that a physician confine his practice exclusively to his specialty. The federation suggested also that medical organizations compile a register of specialists.

Historical Data on the Surgery of Varicose Veins

The Società italiana di storia delle scienze mediche e naturali held recently in Venice its third national convention, which was a pronounced success. Professor Giordano, surgeon and historian, commemorated in his address the centenary of Tommaso Rima's theory of the origin of varicose veins and his surgical method of treatment.

The operation for varicose veins has remote Italian traditions. Cicero narrates that Caius Marius submitted to this operation, the incision extending to a point in the foot, which was at that time the usual procedure for the more valorous. Senator Giordano passed in review the subsequent rich literature on treatment of varicose veins. Rima, active surgeon from 1822 to 1843 in the hospital of Venice, was the first to observe that the true cause of the infirmity is the "inverse movement of the blood," which injures the valves or impairs the tunics. On this conception, Rima based his ligation treatment, and the statistics of his operations show good results. Rima's theory and treatment were combated most vigorously, but at last the truth of his assertions was recognized. Others claimed the merit due him, but Senator Giordano defended resolutely the claims of the Venetian surgeon.

Results of the Antimalaria Campaign in Italy

The bureau of public health reports that malaria has been recognized in fifty-two of the sixty-nine provinces of Italy. The following seventeen provinces are thus far exempt: Ancona, Arezzo, Belluno, Brescia, Cuneo, Florence, Forlì, Genoa, Lucca, Macerata, Massa Carrara, Modena, Parma, Pesaro, Urbino, Piacenza, Porto Maurizio and Turin. The fact that a province is included in the malarial zone is no indication of the incidence of the disease but merely indicates the possibility of the inhabitants contracting malaria. Of the fifty-two infected provinces, manifestations are mild in fourteen, and infrequent and restricted to certain localities in a few communes. The larger part of the malarial territory is along the coasts and in the low or medium alluvial valleys of rivers and mountain streams. Railway construction has contributed to the spread of the infection, because, built for the most part before the mode of transmission of malaria was understood, the railways have many level embankments and undrained excavations. In the provinces of Milan, Pavia and Novara, malaria (diffuse but in a mild form) is due to irrigated fields, especially rice fields. In certain localities of Italy, the Anopheles mosquito is found without the presence of malaria; in many other localities, progressive decrease of malaria has been noted.

The crusade against malaria in Italy began with antimalaria legislation in 1900. Since that date, it has been progressively prosecuted by the directors of public health and the responsible ministers. It is based on: (1) state control of the preparation and sale of quinin salts, through which the communes and various corporations are supplied at reasonable prices; (2) compulsory prophylaxis in certain contingencies, and (3) the obligation on estate owners to eliminate ponds and stagnant waters.

The results of the twenty-year campaign against malaria are seen in the statistics. Before the present legislation went into effect, the mortality for malaria reached 15,000 deaths yearly. Since 1903, the mortality had been steadily decreasing, until in 1914 the total number of deaths had reached 2,045. The war brought a marked recrudescence of the disease, the mortality for 1918 having been 11,487, owing to the coincidence with the influenza epidemic. Since 1919, malaria has again been decreasing progressively and has now about reached the prewar basis. In 1923, there were 3,307 deaths from malaria, or eighty-seven per million of population.

The Session of the League of German Medical Societies

THE KRANKENKASSEN AND THE MIDDLE CLASSES

Since the war, it has become increasingly difficult for the middle classes to secure the money needed in cases of illness. For that reason, the need of health insurance is being more and more strongly felt. A number of schemes for health insurance for the middle classes have already been launched, such as housewives' mutual benefit organizations, craftsmen's chambers, and other similar societies. In this connection, a general antipathy toward panel physicians has developed, and for this reason an endeavor has been made to abolish everything that is reminiscent of the bureaucracy of the *Krankenkassen* and their compulsory membership. The local *Krankenkassen* under the direction of the social democrats are watching the progress of the new endeavors and combating them when their fear is awakened. The newer organizations seem likely to thwart the social democrats in their plan of gradually extending compulsory health insurance to all classes and thus bringing about the introduction of social medicine by way of the local *Krankenkassen*.

At the recent meeting of the Hartmann League during the annual session of the League of German Medical Societies, one of the speakers presented the following points: In 1906, at the regular annual session of the League of German Medical Societies (the so-called *Aerztetag*), held in Halle, the desire of the middle classes for protection against economic losses due to disease and like causes, by means of mutual organization, was recognized by the convention as fully justified. Therefore, under the changed economic conditions of today like endeavors of the middle classes meet with even greater approval of the physicians. Health insurance schemes for the middle classes in the future must not interfere with relations between private patient and physician, and, furthermore, they must provide that membership be limited to the middle classes. The by-laws of such insurance organizations should contain the following fundamental provisions: No contract shall be entered into with physicians or medical organizations for the purpose of determining the conditions on which medical assistance will be rendered. Insured members must not be given either cash or coupons in payment of health insurance claims. Only treatment given by graduate physicians shall be recognized and approved. The insured must himself bear a portion of the fees paid for medical attendance and any other expenses connected with the illness. Representatives of the medical societies should collaborate in the organization of health insurance systems. Health insurance societies that comply with these fundamental requirements will promote the interests of the medical profession and the public health and will combat quackery. They will also prevent extension of federal compulsory health insurance and the growth of bureaucracy in the medical profession. Medical organizations as well as individual physicians will support the new idea. Another speaker on this topic took an unfavorable attitude toward mutual societies for the benefit of the middle classes, whereupon the convention appointed a committee to inquire further into the subject and submit a report.

PROPOSED REGULATIONS FOR MEMBERSHIP IN THE PANEL OF HEALTH INSURANCE PHYSICIANS

Dr. Hadrich discussed the proposed new regulations for acquiring membership in the panel of health insurance physicians, the so-called *ärztliche Planwirtschaft*. The three main provisions of the proposed plan are: (1) a uniform distribution of applicants throughout Germany by announcement of vacancies in the panel and the issuance of warnings against physicians locating in overcrowded districts; (2) pensioning of panel physicians who have reached the age of 70 or who have previously become incapacitated, and (3) constant observation of the labor market so as to have the supply of physicians in a given region correspond to the demand. In the uniform distribution of panel physicians, the numbers of the insured and their families, together with the social and economic organization of the whole population, must be considered. In sending panel physicians to thinly populated or poverty stricken districts, the state or the communal league should subsidize physicians sufficiently to insure them an income commensurate with their profession. The following proposals are made to solve the problems of the transition period: All physicians who, after Oct. 1, 1925, shall be admitted to panel practice shall aid the Hartmann League and the leagues of the *Krankenkassen*, to raise the funds necessary for the support of physicians whose advancing age or physical incapacity compels them to retire. All newly admitted panel physicians shall pay a certain percentage of their incomes (about 10 per cent., possibly) for this purpose, due account being taken of their own needs. Pressure must not be exerted either to induce an applicant for panel practice to accept a place offered him or to persuade elderly physicians to resign. No pensioned physician may continue in panel practice. In order to correlate supply and demand for physicians and to regulate the number of students taking up the study of medicine, the subcommittee of the *Planwirtschaft* must establish the number and the age of the physicians engaged in panel practice. The probable number of panel physicians that will be needed for the next few years, on the basis of the figures thus collected, should be published through the press, the academic bureaus of information and the heads of higher institutions of learning. If the number of medical students does not diminish in accordance with prospective needs, admissions to the study of medicine at the universities should be restricted for a time.

RELATION OF THE PHYSICIANS TO THE KRANKENKASSEN

The relations of the physicians to the *Krankenkassen* took up much of the time devoted to discussion. In their journals the representatives of the *Krankenkassen* admit, to be sure, that the present physicians' fees are not commensurate with the advance in prices of commodities, but they emphasize that the high prices in themselves cause an increased incidence of disease, which, in turn, increases the demand for physicians and thus enhances their incomes. This seems to be a very peculiar point of view to take. It overlooks also the fact that, in many places—for example, in Berlin—panel physicians receive per capita fees, and thus do not get a penny more for their additional work. Some instructive statistics were presented by Dr. Hadrich. In 1914, only 27 per cent. of the *Krankenkassen* provided for the insurance of families of the insured; in 1924, 89.25 per cent. had adopted this policy. Since the number of persons insured in the *Krankenkassen* has increased in proportion to the population, there remains a much smaller percentage of the population from which physicians may get private patients. Dr. Hadrich showed also that the Prussian minister of public welfare was more obliging to *Krankenkassen* officials as regards advances in salary than he was to the physicians with respect to their fees. According to a decree of the minister, dated November, 1924, the salary group classification of *Krankenkassen* officials should have been revised. March 21, 1925, the Prussian minister of public welfare ordered the revision not to be made. As a consequence, 3,625 officials are still classified in Groups 7 and 8, whereas only 659 should be so classified. Similarly, there are thirty-seven officials classified in Groups 12 and 13, in place of eleven really entitled to such classification. It is therefore all the more surprising that the *Krankenkassen* should endeavor to prove that physicians have greater incomes now than they had during the war period. In the statistics of a journal of the *Krankenkassen* it is stated that, as against a fee of 6.39 marks in 1913, the fee for a panel physician in 1924 had been advanced to 12.64 marks. Nothing is said, however, of the great increase of family insurance. Then, too, the *Krankenkassen* have the habit of regarding expenditures for assistants, and things of like nature, as physicians' fees. If all these facts are considered, the fees for 1924 are in reality lower than before the war. How unfavorably the abolition of the free choice of physicians has affected the local distribution of physicians may be distinctly seen in mining and industrial regions. Whereas in Berlin there are 764 inhabitants to one physician, in Stuttgart 913, and in Elberfeld 966, in Essen there are 2,101, in Duisburg 2,267 and in Hamborn 2,749.

PRAGUE

(From Our Regular Correspondent)

Oct. 1, 1925.

Decline in Birth Rate

In a recent discussion in the Czechoslovak parliament, the minister of health, Mr. J. Sramek, called attention to the declining birth rate of Czechoslovakia, and to the measures by which he intends to stop the decrease. The highest national birth rate was that of 1870. The war brought about a real drop, which was succeeded by a rapid but temporary increase, and this, in turn, by a decline below the prewar level. Prague shows the most rapid decline of all, with a decrease of 29 per cent. in the last quarter century. The danger is most acute in the highly developed and thickly populated western provinces, while the eastern provinces show a comparatively high birth rate. The result of these conditions is that the population in the industrial western centers is gradually being replaced by those coming from the eastern provinces. The causes for the decline have their roots in both social and public health conditions. Venereal diseases, housing shortage, contraception and induced abortion each has contributed to the result. Attempts to enact legislation allowing, in selected cases, induced abortion for social reasons have helped to spread the practice. The minister does not expect great results from educational campaigns for bigger families but hopes to attain the same end by promotion of hygienic and social protection of the child. The campaign against preventable diseases should both increase fertility and reduce the death rate.

Legislation on Prostitution

Recent articles in several daily papers maintain that the law of 1921 abolishing control of prostitution resulted in an increase of venereal diseases. This legislation was put through owing largely to the activities of the Czech Association for Combating Venereal Diseases, and Prof. F. Samberger, president of the association, has published a defense of its action. The contention that there has been an increase of incidence of venereal diseases is not supported by facts. On the contrary, venereal disease in the army shows a rapid decline. The figures representing the occurrence of venereal infection among drafted men can be taken as an index of its occurrence in the civilian population, and these figures become more favorable every year. Deductions from the number of patients applying to private physicians are valueless. Prostitution conditions are not ideal, but the blame is to be put on the police, who do not favor the new law and are remiss in cooperation. While the brothels have been abolished, the prostitutes frequent the numerous bars and dance halls which have sprung up. In order to raise public discussion about prostitution to a higher level, the Association for the Combating of Venereal Diseases published, in the Czech language, Dr. Abraham Flexner's book on Prostitution in Europe. It was largely due to this book, says Dr. K. Ulryeh, its translator, that the legislation abolishing control of prostitution was introduced in Czechoslovakia. It is unfair to pass judgment on the effects of the law for several reasons: The time that has elapsed since its promulgation is too short; its positive aspects, especially free obligatory treatment, have been hindered by limitation of public funds and difficulties of organization. The minister of health recently declared the intention of the ministry to investigate the incidence of venereal disease, as it was done in 1921. At that time, for a period of one month, all cases of venereal disease were reported without giving the name of the patient. The ministry plans to repeat this once in five years. The next period of reporting will occur next February.

Memorial to Dr. Albert

Recent numbers of Czech medical periodicals contained memorials of the Czech surgeon Dr. Eduard Albert, the twenty-fifth anniversary of whose death occurred, September 25. Dr. Albert was born in the small town of Zamberk, Bohemia, in 1841. He studied medicine in Vienna, and after his graduation remained in the Vienna medical school. He, together with other Czechs, including Rokitansky and Skoda, have contributed considerably to the glory of the Vienna Medical School. From 1888 to his death he was professor of surgery in Vienna. His well known studies on the surgery of the bones and joints are the fundamentals of modern orthopedics. He was unquestionably one of the greatest teachers of medicine in the last century. Although he spent his whole life in the German environment of Vienna he never severed his connections with his nation. He printed many of his publications in Czech medical periodicals and participated in Czech scientific meetings. His pupils can be found not only among the Czech surgeons, such as Mydl and Bakes, but also among those connected with Vienna University, among whom are Hochenegg, Ewald, Lorenz, Schnitzler and Friedlaender.

Antituberculosis Activities

Several new antituberculosis activities can be reported from Czechoslovakia. The present tuberculosis legislation is out of date and does not afford to the health officials sufficient authority over reluctant patients. A joint committee, recruited from various organizations, recently discussed the measures that should be incorporated in a new law. Some, fearful of expense, recommended a law that should compel only notification of tuberculosis cases, tuberculosis deaths, and prescribe disinfection after the death, or change of living quarters of tuberculous persons. Others, with the revenue from social insurance in mind, advocated, in addition, the erection of pavilions for incurables, erection of sanatoriums, payment of fees in tuberculosis institutions from public funds, and erection of dispensaries. In the end, the second schedule was recommended. Another novelty in Czechoslovakia is the initiation in the sanatoriums of the High Tatras of postgraduate courses in tuberculosis along the lines of those given at Davos or Saranac Lake. The courses were organized under the auspices of the Tatra section of the Czechoslovak Association for the Study of Tuberculosis. The High Tatras in Slovakia is developing into an important region for the treatment of tuberculosis, and a group of sanatoriums, both public and private, is located there.

Marriages

DEANE ROCKHOLD BRENGLE, Detroit, to Miss Hazel Mildred McClay of Bowling Green, Ohio, at Wayne, Mich., October 8.

JOSIAH BENJAMIN HIBBITTS, JR., Nashville, Tenn., to Miss Miriam Burkloe Brown of Baltimore, September 29.

SAMUEL FITZSIMMONS RAVENEL, Charleston, S. C., to Miss Katherine Parr Brown of Baltimore, September 29.

LOUIS ARIEL SCHULTZ, New York, to Miss Mary Mathilda Wimenitz of Philadelphia, August 16.

LEWIS BAER FLINN, Baltimore, to Miss Elizabeth Winchester Waters of Elkridge, October 3.

MILTON H. ALEXANDER to Miss Sophie Beatrice Smith, both of New York, October 6.

HARVEY P. CHARLES to Miss Helen Scott Kay, both of Berkeley, Calif., September 3.

MORRIS AARON GOLDBERGER to DR. GERTRUDE FELSHIN, both of New York, September 18.

JOHN H. KARSTEN to Miss Catherine Clausen, both of Horicon, Wis., October 17.

POWELL G. FOX, Raleigh, N. C., to Miss Shirley Kingsbury of Scranton, Pa., June 20.

Deaths

John Henry Wallace Rhein ⊕ Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1890; professor of neurology, Graduate School of Medicine of the University of Pennsylvania; member of the American Neurological Association, the Philadelphia Pediatric Society, the Philadelphia Neurological Society, the Philadelphia Psychiatric Society, the American Psychiatric Association, the Association for Research in Nervous and Mental Diseases and the Philadelphia Pathological Society; served in the M. C., U. S. Army, during the World War; formerly on the staffs of the Howard, Philadelphia General, Philadelphia Orthopedic and St. Agnes' hospitals and the Philadelphia Home for Incurables; aged 56; died suddenly, October 14.

Henry Clinton Eyman, Massillon, Ohio; Columbus Medical College, 1880; member of the Ohio State Medical Association, and the American Psychiatric Association (president 1919-1920); past president of the American Medico-Psychological Association; professor of nervous and mental diseases, University of Wooster Medical Department, Cleveland, 1891-1905; assistant physician to the Athens State Hospital, 1884-1887; assistant superintendent Toledo State Hospital, 1887-1891; superintendent of the Cleveland State Hospital, 1891-1899, and of the Massillon State Hospital, 1899-1918; aged 69; died, October 7, of cerebral thrombosis.

Edward Wood Walker ⊕ Cincinnati; Medical College of Ohio, Cincinnati, 1878; emeritus professor of clinical surgery, University of Cincinnati College of Medicine; member of the American Surgical Association; formerly member of the city board of health; for thrity years on the staff of the Cincinnati General Hospital and at one time on the staff of the German Deaconess Hospital; aged 72; died, October 6.

Marcus Babcock Heyman ⊕ New York; Medical Department of the University of the city of New York, 1890; superintendent of Manhattan State Hospital for the Insane, Ward's Island; formerly assistant superintendent of the Central Islip Hospital; member of the American Psychiatric Association; aged 58; died suddenly, October 7, of acute dilatation of the heart.

Jesse McClain ⊕ Coshocton, Ohio; University of Illinois College of Medicine, Chicago, 1895; past president of the Coshocton County Medical Society; served in the M. C., U. S. Army, during the World War; for many years a member of the city board of health; aged 57; died recently, of cerebral hemorrhage, following a long illness.

Charles Newton Cox ⊕ Brooklyn; University of Pennsylvania School of Medicine, Philadelphia, 1883; past president of the Medical Society of the County of Kings; at various times on the staffs of the Brooklyn Eye and Ear, Bushwick, Bethany-Deaconess' and St. Mary's hospitals; aged 66; died suddenly, October 9, of cerebral hemorrhage.

Joseph Rex Hobensack ⊕ Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1893; formerly assistant demonstrator and instructor in anatomy at his alma mater; at one time on the staffs of the German and Lankenau hospitals; aged 55; died, October 7, of heart disease.

Ralph O. Dresser ⊕ Paso Robles, Calif.; University of California Medical School, San Francisco, 1901; formerly health officer of Paso Robles; aged 49; died, September 29, at the University Hospital, San Francisco, of acute appendicitis.

Julia Morton Plummer, Cambridge, Mass.; Boston University School of Medicine, 1887; for many years on the staff of the Talitha Cumi Maternity Home and Hospital, Boston; died, October 3, following a long illness.

Frank G. Hackleman ⊕ Rushville, Ind.; Central College of Physicians and Surgeons, Indianapolis, 1882; member of the Indiana Academy of Ophthalmology and Oto-Laryngology; aged 66; died, October 9, following a long illness.

Henry William Heaton, Providence, R. I.; Columbia University College of Physicians and Surgeons, New York, 1889; aged 59; was found dead in a bayou near Clearwater, Fla., October 7, with a bullet wound in his head.

Jesse Robert Talley, Mountain Grove, Mo.; University of Louisville (Ky.) School of Medicine, 1888; member of the Missouri State Medical Association; aged 64; died, September 9, of chronic appendicitis and peritonitis.

Richard Urquhart Burges, Norfolk, Va.; Medical College of Virginia, Richmond, 1895; member of the Medical Society of Virginia; on the staff of the Norfolk Protestant Hospital; aged 52; died in September.

Willis Dana Storrs ⊕ Topeka, Kan.; Kansas Medical College, Topeka, 1895; formerly professor of clinical medicine at his alma mater; aged 55; died, October 5, at Rochester, Minn., of angina pectoris.

Timothy John Bowes, Philadelphia; Jefferson Medical College of Philadelphia, 1891; medical director of the Philadelphia Electric Company since 1907; aged 66; died, October 3, of dilatation of the heart.

Horace M. Lowe, Washington, D. C.; University of Michigan Medical School, Ann Arbor, 1886; served in the U. S. Veterans' Bureau; aged 64; died at the Polyclinic Hospital, New York, October 7.

Patrick H. McGovern ⊕ Milwaukee; University of Pennsylvania School of Medicine, Philadelphia, 1894; aged 63; died, September 30, at the Columbia Hospital, Milwaukee, following a long illness.

Emilien Roch, North Grosvenor Dale, Conn.; University of Montreal Medical Faculty, Montreal, Que., Canada, 1890; member of the Connecticut State Medical Society; aged 61; died, October 5.

Hugh Robert Thomas Ross ⊕ Ladysmith, Wis.; Trinity Medical College, Toronto, Ont., Canada, 1901; aged 48; died, September 26, at Toronto, Ont., of hypertension and chronic myocarditis.

William Howard Knevitt, Brooklyn; Bellevue Hospital Medical College, New York, 1895; on the staff of the Kings County Hospital; aged 63; died, October 13, following a long illness.

Oliver M. Dodson, Baker, Ore.; Willamette University Medical Department, Salem, 1877; Bellevue Hospital Medical College, New York, 1883; Civil War veteran; aged 82; died, October 2.

Frank P. Nourse ⊕ Lewiston, Idaho; Chicago Medical College, 1877; formerly on the staff of St. Joseph's Hospital, where he died, August 30, of uremia, following on operation, aged 73.

John Dade Darby, Oakland, Md.; University of Maryland School of Medicine, Baltimore, 1912; served in the M. C., U. S. Army, during the World War; aged 37; died, October 11.

Jonathan M. Wright, Redlion, Ohio; Medical College of Ohio, Cincinnati, 1869; member of the Ohio State Medical Association; aged 81; died, October 6, of cerebral hemorrhage.

William Kendall Paul, Belmont, N. Y.; Cleveland University of Medicine and Surgery, 1884; member of the Medical Society of the State of New York; aged 64; died, September 5.

George Edward Kincaid, Clinton, Iowa; Barnes Medical College, St. Louis, 1900; member of the Iowa State Medical Society; aged 57; died, October 2, at the Jane Lamb Hospital.

Charles Witt Womack, Lewisburg, Tenn.; Kentucky School of Medicine, Louisville, 1870; member of the Tennessee State Medical Association; aged 87; died, at Nashville, October 1.

William Chambers Phillips ⊕ Clarinda, Iowa; University of Illinois College of Medicine, Chicago, 1903; aged 48; died, October 7, in a hospital at Iowa City, of tumor of the brain.

Henry A. King, Bangor, Me.; Medical School of Maine, Portland, 1888; member of the Maine Medical Association; aged 66; died, July 17, at Brewer, of angina pectoris.

Bailey B. Petty ⊕ Cynthiana, Ky.; Medical College of Ohio, Cincinnati, 1884; aged 66; died, October 5, at the Good Samaritan Hospital, Cincinnati, following an operation.

William Henry Swisher, Dayton, Ohio; Eclectic Medical Institute, Cincinnati, 1898; formerly coroner of Montgomery County; aged 50; died, October 3, of heart disease.

John Henry Carty, Fair Haven, Vt.; University of Michigan Medical School, Ann Arbor, 1882; member of the Vermont State Medical Society; aged 61; died recently.

Eddie Riley, Mayfield, Ky.; University of Louisville School of Medicine, 1912; member of the Kentucky State Medical Association; aged 43; died, October 2, of pellagra.

William French Hazelton ⊕ Bellows Falls, Vt.; Medical Department of Columbia College, New York, 1884; aged 65; died, July 23, at the Rockingham Hospital.

Joseph C. Chapman, Wheeler, Ill.; American Medical College, St. Louis, 1879; president of the State Bank of Commerce; aged 70; died, October 9.

George O. Sikes ⊕ Cincinnati; Medical College of Ohio, Cincinnati, 1904; on the staff of the Good Samaritan Hospital; aged 53; died, October 8.

John F. Synder, Rockford, Ill.; Rush Medical College, Chicago, 1882; member of the Illinois State Medical Association; aged 65; died, October 6.

William E. Link, Abbeville, S. C.; Medical College of Georgia, Augusta, 1859; veteran of the Civil War; aged 93; died, October 1, of senility.

Elias Franklin Lane, Green City, Mo. (licensed, Missouri, 1884); Civil War veteran; aged 81; died, September 19, following a long illness.

Charles P. Davis ⊕ Galena, Ind.; University of Louisville School of Medicine, Louisville, 1881; aged 65; died, October 5, of heart disease.

James Wilmer Strong, Philadelphia; Hahnemann Medical College of Philadelphia, 1879; Civil War veteran; aged 84; died, October 8.

James William Mulhern, Des Moines; Marion-Sims College of Medicine, St. Louis, 1892; aged 59; died, October 6, of heart disease.

James Thomas Jenkins ⊕ Carthage, Ill.; Missouri Medical College, St. Louis, 1890; aged 57; died, October 9, following a long illness.

Louis Albert Cazenove, Seminary, Va.; University of Virginia Department of Medicine, Charlottesville, 1875; aged 74; died, October 5.

Louis Jurist ⊕ Philadelphia; Jefferson Medical College of Philadelphia, 1880; aged 70; died suddenly, October 9, of heart disease.

Louis L. Hertel, Chicago; Kentucky School of Medicine, Louisville, 1893; aged 62; died, October 10, of carcinoma of the rectum.

Frederick Edwards ⊕ Cairo, N. Y.; University of Vermont College of Medicine, Burlington, 1875; aged 74; died, August 12.

William I. Carlock, Everton, Mo.; St. Louis Medical College, 1873; aged 72; died, October 10, following a long illness.

John H. Sutherland ⊕ St. Albans, W. Va. (licensed, West Virginia, under the Exemption Law); aged 72; died recently.

George W. Marter, Philadelphia; Hahnemann Medical College of Philadelphia, 1878; aged 76; died, September 8.

James Begen, New York; Eclectic Medical College of the City of New York, 1877; aged 75; died, October 7.

George W. Akers, Stafford, Kan.; Indiana Medical College, Indianapolis, 1878; aged 86; died in September.

Ira Norman Zeis ⊕ Carey, Ohio; Toledo Medical College, 1894; aged 57; died, October 7, of septicemia.

The Propaganda for Reform

In This Department Appear Reports of The Journal's Bureau of Investigation, of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other General Material of an Informative Nature

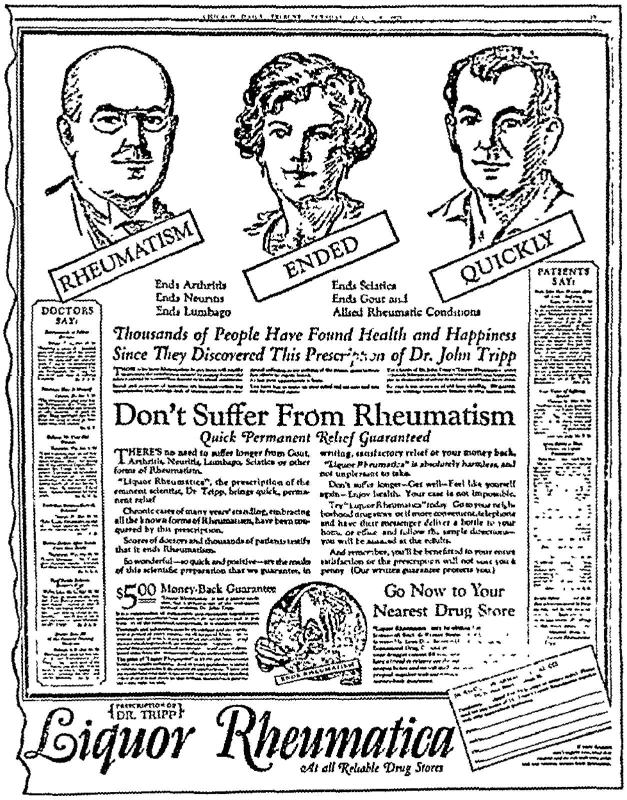
DR. TRIPP'S LIQUOR RHEUMATICA

More Quackery in the Rheumatism Cure Field

During the past year an expensive and high-pressure advertising campaign has been made on a nostrum known as "Dr. Tripp's Liquor Rheumatica." The stuff is put out by a concern calling itself the Norwood Pharmaceutical Co. and having the following officers:

Doak Norwood, President.
Clyde F. Lloyd, Vice-President.
Frank P. Lloyd, Secretary-Treasurer.

Before putting on the newspaper campaign the concern resorted to the old method of trying to work the medical profession first. Physicians—of Chicago, at least—were circularized and urged to use Liquor Rheumatica in cases of "chronic rheumatism." No detailed information seems ever to have been given regarding the composition of the nostrum. The circular addressed to physicians vaguely mentions potassium iodid, "phytolacca-rheuma"—whatever that may be—cimicifuga and calisaya and cinchona compounds. No quantities are given except of those drugs which the federal law demands, in this instance, alcohol 12 per cent.



RHEUMATISM
ENDED
QUICKLY

Ends Arthritis
Ends Neuritis
Ends Lumbago

Ends Sciatica
Ends Gout and
Allied Rheumatic Conditions

DOCTORS SAY:

PATIENTS SAY:

Thousands of People Have Found Health and Happiness Since They Discovered This Prescription of Dr. John Tripp

Don't Suffer From Rheumatism

Quick Permanent Relief Guaranteed

THERE'S no need to suffer longer from Gout, Arthritis, Neuritis, Lumbago, Sciatica or other forms of Rheumatism.

"Liquor Rheumatica", the prescription of the eminent scientist, Dr Tripp, brings quick, permanent relief.

Chronic cases of many years' standing, embracing all the known forms of Rheumatism, have been conquered by this prescription.

Scores of doctors and thousands of patients testify that it ends Rheumatism.

So wonderful—so quick and positive—are the results of this scientific preparation that we guarantee, in writing, satisfactory relief or your money back.

"Liquor Rheumatica" is absolutely harmless, and not unpleasant to take.

Don't suffer longer—Get well—Feel like yourself again—Enjoy health. Your case is not impossible.

Try "Liquor Rheumatica" today. Go to your neighborhood drug store or if more convenient, telephone and have their messenger deliver a bottle to your home or office and follow the simple directions—you will be amazed at the results.

And remember, you'll be benefited to your entire satisfaction or the prescription will not cost you a penny. (Our written guarantee protects you.)

Liquor Rheumatica

At all Reliable Drug Stores

Photographic facsimile of a full-page advertisement of "Liquor Rheumatica" that appeared in the Chicago *Tribune.* In the original this measured nearly 1½ ft. by 2 ft.

With the circular letter sent to physicians there was an eight-page leflet containing four testimonials purporting to be reproduced in facsimile from the originals. Three of these were from laymen. The fourth was on the stationery of and signed by Fred E. Stevens, M.D., 449 Peterboro Street, Detroit, Michigan. It was dated November 15, 1924. For several years past the Directory Department of the American Medical Association has been unable to locate Dr. Fred E. Stevens, and his name in the Directory has appeared, therefore, in the "Address Unknown" list. Neither does his name appear in the Detroit telephone directory.

The files of the Bureau of Investigation reveal an interesting coincidence regarding Fred E. Stevens. Some twelve or fifteen years ago a nostrum known as "Dr. John Tripp's Blood Purifier" was being widely advertised under the claim that it was a positive cure for syphilis as well as for rheumatism and female trouble. At that time the Bureau of Investigation accumulated a complete set of follow-up letters put out by the quacks that were selling this stuff. It was then exploited by Sam J. Davis & Co., Hot Springs, Arkansas. Later the nostrum seemed to be pushed by the John Tripp Remedy Company of Detroit, Michigan, and Buffalo, N. Y. In 1916 a letter was received asking for information about "Tripp's Blood Purifier" and stating that one Dr. Fred E. Stevens of Detroit was connected with the exploitation of the nostrum.

"Dr. John Tripp's Blood Purifier" seems to have been on the market for many years, as we have on file an advertising booklet on this product issued in 1883. At that time the stuff was put out from Buffalo, New York. In July, 1914, the Association's Laboratory reported finding large quantities of potassium iodid with traces of cinchona alkaloids in "Dr. John Tripp's Blood Purifier." These facts should be kept in mind because of what follows.

To revert again to Liquor Rheumatica: This nostrum, after being exploited for a short time to the medical profession, was brought to the attention of the public with a flare of full-page newspaper advertisements in Chicago dailies. One of these, from the Chicago *Tribune,* is reproduced in miniature with this article. The advertisements as well as the circulars sent to the general public stressed the alleged fact that physicians recommended the preparation and published testimonials credited to the medical profession. The full names of the physicians are not published but there are given what purport to be their initials and the cities in which these men live. Some of the testimonials thus published are:

Dr. G. F., Chicago, Ill.	Dr. B. H. D., Owen, Wis.
Dr. C. W. R., Holcombe, Wis.	Dr. L. C. L., Alexandria, Ohio.
Dr. E. T. P., Chicago, Ill.	Dr. S. M. R., Chicago, Ill.
Dr. S. W. R., Grantsville, W. Va.	Dr. J. W. W., Chicago, Ill.
Dr. L. L. A., Wauwatosa, Wis.	Dr. M. C. S., Webster, S. D.
Dr. J. H. J., Anderson, Ind.	Dr. W. H. R., Detroit, Mich.
Dr. P. H. D., Juneau, Wis.	Dr. A. C. K., Chicago, Ill.

As already stated, Liquor Rheumatica (Dr. Tripp) is marketed from Chicago by the Norwood Pharmaceutical Co. The "Medical Director" of the company is one G. E. Fosberg, M.D., whose name has long been in the files of the American Medical Association. His name has also appeared at different times in Chicago newspapers in unsavory connections. Incidentally, Fosberg seems to be connected with what is known as the "Physicians Clinical Laboratory," which is at the same address and has the same telephone number as the Liquor Rheumatica concern.

Some of the claims for Liquor Rheumatica are:

> "Now there is given to the world one of the most amazing discoveries ever made by that famous medical scientist, Dr. John Tripp. It is a tried, tested and approved specific for rheumatic conditions and is called Liquor Rheumatica (Dr. Tripp)—not a patent medicine but a prescription of Dr. Tripp's which has stood most exacting tests in cases of arthritis, sciatica, gout, neuritis, myalgia, lumbago and allied conditions."
>
> "Liquor Rheumatica (Dr. Tripp) is foremost a dissolver of poisons and cleanser of the system, loosening up and dissolving the poisonous products stored up in the glands and tissues."
>
> "Try a bottle of Dr. John Tripp's Liquor Rheumatica today—banish rheumatism forever."
>
> "No case is too severe or of too long standing."
>
> "Chronic cases of many years standing, embracing all the known forms of rheumatism, have been conquered by this prescription."
>
> "Liquor Rheumatica, a prescription of the eminent scientist, Dr. Tripp, brings quick permanent relief."

Because of the number of inquiries received regarding this product, one of them coming from as far west as the Pacific Coast, the Association's Laboratory was asked to analyze the nostrum and report its results. The Laboratory report follows:

LABORATORY REPORT

"Two original bottles of Dr. Tripp's Liquor Rheumatica (Norwood Pharmaceutical Co., Chicago) were submitted to the A. M. A. Chemical Laboratory for examination. Each bottle contained 230 c.c. (approximately 7¾ fluidounces) of a liquid, with a red-brown suspension, having an aromatic odor and bitter taste. The color appeared to be due chiefly to suspended matter. On standing for some time most of the suspended matter settled, leaving an almost clear, pale reddish-yellow, supernatant liquid. The reaction was faintly acid to litmus.

"No information concerning the composition of Liquor Rheumatica was given on the label of the product except that which the law requires in connection with the presence of alcohol. The label read: 'Contains not more than 12 per cent. alcohol.' In the advertising formerly sent out by the Norwood Pharmaceutical Company, however, the presence of potassium iodid, calisaya, cinchona, cimicifuga, and 'phytolacca-rheuma' were declared, although no amounts or proportions of the several ingredients were given. As calisaya is a variety of cinchona, only four drugs (in addition to alcohol) were present, according to the claims. 'Phytolacca-rheuma' is not the name of any drug known to scientific medicine. Possibly the name may refer to poke root, '*Phytolacca decandra*,' which was formerly described in the Pharmacopeia of the United States.

"Qualitative tests indicated the presence of alcohol, potassium, trace of sodium, trace of calcium, iodid, small amounts of cinchona alkaloids and vegetable extractive. The suspended matter was for the most part vegetable tissue and an insoluble red-brown amorphous substance. Under the microscope, the residue of vegetable tissue consisted apparently of finely powdered red saunders (*santalum rubrum*) to which substance the suspension owes its color. In fact, the vegetable residue consisted almost entirely of minute fragments of wood fibers with yellow walls; in the slightly larger masses in which one cell overlaid another, the color was more reddish. There was a trace of starch present, but nothing to indicate the starchy tissues of cimicifuga or of phytolacca root; nor were there present the needle-shaped calcium oxalate crystals of phytolacca. If extractives of these substances are present, it is probable that a fluid extract was employed. The alcohol-soluble portion of the material contained small amounts of a bitter resin. Tests for salicylates, iron, arsenic, cinchophen, colchicum, phenolphthalein, and emodin bearing drugs, such as rhubarb, cascara and senna, were negative. Quantitative determinations were as follows:

"Specific gravity at 25 C	1.0251
"Alcohol (by volume)	9.3 per cent.
"Total solids	7.0 gm. per 100 c.c.
"Potassium iodid	4.2 gm. per 100 c.c.
"Total alkaloids	0.06 gm. per 100 c.c.
"Water-insoluble material	0.57 gm. per 100 c.c.
"Water-alcohol insoluble	0.40 gm. per 100 c.c.
"Ether extract	0.19 gm. per 100 c.c.

Dr. John Tripp's Blood Purifier
A POSITIVE CURE
For
BLOOD POISON,
SYPHILIS, in any Stage,
CHRONIC CATARRH,
RHEUMATISM,
FEMALE TROUBLES, and
All DISEASES of the BLOOD
HOT SPRINGS, ARK.

Photographic facsimile of the letterhead of Sam J. Davis & Co. who in 1911 were exploiting "Dr. John Tripp's Blood Purifier." This product seems to have had essentially the same composition as "Dr. Tripp's Liquor Rheumatica."

"From the foregoing examination, it is concluded that Dr. Tripp's Liquor Rheumatica is essentially a weak alcoholic solution of potassium iodid with a dash of cinchona alkaloids, to which has been added some powdered red saunders to which the product largely owes it physical appearance."

Here, then, we have a water-alcohol solution of potassium iodid with a dash of cinchona alkaloids advertised as "one of the most amazing discoveries ever made by that famous medical scientist, Dr. John Tripp." Eleven years ago when the Association's Laboratory analyzed Dr. John Tripp's Blood Purifier, which was then exploited as a cure for syphilis, the product was found to be a water-alcohol solution of potassium iodid with traces of cinchona alkaloid. From these analyses evidently Tripp's syphilis cure, alleged to have been puffed by Dr. Fred E. Stevens of Detroit, is essentially the same substance as Tripp's rheumatism cure now being puffed by Fred E. Stevens.

The alleged "amazing discovery" of Dr. John Tripp was neither amazing nor a discovery. For years the medical profession has used iodids in the treatment of chronic rheumatism, especially in those cases in which a syphilitic factor may be suspected. Before administering iodids, however, the physician determines whether or not these powerful drugs are contra-indicated. The purchaser of Liquor Rheumatica, of course, has no means of protecting himself against a dosing with iodids that may prove disastrous, because he is given no information regarding the presence of these drugs, and if he were, would have no knowledge of the dangers involved in their use. There is no excuse for the exploitation of a mixture such as Liquor Rheumatica in the form of a "home remedy" for self-drugging.

Correspondence

"IS ACRODYNIA A NEW DISEASE?"

To the Editor:—Your editorial on this subject (THE JOURNAL, October 17, p. 1225) interests me greatly. You speak of "the name acrodynia which Weston introduced to differentiate the disorder from pellagra." Allow me to call your attention to a paper of my own entitled "Acrodynia: Its Place in Medicine and Its Relation to Pellagra" (*Am. J. Trop. Med.* **1**:291 [Sept.] 1921). In this paper an effort is made to trace the history of this strange affection. One will find there recorded that, Aug. 26, 1828, M. Chomel (*Arch. gén. de méd.* **18**) called the attention of the Academy of Medicine to the disease which was designated épidémie de Paris, and a commission was named to study it. The first reference to this outbreak which I have been able to find was that of Genest in 1828 under the title, Recherches sur l'affection épidémique qui regne maintenant à Paris (*Arch. gén. de méd.* **18**). It is interesting to read that in one of the Paris cases the great Louis performed the necropsy and exposed the spinal cord and the nerve trunks searching for the lesion, without result of a positive kind.

In 1848 the Irishman Graves, in his Clinical Lectures, gave a splendid account of the disease picture.

My own experience with acrodynia did not occur until after the appearance of pellagra in the South. From 1907 to 1915, it occasionally happened that I felt justified in making the diagnosis of acrodynia. I recall one woman whom I found in my waiting room with her shoes off because of the terrific pain in the feet. In a number of cases after the diagnosis of acrodynia had been made, the unmistakable picture of pellagra developed. The occurrence of a palmar and plantar skin lesion in pellagra is by no means common, but it does occasionally occur and in every case in which I first recorded the diagnosis of acrodynia a revision had to be made and pellagra substituted.

Those interested will find in the French literature of 1828-1830 many excellent accounts of pellagra among the acrodynia cases.

It is well worth while in this connection to remember that the whole skin surface at various times has been affected by the pellagrous lesion. Extreme pain and other sensory subjective symptoms, especially in the extremities, is not infrequent in pellagra and, in fact, no symptoms recorded in acrodynia are lacking in pellagra, if a sufficiently large series of cases is considered.

After a study of about 2,000 cases of pellagra and after seeing during this period numerous illustrations of what was seen in Paris during the epidemic of 1828-1830, I felt justified in the belief that acrodynia is a type of pellagra, and that if the case is kept under observation over a considerable period the justification will be found in the occurrence of the typical pellagra picture.

Certainly the term acrodynia was coined in Paris about 1830. Edward Jenner Wood, M.D., Wilmington, N. C.

COMPLETE ANURIA

To the Editor:—The following report of a case of complete anuria should have been reported ten years ago; it is sent now because of current interest in such cases.

Mrs. L., aged 35, had an operation for suspension of the right kidney in 1903, and another operation of the same character on the same kidney in 1905, both operations having been performed elsewhere. When I first examined her, a large mass could be palpated in the right side of the abdomen. A diagnosis of hydronephrosis of the right kidney was made, and nephrectomy of the right kidney was done, May 4, 1915. A preliminary cystoscopic examination and pyelogram to establish the presence of the left kidney were not made.

Twenty-four hours after operation, the patient did not urinate. On catheterization, 2 ounces of urine was obtained. From that time on, no urine was excreted. The patient lived twenty-three days.

At necropsy the left kidney was discovered to be absent (congenital).

The patient had all her mental faculties to the last, with no symptoms of uremia at any time. There was profuse sweating, with a disagreeable, pungent, urine-like odor always present in her room, and even in the corridor outside. The case emphasizes the importance of making preliminary examination to establish the presence of the other kidney before nephrectomy. Few cases are reported in which the patient lived over twenty days.

A. H. Farnsworth, M.D., Grand Island, Neb.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

THE MELLON INSTITUTE AND POSTUM CEREAL

To the Editor:—The Mellon Institute of Industrial Research, University of Pittsburgh, has sent out some research material, "Coffee Drinking by the Aged" and "Coffee Drinking by Children." Will you please tell me who or what they are, and if this is propaganda?

H. N. Jennett, M.D., Kansas City, Mo.

Answer.—The Mellon Institute of Industrial Research of the University of Pittsburgh is said to have for its essential aim the creation of new knowledge by scientific investigation in accordance with the Industrial Fellowship system. The institution was founded by Messrs. Andrew W. Mellon and Richard B. Mellon. An industrial concern or an association of industrial concerns may donate a certain sum of money for an industrial fellowship in which will be done work on a problem or group of problems that are of interest to the donors. In the instance referred to by Dr. Jennett, the Mellon Institute has recently sent out the two articles "Coffee Drinking by the Aged" and "Coffee Drinking by Children." These are accompanied by an introductory letter from the Mellon Institute stating that they are the result of some research that the institute is carrying on in a scientific investigation of "The Rôle of Hot Beverages in the Diet." The letter further states that this research is being carried out through an industrial fellowship. The two articles already mentioned seemed such obvious ex parte statements derogatory to coffee and caffein beverages that the Mellon Institute was written to and asked whether the donor of the industrial fellowship under which this work was being done was a commercial organization interested in the sale of coffee substitutes. The institute replied that with the permission of the fellowship donor they would gladly give the information asked for and stated that a copy of the request for information had been forwarded to the donor. A few days later a second letter came stating that the donor of the fellowship, Postum Cereal Company, Inc., Battle Creek, Mich., had granted permission to give the information desired. The company had stated also that other inquiries should be treated the same way. The Postum Cereal Company, Inc., shows an intelligent appreciation of the public's rights in the matter. Such industrial fellowships may well prove of incalculable value to the industries of the nation and the general plan for carrying on such work is altogether admirable. In sending out the results of work of this kind, however, public interest would be better served if the Mellon Institute would plainly state that the work is being financed by an industrial concern, and frankly give the line of business in which this concern is engaged.

EXCESSIVE PERSPIRATION

To the Editor:—I have become accustomed to bring my difficulties before you; this one is of a most distressing and personal nature. For ten years I have practiced surgery under the handicap of a most profuse activity of the sweat glands of the head and face. Incased within a Mayo type mask, I yet leak through each crevice and fold. The physical discomfort is enormous, and the mental worry over fear of infecting the wound through dropping globules is even greater. Can you make any suggestion as to eradication or additional safeguards? Normally of a nervous temperament, complicated surgery increases my rainfall. Atropin, in large dosage, gives considerable relief, but the rapid heart action, dry throat and tongue, etc., are unpleasant and, I fear, not particularly good for my well being. Would the employment of a small electric fan directed upward toward the face be an added danger to the patient, in your opinion? If published, please use initials only.

R. E. S.

Answer.—This seems to be purely a physiologic hyperhidrosis, very difficult to control. Aluminum chlorid solution is the best local application for it, used in a strength of 25 per cent. solution in water. Before it is applied, the surfaces should be rinsed so that they are free from grease or soap. A few drops of this solution is lightly applied over the surface. This can be repeated three days in succession and then should not be used for several days more. It usually causes marked reduction in the amount of sweating. Aluminum chlorid is a strong irritant, and this solution must be applied with care. If it produces irritation it should be washed off with plenty of water. The only thing that would produce an actual change in the sweat apparatus would be the application of roentgen rays to the point of causing slight atrophy of the sweat follicles. This has to be done very cautiously and should be done only by one who is skilful in the therapeutic application of roentgen rays. Sometimes, with the amount of the application of roentgen rays that one is warranted in giving, this method fails, but it can often be successfully carried out.

GLY-SO-IODONATE — "G. S. I."

To the Editor:—As surgeon for several industrial plants located in this city, I have had brought to my attention the products of the National Medical Research Laboratories, Milwaukee, which get out a surgical fluid called G. S. I. which they claim to be superior to tincture of iodin and all other known antiseptics. They do not publish the formula. Will you kindly investigate and inform me as to this preparation?

C. E. Burt, M.D., *New Bedford, Mass.*

Answer.—Gly-So-Iodonate ("G. S. I.") was refused admission to New and Nonofficial Remedies (The Journal, Dec. 22, 1923, p. 2118) because it was exploited under a nondescriptive and misleading name and with a statement of composition not only chemically absurd but obviously incorrect. Examination showed it to possess properties which were virtually "those of a solution of potassium mercuric iodid to which had been added a chemical hodge podge." In the same issue of The Journal, editorial comment was made on the Council on Pharmacy and Chemistry's findings concerning the unscientific character of the claims made for "G. S. I." The attention of the Bureau of Investigation having been called to the advertising methods used to exploit this preparation, an inquiry was made among a number of hospitals and industrial concerns the names of which appeared in "A Partial List of Representative Industries Protecting Their Many Thousands of Employees with G. S. I.," a circular sent out by the exploiters. The published result of this inquiry (The Journal, June 7, 1924, p. 1881) revealed no enthusiastic users of "G. S. I.," and showed that the exploiters were using some references as misleading as the "formula" of their nostrum.

PONNDORF'S VACCINATION

To the Editor:—Kindly discuss Ponndorf's vaccination, and give references. Please use initials only. J. V. S., Chicago.

ANSWER.—Most of the interest in Ponndorf vaccination therapy has been confined to Europe. Some European articles have been abstracted in THE JOURNAL; for instance,

La Baume, F. S.: *Med. Klin.* **17:** 1289 (Oct. 23) 1921; abstr., THE JOURNAL, Jan. 14, 1922, p. 154.
Simon, W. V.: *Ztschr. f. Tuberc.* **35:** 449 (March) 1922; abstr., THE JOURNAL, May 13, 1922, p. 1502.
Chéinisse, L.: *Presse méd.* **31:** 325 (April 4-11) 1923; abstr. THE JOURNAL, June 9, 1923, p. 1738.
Paul, G.: *Wien. klin. Wchnschr.* **38:** 984 (Sept.) 1925; abstr., THE JOURNAL, Oct. 17, 1925, p. 1265.

According to the first of these, the method is as follows: "About twenty scarifications are made in the skin of the upper arm, each as long as a finger, stopping just short of the papillary layer, the scratches bleeding slightly. Then a concentrated tuberculin is dropped into the malpighian layer of the skin thus opened up by the scratches. As almost all diseases accompanied by eruptions immunize against further attacks, it seems rational to assume that by inducing intense esophylactic processes in the malpighian prickle layer of the skin, in this way or its equivalent, a tendency to immunization might be induced."

As to its efficacy as treatment, no concord of opinion exists.

Florida June Examination

Dr. William M. Rowlett, secretary of the Florida Board of Medical Examiners, reports the written examination held at Tampa, June 15-16, 1925. The examination covered 10 subjects and included 100 questions. An average of 75 per cent. was required to pass. Of the 251 candidates examined, 204 passed and 47 failed. The following colleges were represented:

Book Notices

Pediatric Nursing. A Textbook for Nurses. By Abraham Levinson, B.S., M.D., Associate in Pediatrics, Northwestern University Medical School. Cloth. Price, $2.50. Pp. 251, with 28 illustrations. Philadelphia: Lea & Febiger, 1925.

It requires a fine sense of discrimination to write a textbook for nurses. It is difficult to present the subject matter at the proper level for the student or graduate nurse. If the material presented is too technical, the wearied nurse cannot comprehend or nods asleep during her study hour. Levinson evidently had this in mind when he prepared this little book. He has given a great deal of detailed information in concise form, and he has spoken in simple English so that all may understand. A nurse who will carefully prepare herself with this volume in hand will know all the facts necessary in nursing sick children. It is important that nurses should read well constructed texts. Levinson discusses the anatomy, physiology and general care of infants. He also gives instruction to the nurse in the general methods of examination. He shows her how to hold the child, how to prepare the patient for the various examinations, how to collect the urine, how to take the temperature. Indeed, he emphasizes the nursing technic that should accompany a well conducted physical examination. His chapter on treatment is short and to the point, and he gives a table of doses of various drugs which should be invaluable to the bedside nurse. He considers briefly a group of the more common diseases, and indicates the proper treatment of each. In the concluding chapters he gives some good advice based on psychology and common sense. He has written a very readable book. However, it may be said of nurses that no matter how many college degrees they bear, how many honorary keys they have won or how many textbooks they have read, the art of nursing is learned in the hospital ward. The gift of administering gently to the sick is heaven born. The good nurse has a gentle hand and a noble heart, and strives to serve and to heal.

Die medikamentöse Behandlung der Harnrohrengonorrhöe des Mannes und deren pharmakologische Grundlagen. Von Dr. Alfred Perutz, Privat-Dozent für Haut- und Geschlechtskrankheiten an der Wiener Universität. Paper. Price, 9 marks. Pp. 266, with 13 illustrations. Berlin: Urban & Schwarzenberg, 1925.

This book approaches the treatment of urethral gonorrhea in the male from a medicopharmacologic point of view only. In the introductory chapters the nerve supply of the male genito-urinary apparatus is discussed at length and its differential reaction toward drugs analyzed as to the subsequent response of the parts involved, particularly the vas deferens and the epididymis. Valuable information is conveyed by the analysis of the specific action of the drugs to be employed and how antagonistic effects may be prevented in combining these, avoiding incompatibility produced by faulty concentration or inappropriate mixture. Special stress is laid on the general therapeutic and dietetic regimen. After these general principles are elucidated, the special forms of treatment are taken up, the pharmacodynamic action of the various medications always being considered. The serodiagnosis of gonorrhea and passive and active immunization are also explained. A valuable chapter deals with parenteral protein therapy, which recently has aroused much attention. The closing chapters are devoted to a discussion of the complications occurring during the course of urethral gonorrhea and to a survey of the provocatory methods.

Diseases of the Bronchi, Lungs and Pleura. By Frederick T. Lord, M.D., Instructor in Medicine, Harvard Medical School. Second edition. Cloth. Price, $8. Pp. 776, with 110 illustrations. Philadelphia: Lea & Febiger, 1925.

In this edition, Dr. Lord has accumulated the newer contributions to his subject during the last decade, especially along bacteriologic and immunologic lines and in the advance of thoracic surgery. The literature as a whole is reviewed up to 1923. In its present shape, the book represents a reliable and rather conservative guide through the vast and bewildering field which it covers with a remarkable completeness as to the variety of pathologic conditions. The text abounds in references, and the fact that Dr. Lord always refers to the original works and the classics in medicine makes it particularly valuable as a reference book. A new chapter on pulmonary tuberculosis is added, which does not reach the standard of the other chapters. While divergent opinions, wherever they arise, are objectively enumerated, the expression of a personal opinion and the results of the author's vast experiences are rather missed throughout the book; this applies especially to all discussions on therapy. A reader without experience will find little advice from Dr. Lord, but a wealth of statistical data and strictly objective compilations. It is felt that the great variety of even very rare conditions discussed is somewhat at the cost of the completeness of the individual subjects. All this makes this book valuable in the hands of the experienced reader, but less suitable as a textbook for the beginner in this special field of medicine.

Diabetic Diet. A Handbook for Diabetics. By A. Doris McHenry, B.A., and Marjorie M. Cooper, B.A. With a Preface by J. A. Gilchrist, B.A., and M.D., and F. G. Banting, M.C., M.B., M.R.C.S. Cloth. Price, $2. Pp. 62. New York: Harper & Brothers, 1925.

There are now available numerous books on diet for the patient with diabetes. The present little book emanates from the Banting clinic in Canada. It presents the very essentials of the subject in brief form, including discussions of weights and measures and the routine analysis of urine. Most of the sixty pages are filled with recipes. The book is safe for public recommendation.

Internal Secretion and the Ductless Glands. By Swale Vincent, LL.D., D.Sc., M.D., Professor of Physiology in the University of London. Third edition. Cloth. Price, $10. Pp. 463, with 112 illustrations. New York: Physicians and Surgeons Book Company, 1925.

Physicians will welcome the new edition of this standard and scholarly book. The author has devoted more than twenty-five years to intensive study and research in the field of the endocrine glands. The exposition of the physiology and pathology of the ductless glands is comprehensive, clear and thorough, and his conclusions are rational when conflicting views of uncertain relationships are dealt with. The present edition contains much new matter, especially in the chapter on the pancreas and the chapter on the reproductive organs. The number of illustrations has been increased from 105 to 112, and a short chapter on organotherapy has been added to the book. The portions dealing with clinical subjects have been still further expanded, and this will make the book still more useful to medical students and practitioners.

Hand-Atlas of Clinical Anatomy. By A. C. Eycleshymer, B.S., Ph.D., M.D., Dean of College of Medicine and Director of Department of Anatomy, College of Medicine, University of Illinois, and Tom Jones, B.F.A., Director of Anatomical Illustration and Instructor in Anatomy, College of Medicine, University of Illinois. With special dissections by O. E. Nadeau, B.S., M.D., Associate in Surgery, University of Illinois. Cloth. Price, $11. Pp. 424, with 395 illustrations. Philadelphia: Lea & Febiger, 1925.

During the war, a special manual of surgical anatomy was prepared under the direction of Dr. Eycleshymer. It met immediate acceptance and popularity and quickly reached an edition of 10,000 copies. The present edition of this work includes the anatomy of the female, and the addition of some 150 new and original plates and 207 new drawings. There is a complete explanatory index which makes the descriptive text unnecessary. This volume is one of the most valuable atlases available to the medical student or the surgeon.

Manuel élémentaire de puériculture. A l'usage des mères, des infirmières visiteuses, du personnel des crèches, pouponnières, chambres d'allaitement, garderies, consultations de nourrissons et des diverses œuvres d'assistance a la maternité. Par Dr. Clotilde Mulon. Médecin-chef de la pouponniere du camouflage. Préface de M. le Professeur Marfan, Membre de l'Académie de médecine. Second edition. Paper. Price, 10 francs. Pp. 234, with 21 illustrations. Paris: Masson et Cie, 1925.

This book is similar to many of a like nature that have appeared in this country. It begins with a discussion of infant mortality, and one is struck with the fact that deaths from diarrhea are given a first place and apparently occur three times as frequently as do respiratory conditions in

France. This chapter is followed by chapters on hygiene, preparation for delivery, physiology of nutrition, care of the premature or debilitated infant, breast nursing, artificial nursing, weaning, the diseases of children, instruction and care in dispensaries, infant welfare stations, and day nurseries. The volume closes with chapters on the laws of France governing child care and protection.

Medicolegal

Evidence of Reputation of Mental Condition Barred

(In re Wah-kon-tah-he-um-pah's Estate (Okla.), 234 Pac. R. 210)

The Supreme Court of Oklahoma, in affirming a judgment admitting to probate the will of an Osage allotee, says that the contestants complained because the trial court would not permit them to show by one witness that the testatrix was generally known and referred to by her acquaintances as the "old crazy woman." No case was pointed out to the supreme court wherein evidence of the general reputation of being crazy was admitted, in the trial of a will contest, as bearing on testamentary capacity, or the lack thereof, of the testator. This court knows of no such case. In the absence of a case deciding the point, this court is inclined to think that evidence of general reputation as to mental capacity or incapacity of a party making a will is not admissible. Even if the court had admitted the proof of general reputation offered, and all of the contestants' witnesses had testified that the testatrix had the general reputation of being an old crazy woman, still the court should apply the rules laid down by the cases in determining the testamentary capacity or lack thereof; and if the testatrix should measure up to the rules laid down by this court for determining mental capacity, as applied at the time the will was made, the court would be constrained to follow the decided cases, rather than evidence of general reputation. This court thinks that evidence of general reputation of mental condition of the testatrix was not admissible for the purpose of determining testamentary capacity, or the lack thereof, at the time the will was made, and that the trial court did not err in excluding such evidence.

Identification of Roentgenograms—Basis of Testimony

(Mattice v. Terminal R. R. Ass'n of St. Louis (Mo.), 270 S. W. R. 306)

The Supreme Court of Missouri, Division No. 1, says that in this action for personal injuries a physician testified that he was a roentgen-ray specialist, had "examined x-rayically the right arm of the plaintiff," and had the "x-rays" that he made at that time. The plaintiff offered the roentgenograms in evidence in connection with the testimony of another physician. Objection being made that they had not been sufficiently identified, the plaintiff did not press his offer but later recalled the roentgenologist. The latter testified that one of the roentgenograms was a roentgenogram of the plaintiff's right forearm; that it bore the title "Mr. Mattice, File 17927, Nov. 1922," which was the date the roentgenogram was made, adding: "I didn't examine the hand myself, any more than just the x-ray; no physical examination at all." On cross-examination he testified that he took the pictures himself, but did not do the development of them himself; that "you get them out of the dark room, and you send them back, and watch them after they are developed and check these things all during the process. Although I wasn't in the dark room, I know this is the same plate that I took of plaintiff's arm because you go in there as soon as they are in the hypo; you see these things before the process of silver elimination is complete. . . . I am positive that this is the plate that I took, although it passed out of my hands and stayed a while in the dark room." Again he testified: "These pictures were developed immediately after the exposures were made, before the man leaves the office. They are checked up before he gets out. We do not have more than one patient's plates in there at a time, that is, being developed at the same time. We take a patient and finish him up, especially on work of this sort. . . . I have an idea we did have some other broken arms that same morning, but that is a roentgenogram of this man's arm." Such being the testimony, and the defendant standing on its objection to the introduction of the roentgenograms in evidence, plaintiff's counsel withdrew his offer of the roentgenograms.

The roentgenologist had also been examined at length concerning what was shown by the roentgenograms, and at the close of the evidence defendant's counsel asked the trial court to exclude the roentgenologists' testimony and to instruct the jury to disregard it, on the ground that his testimony was based on plates that he held in his hand and from which he testified, which had not been sufficiently established to justify him in testifying from them. The trial court refused that request; and the supreme court holds that was not error, under all the circumstances. The trial court did not have an opportunity to rule directly on the admissibility of the roentgenograms, because the plaintiff withdrew his offer of them, but the supreme court concludes that there was sufficient identification of them to make them admissible in evidence, and to make them the proper basis, as the trial court held, of the testimony of the roentgenologist. However, it seems clear to the supreme court that if the evidence was insufficient to warrant the introduction of the roentgenograms themselves, as pictures of the arm of the plaintiff, then the evidence was equally insufficient as a basis for the admission of testimony by the witness as to what they showed as to the condition of the plaintiff's arm. There was no theory or situation developed such as made the roentgenograms or testimony as to what they showed valuable or admissible except they were pictures of the plaintiff's arm and wrist.

Privilege Not Physician's—None Under Workmen's Act

(Doty et al. v. Crystal Ice & Fuel Co. (Kan.), 235 Pac. R. 96)

The Supreme Court of Kansas says that in this action, brought by the widow of a workman on behalf of herself and minor children as dependents under the workmen's compensation act, the plaintiffs endeavored to show that the death of the workman was the result of an injury which he sustained, January 20, by falling from a scaffold and striking his head either on the floor or on an iron pipe. He lay off three days and then returned to work, making no complaint about his injuries. About May 20 he was taken sick, and he died, May 31. The physician's certificate showed that death resulted from cerebrospinal meningitis. The man's physical condition from the time of the injury until his death was detailed by the plaintiffs and other witnesses. The nurse who attended him in his last sickness testified that there was nothing about his symptoms to indicate spinal meningitis, though the attending physician took a specimen of the spinal fluid. Two physicians testified from a hypothetic question that death resulted, or might have resulted, from the injury. The defendant called the physician who attended the man in his last sickness and who made out the death certificate, and asked him several questions pertaining to the cause of death, the taking of specimens of spinal fluid, and the laboratory test. Counsel for the plaintiffs advised the witness that he was privileged to refuse to testify. The widow for herself waived the privilege of the witness. The trial court held that the privilege was personal to the physician, who claimed the privilege and was not required to testify. But the supreme court holds that the provision of the Civil Code of Kansas that a physician or surgeon shall be incompetent to testify concerning any communication made to him by his patient with reference to any physical disease or injury or concerning any knowledge obtained by a personal examination of the patient, without the consent of the patient, does not create a privilege personal to the physician, and that the trial court erred in holding the privilege created to be a privilege personal to the physician. Furthermore, it seems clear to the supreme court that the plaintiffs waived the privilege of the witness, if one existed, not only by the waiver by the widow in open court, but by the nature of the evidence offered by them.

Still another reason why the ruling of the trial court was erroneous was that the provision of the civil code referred to above has no application to the testimony of physicians in claims for compensation under the workmen's compensation act. That act embodies a plan to compensate workmen, or their dependents, for loss of earnings because of personal injuries received by the workman, arising under the circumstances designated in the act. Necessarily, the inquiry in every case is the nature and extent of the physical injury produced by the accident, which includes, of course, whether the physical injury, or the death, was caused by the accident or resulted from other causes. This, ordinarily, is essentially a medical question, which can be determined only by the testimony of a physician who examined or treated the workman. Hence the Kansas statute provides for such examination and the use of the testimony of the physician.

Views and Ruling Concerning Charitable Hospitals

(Roberts v. Ohio Valley General Hospital (W. Va.), 127 S. E. R. 318)

The Supreme Court of Appeals of West Virginia says that this was an action for damages for an alleged injury from negligent and unskilful treatment by one of the defendant's nurses while the plaintiff was a paying patient at the defendant's hospital. The defendant filed a special plea setting forth its character as a charitable institution. An objection to the plea was sustained and the plea rejected. The case was then certified to this court on the joint application of both parties to the suit, who desired a ruling on the sufficiency of the plea. The exact question involved had never been determined by this court.

Public policy demands that charitable institutions be fostered and preserved. To this end, the law should deal with them more leniently than with institutions conducted solely for private gain. No human endeavor of any magnitude is immune from mistakes. No matter how strict a rule might be enforced against institutions of this nature, mistakes in treatment would occasionally happen. Employees and servants selected with ordinary care, however, will execute the charity with but few mistakes. If no care be had in their selection, mistakes will necesarily multiply. The purpose of the founders of a charity is to help those who need assistance. They propose, not unskilful or incompetent aid, but humane and efficient treatment. The subject of an employee's negligence is harmed instead of helped by the charity. The will of the donors is thwarted instead of served when an object of their beneficence suffers from such neglect. When administered by incompetent servants, charity, instead of being a great boon to humanity, may become a menace. One who enters a hospital expects, and has a right to expect, more skilful treatment than is obtainable in the home. If such institutions be not held to reasonable care in the selection of their employees, confidence in their efficacy will be shaken. Many who need, will fear to accept hospital treatment, and those who do apply therefor will lack the faith therein that is so frequently half the battle in the contest with disease.

In order that the high purpose of the donors of a charitable hospital may be best served, that those who need aid may not hesitate to accept the charity, and to prevent as far as may be human suffering from acts of negligence and incompetence, it would seem imperative to require of those in charge reasonable care in the selection and retention of the employees. The fact that one is a paying patient does not alter the rule. Such patient is the recipient of the donors' gratuity only in a lesser degree than one who makes no payment. The hospital building, with its equipment, management, and its great possibilities for the alleviation of suffering, was provided by charity. In using the organization made possible and supported by that charity, a paying patient, to that extent, benefits by the charity.

Because of its failure to allege that the defendant used reasonable care in selecting the nurse of whose negligence the plaintiff complained, this court holds that the plea as presented did not in terms state a defense to the action, and the judgment of the lower court is therefore affirmed. As stated in the syllabus by the court, it is incumbent on a charitable hospital to use reasonable care in the selection and retention of its physicians, nurses and attendants; and for failure to do so it is liable for injuries due to their incompetence, received by its patients.

Privilege as to Physicians and Third Persons

(Southwest Metals Co. v. Gomez (U. S.), 4 Fed. R. (2d) 215)

The United States Circuit Court of Appeals, Ninth Circuit, in reversing a judgment obtained by plaintiff Gomez, says that this was an action to recover damages for personal injuries, based on the employers' liability law of Arizona. The plaintiff testified that after the accident certain physicians removed dirt from his eye. The physicians who attended him were called by the defendant company, and an inquiry was made as to the truth of that statement. The testimony of the physicians was objected to on the ground that the relation of physician and patient existed and that the testimony was incompetent. The objection was sustained. The nurse who assisted the physicians was then called as a witness, but her testimony was objected to for the like reason and the objection sustained.

If the question were an open one, much might be said against the justice and wisdom of a rule that permits a party to a suit to offer testimony tending to show that a physician removed dirt from his eye, or fragments of bone from his leg, and forbids the physician to give testimony controverting that fact; but that such is the effect of the statute of Arizona with regard to privileged communications, as construed by the supreme court of the state, does not admit of question: and that statute of the state, as construed by its highest court, is binding on this court.

The claim of privilege on behalf of the nurse presented a more difficult question. All the authorities agree that the privilege or exemption does not extend to a third person who is present and overhears the communication between the physician and the patient. Under such circumstances, some of the cases hold that both the physician and the third person may testify, while others hold that as to the physician the privilege is not waived. The plaintiff did not controvert this general rule, but contended that it has no application where the third person acts as agent of or assistant to the physician. This court has examined the cases cited in support of this contention, and many others, and finds that in every case the agent or assistant was himself a physician or surgeon. The rule excluding hospital records kept under the direction of the physician had no application here, and the same was true of cases in which the intervention of a third person was strictly necessary to enable the physician to communicate with the patient. The statute is limited by its terms to physicians and surgeons. If public policy demands that the privilege of the physician and surgeon should be extended to nurses and other attendants who are neither physicians nor surgeons, the change should be made by the legislature, not by judicial construction. The ruling excluding the testimony of the nurse was prejudicial error.

Objection to the question asked on cross-examination of a physician who testified for the plaintiff, "Do you make it a habit of appearing for plaintiffs in these personal injury cases?" was properly sustained on the ground that the question was too indefinite and called for the conclusion of the witness, if for no other reason.

Society Proceedings

COMING MEETINGS

Central States Pediatric Society, Chicago, November 6-7. Dr. H. T. Price, Westinghouse Building, Pittsburgh, Secretary.

District of Columbia, Medical Society of, Washington, D. C., Dec. 2. Dr. C. B. Conklin, 500 Medical Science Bldg., Washington, D. C., Sec'y.

Philippine Islands Medical Association, Manila, Dec. 16-19. Dr. Isabelo Concepcion, College of Medicine and Surgery, Manila, Secretary.

Porto Rico, Medical Association of, Coami, Dec. 14-15. Dr. R. M. Suarez, Box 314, Santurce, Secretary.

Radiological Society of North America, Cleveland, Dec. 7-11. Dr. Robert J. May, St. Luke's Hospital, Cleveland, Secretary.

Southern Medical Association, Dallas, Texas, November 9-12. Mr. C. P. Loranz, Empire Bldg., Birmingham, Ala., Secretary.

Southern Surgical Association, Louisville, Ky., Dec. 15-17. Dr. Hubert A. Royster, 423 LaFayette Street, Raleigh, N. C., Secretary.

Western Surgical Association, Wichita, Kan., Dec. 18-19. Dr. Harry P. Ritchie, Lowry Building, St Paul, Minn., Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal for a period of three days No foreign journals are available prior to 1920, nor domestic prior to 1923 Periodicals published by the American Medical Association are not available for lending, but may be supplied on order Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested)

Emotional Reactions IV. Metabolic Rate C. Landis, Minneapolis —p. 188
Heat Regulation and Water Exchange X Water, Salt and Lipoid Accumulation in Serum as Preliminary to Sweating H G Barbour, M H. Dawson and I. Neuwirth, Louisville —p 204

Effect of Abdominal Pressure on Urine Volume.—Griffith and Hansell assert that diuresis analogous to that obtained in baths occurs on the application of appropriate pressure to the abdomen The evidence would seem to indicate that there is an optimum pressure for producing diuresis, different for different individuals, and that the more nearly the applied pressure approaches the optimum pressure the greater the diuresis Thus too low pressures might be ineffective, while too high pressures may even cause partial suppression It would appear that the cause of the diuresis on application of pressure should be sought in connection with increased venous pressure or other physical phenomena, rather than in greater urea excretion

Glyconeogenesis.—Markowitz' experiments, together with those quoted from the literature, demonstrate that glycogen is an obligatory, and not an optional step in the formation of blood sugar from the noncarbohydrate stores of the organism

Extraheptic Formation of Bilirubin.—The evidence presented by Mann et al would seem to be final evidence that the pigment which develops in the dehepatized animal is bilirubin and that extrahepatic formation of bile pigment is possible.

Effects of Bilateral Vagotomy on Blood Pressure.—An analysis is presented by Reed of 103 experiments in which the results of bilateral vagotomy were studied. There was no close correlation between cardiac and vasomotor responses to this operation. In experiments in which the operation was performed in the early stages of anesthesia and before any pronounced degree of shock had occurred, the predominant response was a rise in blood pressure independent of changes in heart rate, which was persistent and progressive in nearly all cases In many experiments in which a profound degree of shock had occurred the response to vagisection was a characteristic rise in arterial blood pressure, showing that the post-vagotomy depression in blood pressure does not invariably follow a condition of general shock

Intravascular Use of Heparin.—Reed asserts that heparin is valuable as an in vitro anticoagulant when it is desirable to retain all other physical and chemical properties undisturbed. Ten milligrams per kilogram of body weight is the minimum dependable dosage. Precautions for its use are mentioned.

Effect of Sleep on Blood Pressure.—The blood pressure averages of twenty-five patients for thirty-eight nights are offered by Blankenhorn and Campbell, showing the occurrence of the minimum systolic point (101 mm) at the fourth hour of sleep, a slight rise before waking and an abrupt rise after waking to a point equal to the first hour of sleep. The diastolic pressure shows a like though lesser fall. The pulse shows a curve almost similar to that of the pressure. The fall of the pressure is due mainly to the fall of pulse rate, though it is probably somewhat influenced by the peripheral relaxation.

Contractions of Gallbladder.—A method is described by Taylor and Wilson for recording contractions of the gallbladder in dogs which eliminates some defects. A marked contraction of the gallbladder on injecting 40 c.c. of a 33 per cent. magnesium sulphate solution into the duodenum was found in one dog out of eight; slight tonic contractions were seen in several others. Epinephrin intravenously caused a fall in gallbladder pressure, succeeded by a marked rise in pressure and increased amplitude of the rhythmic contractions Repeated injections abolish the initial fall, but increase the tonic effect Pilocarpin raised the tone slightly, but had no effect on rhythmic activity. Bile (3 c c.) intravenously lowered tone and depressed the rhythmic contractions Morphin and apomorphin slowed the rhythm, without affecting the amplitude. Secretin intravenously had no appreciable effect on the motor activity Ten cubic centimeters of 30 per cent. sodium chlorid intravenously temporarily increased the rhythmic contractions.

Tonus Rhythms in Bowel.—In addition to the segmenting movements and the peristaltic rushes in the bowel, Alvarez has noted slow tonus waves. In the duodenum and jejunum of the cat, this tonus rhythm can exist alone. This tonus rhythm is sometimes captured by the stomach and made to follow it for a time The tonus waves do not seem to travel along the bowel. They appear in records from the excised bowel and in records made with a balloon in the jejunum of a man. At the height of the tonus contraction, there is sometimes a marked increase in the rate of the superimposed rhythmic contractions. Mere distention of the bowel does not ordinarily produce such an increase in rate Tonus waves in one part of the digestive tract will sometimes seem to affect positively or negatively the activities of another part These waves probably have a good deal to do with starting and stopping the peristaltic rushes.

*Hanger Method for Repair of Procidentia Uteri. G. W. Crile, Cleveland.—p. 509.

Surgical Treatment of Criminals.—The form of treatment advocated by Oschner consists in the ligation and section of the vasa deferentia.

Septicemia; Fate of Microbes in Blood Stream.—The point emphasized by Martin is that in the generalization of infection a very complex process is going on in the body. The presence of microbes in the blood is but one phase or part of this process. To speak of the blood as infected in the sense that the cellular tissue is infected in a spreading phlegmon is erroneous and misleading. To speak of the blood being sterilized by the intravenous injection of a chemical as a test tube containing a broth culture is disinfected, is equally misleading and erroneous.

Fat Embolism.—The two cases cited by Elting and Martin were both closed fractures. Fat emboli were found at necropsy in virtually all the organs; heart, lungs, liver, kidney, spleen, pancreas, gastro-intestinal tract, suprarenals, seminal vesicles, lymph nodes and brain.

Surgical Treatment of Angina Pectoris.—In eight cases in which Kerr performed the so-called American operation, the left superior sympathetic ganglion was removed. In two cases the operation was repeated on the right side and in one case, at a third seance, the middle cervical and stellate ganglia were also avulsed under local anesthesia. In five cases, complete relief from the angina was obtained, in two partial relief, and in one case no relief. In those cases with still a residue of pain in the form of a substernal ache on exertion or effort, the relief is so great that the patients are restored to subnormal activity and feel immensely repaid for their short stay in the hospital. The permanent results of superior sympathectomy are anesthetization of the area above the oblique scar, from division of the superficial branches of the cervical plexus. There is also produced an enophthalmos and contraction of the pupil on the operated side.

Value of Radiotherapy in Breast Cancer.—Lee and Herendeen are convinced that preoperative and postoperative radiation are of value as an adjunct to surgery in the treatment of carcinoma of the breast. The best results were obtained when both preoperative and postoperative radiation were employed. The end results will be largely determined by the plan of irradiation followed and the dosage employed.

Splenectomy for Purpura Hemorrhagica.—Two children have been splenectomized by Clopton, both of them over fifteen months since, one with such marked improvement that it can reasonably be called a cure; the other with marked improvement, but with occasional hemorrhages that are easily controlled. A more recent case, a woman, 34 years old, has had no reappearance of purpura or hemorrhages since her operation eight months ago.

Resuture of Abdominal Incisions.—Shipley describes a method of closure for broken down abdominal wounds in which interrupted silver wire sutures are used to effect approximation of the wound edges. The wires are tightened a little more each day until the wound edges are healthy when they are contracted and healing occurs quickly.

Implantation of Ovary.—When the oviduct is permanently obstructed Estes exsects the uterine end of the tube and implants the ovary-cut surface into this denuded spot on the uterine horn, thus bringing the ovary into direct contact with the uterine cavity. This method of implantation of ovarian stroma has resulted in pregnancy in over 10 per cent. of the cases.

Hanger Method for Repair of Procidentia Uteri.—Crile removes a wedge-shaped section of the central part of the uterus, the apex extending down to the cervix, leaving a lateral strip of uterus free of mucosa on each side, together with the attachments of the round, the broad, the anterior and the uterosacral ligaments. Bleeding is controlled and the raw surface of each side and across the cervix is covered by suturing. The entire group of organs—the bladder, the rectum, the cervix and the vagina—involved in the descensus may be raised or lowered by these two handles and it remains only to find the anchorage whereby the group may remain permanently elevated by these handles. To this end a short incision is made through the external fascia, muscle and peritoneum, parallel to the original incision but just to the left of the median line as in a Gilliam operation, this opening, however, being made just large enough to draw through it the left "handle" of the descensus complex; the right handle is brought up through the primary incision. Thus the two "strap handles" emerge well up and out of the right and left incisions with a substantial and dependable strip of abdominal wall lying between them. The two handles are crossed over this strip as if to grasp it and are sutured there, thus forming a permanent immovable opponent to further descensus.

Action of Oils in Production of Tumors.—Burrows and Johnston state that cancer is an independent growth of body cells. It may be induced by any one of a number of conditions and substances. Once established, it proceeds independently of these causative agents. An active independent growth of body cells depends on a crowding of the cells together in a stagnant area or an area having a relatively poor blood supply. Cancer has this kind of an organization. It has been found that such an organization can reproduce itself through the fact that it destroys through its growth the normal tissue and blood vessels about it. The action of drops of corn oil and coal tar on the tissue has been investigated. It has been found that they act to build a dense, stagnant mass of cells by drawing the tissue cells to them and away from their intercellular substances and blood vessels. The bacteria that induce cancer act in the same manner to build a densely cellular stagnant mass of cells, but by a different means. They induce such a mass of cells to form by stimulating the cells of the tissue to proliferate without forming to any extent intercellular substances and blood vessels. These factors of stagnation and cell crowding become important for growth because the growth of body cells depends on a certain concentration of a primary product of the oxidation of the cells, the archusia. This substance is soluble in blood. The cells cannot retain it in quantity. Its concentration is at all times under the control of the environment. Function is likewise determined by the environment. Body cells can be made to grow not only through the accumulation of their own archusia, but by adding archusia from outside sources. Function is something that maintains only in an environment that inhibits an independent growth.

Value of Iron in Anemia.—Williamson and Ets have found that inorganic iron, whether given by mouth, subcutaneously or intravenously, is absorbed and may be found especially in the liver and spleen, but is not converted into hemoglobin. Animals made anemic by one or several large bleedings do not recover any more rapidly when inorganic iron is given in any of these ways. The efficiency of food iron is very pronounced, and animals on a diet containing food iron only recover very rapidly from hemorrhages that remove an amount of iron greater than exists in the entire body outside the blood. In the light of the foregoing experiments, the administration of inorganic iron has no therapeutic value in anemia.

Effect of Phenobarbital on Blood Pressure in Hypertension.—Phenobarbital decreased the arterial blood pressure in 85 per cent. of cases of hypertension in which it was used by Gruber, Shackelford and Ecklund. It appears to become less and less effective in most instances on prolonged administration. It has the same effect on both ambulatory and hospital patients. In moderate doses it has probably no harmful effect on the kidney tissues and on the phenolsulphonephthalein excretion. Immediately with the fall in blood pressure the phenolsulphonephthalein excretion is increased, but later, in some instances, its elimination is diminished. The elimination again returns to its original level after withdrawal of the drug. It produces marked toxic symptoms in large doses and therefore should not be prescribed indiscriminately.

Effect of Atmosphere on Basal Metabolism.—The results of the experiments made by McConnell and Yaglogou lead them to the following conclusions: The rates at which oxygen is consumed and carbon dioxid is produced increase with exposure to either high or low temperatures. There is a zone of minimum metabolic rate between 75 and 83 degrees effective temperature within which basal metabolism should be measured. The metabolic rate increases rapidly when the temperature of the environment is higher than that of the body. Body temperature and pulse rate correlate fairly well with the rate of basal metabolism.

Metabolism of Obesity.—The energy derived from the various nutrients by obese, normal and thin people after the ingestion of meals high in protein, carbohydrate and fat, respectively, was made the subject of the study by Wang and Strouse. There were twenty-six tests on obese subjects, twenty-one on thin subjects and twelve on normals. After the ingestion of protein, obese persons have a tendency to derive their energy from carbohydrate, whereas thin and normal persons use less carbohydrate than during starvation. Calories derived from fat decrease in the obese after the meal, but show little change in the thin and normals. The two latter groups, however, show a decided rise in calories derived from protein after the meal, but the protein consumption is little affected in the obese. This confirms previous findings that there is very little specific dynamic action of protein in obese persons. All subjects derive more energy from carbohydrate after the ingestion of a high carbohydrate meal, and less from fat. Calories derived from protein after this meal vary little, however, in any group from the starvation figures. After the high fat meal all groups show an increase in energy derived from fat. The obese continue to use carbohydrate in greater amounts than the two other groups. The protein consumption shows very little change, especially in the obese and normals. There is no relation between the pulse rate and energy production computed on the basis of heat produced per square meter of body surface. The fact that the obese subjects derive less energy from fat than either the thin or the normals after meals indicates a reason for excessive fat storage.

Auricles in Auricular Fibrillation.—It was evident to Frothingham from a study of cases that there is no typical lesion in the auricles that could be looked on as the cause of auricular fibrillation. A slight degenerative lesion was found in the muscle fibers of the auricles much more frequently with auricular fibrillation than in regularly beating hearts of the same age. It is interesting to speculate whether this lesion was the result of the irregularity of rhythm or a factor in its production, by causing some defect in the conduction of impulses or in the ability of the muscle to respond to the impulses.

Uremia in Acute Glomerular Nephritis.—The uremic symptoms in acute glomerular nephritis in children are discussed by Blackfan and Hamilton on the basis of observations made on eleven patients. The form of uremia seen in acute glomerular nephritis in children is characterized by headache, vomiting, visual disturbances, delirium or coma and convulsions. It is always preceded by a steady rise in arterial tension and by visible but not necessarily marked edema. A steady increase of arterial tension is the most reliable indication of approaching uremia. Intracranial tension resulting from edema of the brain is probably the causative factor of the symptoms in this form of uremia. This is suggested by finding an edematous brain at necropsy and the relief afforded by treatment favoring a decrease of cerebral edema. Arterial hypertension is probably the result of increased intracranial pressure. The intravenous injection of 1 per cent. solution of magnesium sulphate together with the administration of large doses of the salt by mouth and by rectum has been found to be effective in the treatment of this form of uremia. The intravenous injection should be repeated if necessary at twelve to twenty-four hour intervals until the blood pressure remains at a low level and the cerebral symptoms have subsided. Intravenous treatment is not effective during the medullary cone phase or in the terminal stages. Lumbar puncture should be used guardedly in order to avoid incarceration of an edematous brain in the foramen magnum. The term uremia is misleading as the symptoms are not dependent on the retention of nitrogenous end products. It is suggested that the characteristic symptoms with arterial hypertension be referred to as the cerebral symptoms of acute glomerular nephritis.

Application of Thiersch Skin Grafts.—The technic used by McLellan in the case of a small boy with an extensive burn of the anterior medial and lateral aspects of the thigh, was as follows: A strip of zinc oxid adhesive plaster, 1 inch wide and long enough to go completely across and adhere firmly to the skin on both sides of the raw area, was laid, with adhesive side up, on a sterile towel. Six or eight thicknesses of gause, 1 inch wide and long enough to go completely across the wound, were cut and applied lengthwise to the center of the adhesive plaster strip. With a sterile applicator, a thin layer of sterile petrolatum was applied to the surface of the gauze. Thiersch grafts were taken in the usual way and applied, raw side up, to the greasy surface of the gauze. Taking the adhesive by both ends, the graft was thus applied to the raw area, the adhesive being stuck firmly to the good skin on each side of the wound. This was left in position for eight days, at the end of which time the adhesive plaster was clipped at the junction of the raw surface and the good skin. Having turned the adhesive and gauze strips back carefully, the graft was found to be adherent to the raw surface.

Calcium and Potassium Chlorid in Treatment of Arterial Hypertension.—Addison and Clark assert that calcium and potassium chlorids will produce a decided fall in blood pressure in a large parcentage of cases of hypertension with a coincident improvement of the patient's symptoms. Edema will improve and disappear under their action. The treatment must be persisted in for three or four weeks to get results. From 90 to 180 grains should be given daily. The only serious objection is the possibility of producing symptoms of an inorganic acidosis.

Intracranial Dermoid Cyst.—A congenital inclusion dermoid of the posterior fossa of the cranium is reported by McEachern. The cyst contents consisted of a soft material containing many hairs but no other organized structures. This anomaly was associated with a double ureter.

Pulpless Teeth.—Haden asserts that a very high percentage of teeth that are negative in the roentgenogram harbor infection. A fairly large percentage of teeth which were positive in the roentgenogram did not harbor any infection or sufficient infection to be a factor in systemic disease at the time the culture was taken. In such cases, the infection has probably run its course and become bacteria free, just as happens in infections elsewhere in the body. The periapical tissues of a certain percentage of pulpless teeth, either positive or negative in the roentgenogram, are sterile when cultured in glucose brain broth. This does not prove that such are really sterile, since some other method of culture might reveal organisms. The findings suggest, however, that a pulpless tooth is not necessarily infected. The bacteria concerned in chronic foci are quite pathogenic, as judged by their ability to produce lesions in animals on intravenous injection. In selected cases, one can prove an unmistakable tendency of bacteria from chronic foci to localize in certain parts of the body. These cases afford valuable experimental proof of a causal relation of a chronic focus to systemic disease.

Iodin Content of Parathyroids.—Parathyroid preparations made from the external bovine glands by Hjort, Gruhzit and Flieger were not contaminated with thyroid tissue. The iodin content of the parathyroids is of no greater magnitude than that of the ovaries, pituitary and thymus. The iodin found in these glands probably represents the normal distribution of that substance throughout the body tissues.

Autolysis of Spleen in Vivo.—Autolysis of the spleen free within the abdominal cavity has been accompanied by death in 50 per cent. of the animals studied by Mason, Davidson and Matthew. Death from spleen autolysis has not followed so soon after operation as death from liver autolysis, the earliest death being thirty-six hours after sectioning the spleen. It is suggested that the spleen either does not undergo as rapid autolysis as the liver tissue or that the toxic material liberated is not so potent. Apparently the blood chemistry is but little altered in the animals which survive sectioning of the spleen, while those dying following the operation show some changes. The analysis of the abdominal fluid present at death due to spleen autolysis shows the nonprotein nitrogen constituents are essentially the same as in those cases of death due to liver autolysis.

Laboratory Diagnosis of Throat Infections.—A report of the findings on direct examination of throat swabs is presented by Young and Crooks. Smears made from swabs mailed to the laboratory showed diphtheria-like bacilli in about 60 per cent. of the positive cultures. The organisms of Vincent were found in many cases which were clinically confused with diphtheria. Smears from both the swabs and cultures were stained with Loeffler's alkaline methylene blue and a diagnosis made on staining reaction, morphology and arrangement.

Kahn Test for Syphilis.—A series of 2,500 cases, clinically free from syphilis, were studied by Keim and Kahn with the Kahn precipitation test. Negative reactions were obtained in 2,493 cases; 1 plus reactions were obtained in four cases; 2 plus reactions in two cases; and a 3 plus reaction in one case. These results indicate that the Kahn test possesses a high degree of specificity for syphilis.

Hemoglobin and Iron in Blood.—Sackett attempted to compare the percentage of hemoglobin found by Newcomer's method with the grams of hemoglobin present, and also to help establish a normal hemoglobin standard expressed in grams per hundred cubic centimeters corresponding to a five million red cell count. One hundred per cent. hemoglobin by Newcomer's method represents 16.4 gm. of hemoglobin per hundred cubic centimeters of whole blood. The normal standard corresponding to a five million red cell count is 16.4 gm. hemogobin per hundred cubic centimeters of whole blood.

Ephedrin in Shock.—Chen states that ephedrin raises blood pressure in hemorrhages and in experimental shock induced by histamin, peptone, anaphylaxis or surgical manipulation. The rise in blood pressure is permanent under favorable conditions and this effect of the drug is due to increased cardiac output and not to arterial constriction. Ephedrin fails to act when the heart beat becomes impaired, or respiration ceases, or the degree of shock is too extensive, or when hemorrhage exceeds 25 per cent. It has, however, no harmful effects.

Study of Benzyl Compounds.—Jensen's review and experimental studies of benzyl compounds suggest the following conclusions as to the importance of the various chemical groups in the benzyl nucleus: Introduction of a carbinol group decreases the toxicity and physiologic activity of phenol and aldehyd benzyl compounds. The position of the carbinol group in the molecule appears to be of some importance for the local anesthetic properties of the compound. The carbinol group seems to be the chief anesthesiophore group in benzyl compounds. The introduction of a carbinol group reduces the anthelmintic action of phenolic compounds. Bactericidal properties of benzyl compounds carry with the side chain groups in the following order, beginning with the most effective: phenol group, aldehyd group and the carbinol group. Anthelmintic properties of benzyl compounds are dependent on the side chain groups for their activity similarly to the bactericidal properties. Specific physiologic actions cannot be ascribed only to a definite chemical group. There is some suggestion that the physiologic activity of benzyl compounds depends on the number of hydrogen atoms in the benzyl nucleus. Pharmacologic actions seem to correspond to the most active chemical group in the molecule, i. e., the aldehyd action predominates in the alcohols of salicylaldehyd and *p*-oxybenzaldehyd.

Spartein Sulphate in Auricular Fibrillation.—Crawford found that spartein sulphate in appropriate dosage can cause cessation of auricular fibrillation induced by faradic stimulation of the dog's auricle. It does this probably by virtue of its depressant action on heart muscle. The power of stopping fibrillation of the auricle is not peculiar to one individual drug or group of drugs, but may be common to those drugs which depress the activity of cardiac muscle.

Aphasias of Childhood.—McCready urges that knowledge of the occurrence, prevalence and importance of aphasic conditions in children should prevail more extensively among those coming in contact with children during their early school years in order that these cases may be differentiated from the actually defective in intelligence and that the proper remedial measures may be applied. Isolated defects and disabilities of varying degree in the zone of language are a frequent cause of interference with the educational progress of the individual and of undesirable affective states leading to serious temperamental, character and behavior difficulties. In some instances the defect may be so extreme in degree and in its results as to lead to the conviction that the individual is markedly defective in general intelligence unless a careful analysis is made.

Use of Oxygen by Body.—Robinson states that the administration of oxygen is of no avail in congenital heart disease, nor is it indicated by cyanosis of cardiac origin when the lungs are comparatively clear. The chronic cyanosis of emphysema can also only be temporarily relieved by oxygen. It is in the acute failure of the lungs to furnish the blood with an adequate supply of oxygen in which oxygen administration is especially called for. The presence of anemia or of heart failure emphasizes the importance of adequate ventilation of the blood, and it is the combination of acute pulmonary failure that takes place in pneumonia and pulmonary embolism, together with inadequate ability for compensation by the heart and blood that call especially for the therapeutic use of oxygen. Oxygen may also be of service when heart failure occurs in patients with chronic emphysema. Robinson emphasizes that it is not the spasmodic use of oxygen that is of value. The gas should be administered over hours or days, and when properly arranged, need not interrupt sleep. Its rational use should be encouraged, as it tends to combat one of the fundamental causes of death, and when properly administered in suitable cases, it may relieve distressing symptoms.

Blood Serum Agglutination of Proteus Bacilli.—The study by Weeter and Motyca showed that human serums from the patients with no known history of proteus infections agglutinated *Proteus X* 19 both early and completely in dilutions which have been described by previous workers as indicative of typhus fever in the early stages The highest dilution recorded giving positive agglutination with normal serum was 1 : 200. Proteus bacilli were isolated from six of ten specimens of stools and three of ten specimens of urine from seventeen different patients whose serums agglutinated *Proteus X* 19 in higher dilutions. These differed from *Proteus X* 19 in gelatin liquefaction and in their behavior toward *Proteus X* 19 immune serum A culture of *Proteus vulgaris* and one of *Proteus mirabilis* were not agglutinated so readily or in such high dilutions by certain of the foregoing serums as was *Proteus X* 19.

Basophilic Leukocytosis in Experimental Syphilis.—Unusual degrees of total and relative basophilic leukocytosis were observed by Graham and Grigg during the course of a study of experimental syphilis in the rabbit The basophils reached levels of 25 to 35, and, in one instance, 39 per cent. of the total leukocytes. Explanation for such basophilic leukocytosis is not complete on the basis of the work reported. The most constant factor in its production appeared to be the presence of active syphilitic infection. The reaction is interpreted as the result of degenerative changes in the hematopoietic tissues.

Hookworm Reinfestation.—Two areas in different parts of Porto Rico were treated for hookworm disease, and a year later were resurveyed. The first area, situated in an untreated, unsanitated section of the island, was treated without preliminary or subsequent sanitation of either the area itself or the surrounding territory. In the second area, latrines were constructed at all houses of it and the surrounding territory some time before treatment. Treatment also included the territory affecting the area In the first area the intensity of infestation was reduced approximately 84 per cent. while it was reduced 97 per cent in the second area. Resurvey one year later showed reinfestation universal in the first area, with the intensity half that of the previous year. In the second area almost half the inhabitants harbored hookworms, but the intensity was only 12 per cent that of the previous year The conditions causing this difference in degree of reinfestation are discussed by Hill.

Use of Fluoroscope in Litholapaxy.—Goldstein combines litholapaxy with fluoroscopy in an air medium. The method has been reported previously, but some changes in technic and the operation of additional cases are detailed in this paper.

Incision for Femoral and Inguinal Herniorrhaphy.—The incision advocated by Carney is from 3 to 5 inches in length and about 2½ inches from the midline of the body. The upper end of the incision is on a line with or slightly below the level of the anterior superior iliac spines; and the lower end crosses Poupart's ligament at the junction of the middle and lower third of the ligament This gives a free exposure of the conjoined tendon and external oblique fibers By slightly undermining the lower border of the inner flap, the spermatic cord can be picked up By undermining the outer flap the fibers of the exterior oblique can be exposed to any desired extent. The incision is such that Poupart's ligament is exposed without undue traction and the necessary repair is completed as easily as in the customary incision. Using the same incision, with Poupart's ligament readily exposed, it is an easy matter to do an inner repair for femoral hernia

Mild Typhus in Rio Grande Valley.—Mild typhus (Brill's disease)—perhaps a permanently attenuated strain—is endemic in the lower Rio Grande Valley and has been there for some years, occurring sporadically, not attaining a very wide spread, and largely passing unrecognized under the name of paratyphoid fever, Rio Grande fever, etc. Maxcy regards it as not unlikely that *Pediculus humanus* var. *capitis* may be the vector responsible for the transmission of these cases.

Blood Sugar in Eczema.—A study of twenty cases of eczema by Haldin-Davis and Wills has shown that cases of eczema in patients who are not suffering from diabetes are often (apparently in about 66 per cent. of the total number) associated with some abnormality of the blood sugar level. This abnormality may consist either (1) in an abnormally high blood sugar content during starvation, (2) in the appearance of abnormally high amounts of sugar in the blood soon after the ingestion of glucose; and moreover, these high amounts may either disappear quickly or be slow in departure. These abnormalities in the blood sugar are not associated with any particular type of eczema. Blood sugar abnormalities seem more likely to be found when the eczema is widespread and there is a good deal of edema of the skin, but this is not an invariable rule by any means. Furthermore, the dietetic treatment of eczema in patients who are not prone to obvious excesses in one direction or another is unsatisfactory.

*Acute Thyroidism Following Ligation. F. W. Gifford Nash.—p. 519.

Double Ectopic Gestation.—In the case reported by Oliva an ovarian gestation about 26 weeks old was found on the right side, and a tubal gestation about 8 weeks old on the left. The woman complained of a tumor, abdominal discomfort, loss of weight, occasional pyrexial chills, constipation and amenorrhea for eleven months. Two months earlier she had had a bloody discharge from the vagina, accompanied by much pain on the left side of the abdomen; she believed this to be a return of menstruation, but she had no period in the following month. She had noticed the tumor some six months previously; the swelling had progressively increased in size from that time, but had ceased growing latterly. She was never inconvenienced in any way, apart from the natural sensation of weight caused by the tumor itself. A median laparotomy was performed. The tumor on the right side was unquestionably an ovarian pregnancy, which had grown between the two layers of the broad ligament. The relation of the tube to the sac wall seemed to prove this, besides the total absence of ovarian tissue on that side. The interesting points in the case are: the long duration of the gestation, the lack of distinctive symptoms, and the impregnation of the opposite tube, which caused the patient to seek medical advice.

Acute Thyroidism Following Ligation of Superior Thyroid Artery.—Nash reports a case of acute thyroidism following ligation of the superior thyroid artery for a large vascular goiter and extreme exophthalmos. The patient recovered.

Cephalandra Indica in Diabetes.—Telakucha (Cephalandra indica) has the reputation in Bengal of having a remarkable effect in reducing the amount of sugar in the urine of patients suffering from diabetes mellitus. Chopra and Bose tested the drug pharmacologically and clinically. They found that it contains an enzyme with amylolytic properties, a hormone and traces of an alkaloid, but none of these substances reduces sugar when administered subcutaneously to rabbits. Fresh juice extracted from the leaves, stem and root of the plant produces no reduction of sugar in the blood or urine of patients suffering from glycosuria.

Estimating Amount of Quinin in Solutions.—The method described by Sinton depends on the relative opacities produced in quinin solutions of varying strengths by the addition of equal amounts of Tanret's modification of Mayer's reagent.

Hemogregarines in Blood.—The points brought forward by Sinton strongly support Wenyon's view that the bodies described from smears of human blood as "hemogregarines" are not of a protozoal, but of a vegetable nature, that they are not parasites but contaminations of extraneous origin, and that "hemogregarines of man have still to be discovered."

Blood Sugar and Tolerance Test.—Blood sugar was estimated by Bhatia and Coelho in thirty-eight normal subjects, of whom eighteen lived on a "mixed" diet, and twenty were pure "vegetarians," partaking of large quantities of carbohydrates. In the former class (nonvegetarians), the average blood sugar was lower, tolerance for carbohydrates greater, and glycuresis less common than in the latter (vegetarians). The significance of these differences in the two classes of individuals is discussed.

Does Bedbug Transmit Kala-Azar?—A total of 138 *Cimex hemiptera,* all caught in the bedding of cases of kala-azar, were examined by Shortt and Swaminath by culture of the entire gut in NNN medium. The cultures were uniformly negative.

Experimental Kala-Azar.—Shortt and Swaminath assert that intradermal inoculation of a comparatively small amount of infective material from kala-azar resulted in a well marked and enduring invasion of the internal organs by the parasite of kala-azar, a result in marked contrast to the slight and transient infections described by some writers.

Experimental Kala-Azar.—The question as to whether kala-azar infection can occur through ingestion would seem to be answered in the affirmative by the results of experiments reported on by Greig and Chirstophers, though further positive results are necessary to confirm this finding.

Effect of Epinephrin on Wassermann Reaction.—Anderson and Sinton are of the opinion that if their technic is used, no reaction which would give rise to a false "positive" Wassermann reading is likely to follow the subcutaneous injection of epinephrin hydrochlorid in doses of 1 mg.

*Acute Pernicious Anemia with Epistaxis. J. J. Woodburn.—p. 257.
*Maydl's Hernia. G. Bell.—p. 258.

Acute Pernicious Anemia with Hemorrhage.—Woodburn's patient had hematuria for eight days and several severe attacks of epistaxis. The onset gave no clue to the ultimate diagnosis and termination of the case. The history suggested some lesion of the spine and hip joints and of the renal tracts. As was shown by examination these systems were unaffected. The patient's condition was probably one of a rapidly advancing hemolytic anemia (possibly of unknown streptococcal origin) with rapid destruction of red cells and reversion to a primitive type of megaloblastic red cell formation. That is, it was an acute pernicious anemia probably due to some unknown infecting organism, as shown by the rise in temperature and pulse rate. The pain in the spine and in the region of the hip joints was probably due to the changes taking place in the bone marrow. The hemorrhages, of course, are usual in any form of pernicious anemia, more especially in such an acute case as this. The necropsy findings confirmed the diagnosis.

Maydl's Hernia with Gangrene.—The importance of withdrawing and inspecting that portion of the gut which lies within the abdomen and immediately proximal to the constriction is shown by Bell's case. An intra-abdominal and intermediate loop of bowel, continuous with the two loops in the sac, was drawn down. It was 12.5 cm. (5 inches) in length and gangrenous. The strangulation was of the variety often referred to as "retrograde" and the hernia one sometimes referred to as Maydl's hernia. There was very slight distension of the bowel above the site of constriction. Twenty-five centimeters (10 inches) of small intestine including the gangrenous segment were resected. A lateral anastomosis was made. The lower end of the portion of ileum resected was 30 cm. (12 inches) from the ileocecal valve.

Splenectomy in Hemorrhagic Purpura.—The clinical picture presented by Cowen's patient, characterized as it was by the presence of multiple spontaneous hemorrhages, suggested at once that she was suffering from an acute blood disease. Hemophilia could be excluded, owing to the sex of the patient. Moreover, in hemophilia extensive purpuric skin lesions are unusual, the hemorrhages are not spontaneous but follow some injury, however slight, and the bleeding time and platelet count are normal, though the coagulation time is greatly prolonged. It was, therefore, obvious that the case must be classed as one of purpura.

Hookworm Disease in China. W. W. Cort and N. R. Stoll.—p. 282.

Scarlet Fever Serum.—Throat swabs were taken by Chen from all the severe cases of scarlet fever encountered at the hospital, and *Streptococcus hemolyticus* was isolated from each case. A serum was prepared and from this organism, nineteen strains were used. This serum appears to have a decidedly curative effect in severe cases of scarlet fever, especially those which a long experience considers as likely to end fatally without it. The serum should be administered early in the disease. Although unconcentrated, the serum is required in a much smaller quantity than any of the other antiscarlatinal serums now available. Given early in virulent cases, it appears to ward off serious complications. This serum has not been made use of in the milder cases. In some severe cases it has the effect of bringing the temperature down by crisis. It appears to be of benefit in erysipelas developing in scarlatinal cases, by cutting short the course of the disease.

Scarlet Fever Serum.—Nineteen strains of hemolytic streptococcus isolated from the throats of scarlet fever patients were used by Tsen and King in the preparation of this serum. These organisms were grown in 0.5 per cent. glucose broth. After twenty-four hours' incubation at 37 C., the broth cultures were mixed together and centrifugalized; the supernatant clear fluid was then removed, and the sedimented bacteria were suspended in normal salt solution. This new suspension was recentrifugalized, and the sedimented bacteria were resuspended in normal salt solution and strained through sterile, fine-meshed gauze. By comparison with a standard suspension of barium sulphate, the bacterial count was adjusted to 5,000 million per cubic centimeter. This suspension was injected into the horse immediately. For immunizing the horse, dead cultures were used first. These were prepared by heating the bacterial suspension at 55 C. for one hour after it had been strained through gauze. Altogether twelve doses of dead and fourteen doses of living cultures of gradually increasing amounts were injected intravenously in the usual way. Test bleedings were begun after the fifth injection of the living cultures. When the serum was found to be satisfactory by means of protection tests on mice, regular bleedings were made. The serum, after separation from the blood clot, was preserved with 0.25 per cent. tricresol. Finally, tests for sterility, toxicity and potency were made. Two-tenths cubic centimeter of serum protects a mouse against 1,000 fatal doses of this organism.

Coexistence of Tuberculosis and Plague.—Experiments made by Jettmar show that plague bacilli do not penetrate into caseated tuberculous tissue and are only seen in small numbers in the tuberculous epitheloid tissue. Small tuberculous and plague necroses may fuse together. Plague bacilli when mixed with tubercle bacilli do not show any involution forms. In vitro the two kinds of bacteria do not essentially injure each other.

Technic for Methylene Blue Treatment of Cystitis. Blanc.—p. 144.

Interrupted Micturition.—Mercier has observed that hypertrophy of the trigon, forming a bar between the mouths of the ureters, is liable to interrupt the flow of urine. As the bladder contracts, this bar stiffens and holds back the urine. Then, as the bladder relaxes, this bar relaxes with it, and the pent up urine escapes. Interrupted micturition is thus not peculiar to a diverticulum.

Suprapubic Prostatectomy.—Salvini states that 70 per cent. of 180 operations of this kind cured the patients completely and permanently (1921-1924). To prevent orchitis, the vasa deferentia are systematically ligated and severed. This does not impair potentia coeundi. The mental condition improved, and in one case there was no return of the epileptic seizures of the preceding few years. One man developed neurasthenia after the operation, and committed suicide in delirium. Tardy hemorrhage occurred in three cases; in two, probably from the dropping off of the eschar; in the other case, the hemorrhage a year later cannot be explained so easily. No recurrence of the adenoma was known in any instance.

Hematuria in Pyelonephritis.—Blanc presents evidence to demonstrate the remarkable efficacy of simple catheterization of the ureter in arresting a hemorrhagic tendency in pyelonephritis, supplementary to the usual measures.

*Jaundice of the New-Born. G. L. Hallez.—p. 297.
The Microscopic Lesions in Rickets. J. Debray.—p. 312.

Pathologic Phenomena of the First Dentition.—Marfan reiterates that there are no bodily disturbances for which the dentition is directly responsible. But in an infant with the spasmophilic diathesis, spasm of the larynx or generalized convulsions may be brought on by a difficult eruption of teeth. Fever during teeth cutting may be due to inflammation around the tooth crown, or to a latent disease aroused by the dentition. It is possible that eruption of teeth, especially if it is difficult and abnormally prolonged, might produce humoral disturbances, favoring the appearance of pathologic phenomena. The latter in certain cases may be rapidly relieved by opening the dental sac through a crucial incision of the gum.

Causes of Jaundice in the New-Born.—Hallez' conclusions are based on thorough examination of nineteen cases. Icterus neonatorum is caused not only by an intense hemolysis in the first hours of life, but also by a transient functional deficiency of the liver, as revealed by hypercholemia, frequent choluria and even urobilinuria.

*Bone Implants in Lower Jaw. H. Rouvillois.—p. 237.
Physiotherapy in Respiratory Affections. G. Rosenthal.—p. 245.
Organotherapy for Sterility in Women. E. Pouget.—p. 249.

Bone Grafting in Pseudarthrosis of the Lower Jaw.—Rouvillois employed bone implants in three cases of pseudarthrosis complicating a gunshot fracture of the jawbone. The grafts were taken from the tibia, and the usual bone grafting technic applied. Consolidation of the bone parts was manifest after four months, allowing mastication with artificial teeth. The bone implants were not applied until several weeks or months after the infectious process had healed, and all traces of osteomyelitis or fistula had disappeared.

*Treatment of Gonorrhea. A. Tansard.—p. 1254.
*Vaccination Against Measles. M. B. Sindoni.—p. 1255.

Autovaccination Associated with Protein Therapy in Gonorrhea.—Tansard suggests that injections of vaccine and protein should be given simultaneously in treatment of gonorrhea. Three cases of chronic urethritis were cured by this method, while the same injections, given separately had been without results. Under the simultaneous injections, fifteen patients with acute or chronic urethritis recovered, without local treatment. From fifteen to twenty injections were usually applied; in certain cases more injections were necessary. In one case of thirty years' standing, an apparently inevitable prostatotomy was avoided by this treatment, prolonged for three and a half months. An autogenous vaccine, six thousand millions of bacteria per cubic centimeter, was used in six cases with a periurethral abscess. A dose of 0.2 c.c. was given at the first injection, gradually increased by 0.1 to 1 c.c. A dose of 1 c.c. of protein was used in the first injection. If the reaction was not pronounced, 5 c.c. was given the next time. The injections were given daily, or thrice weekly. In the abscess cases, the suppuration stopped and the fistula healed after four or five injections. A patient with gonorrheal rheumatism of the pseudophlegmonous form recovered without the slightest ankylosis. In this case one injection of over 3 c.c. of autovaccine and one of 6 c.c. of protein had been given daily for twelve days. Seventeen injections of a stock vaccine, containing gonococci and staphylococci, given before, had been ineffectual. Shock, characterized by moderate fever and general malaise, may occur after the first four injections. Tansard advises a vegetarian diet the day of injection, and constipation averted during the treatment. A colloidoclastic diathesis and asthma are contraindications for these injections. With a periurethral abscess, this treatment gives better results than an operation or a vaccine alone, since folliculitis and urethritis are cured at the same time as the abscess.

Prophylactic Vaccination Against Measles.—Sindoni used vaccine prepared from cultures treated with phenol at 0.5 per cent. From three to five injections of 2 c.c. each, were given intramuscularly every second day. About 346 children in asylums, aged from 1 day to 14 years, were vaccinated. In the asylum where vaccination was applied immediately after the occurrence of a few measles cases, only one child developed the disease. In another asylum, where vaccination was late, eighty children out of the hundred developed measles. Sixty children, aged from 6 months to 12 years, were vaccinated in private homes. None developed measles. About 133 children of the same age, that had been directly exposed to measles infection in the hospitals, were vaccinated. The disease developed in eight.

*Review of Research on Measles. R. Pollitzer.—p. 1269.
*The Dual Innervation of the Voluntary Muscles. P. Oury.—p. 1271.

Embolectomy.—Lian and Moure report a case in which an embolus was removed from the axillary artery in a man with a failing heart. The incision of the artery and extraction of the embolus under local anesthesia brought complete restoration of the circulation, demonstrated by the arterial pressure and the oscillometer findings. The arm regained normal function. They reiterate that the operation is indicated only for an embolus and not for a thrombus. The embolus may be differentiated by the exaggerated pulsation of the artery above the point of obstruction, compared with the sound side. This excessive pulsation, cephalad, is not observed with a thrombus.

Spleen Extract in Treatment of Tuberculosis.—Bayle reports as the first results of this treatment, which he has applied in several hundreds of cases since 1903, a gain in weight of 4 or 6 pounds. This was manifest the first two or three weeks of the treatment; and an average of 24 pounds was gained in the year. Lesions of the first stage of tuberculosis improved within the first month. Cold abscesses of the elbow were cured in one month; of the knee in two or three; of the hip joint in six or eight months. Nonsuppurating bone and joint lesions retrogressed, and the limbs regained normal function. A surprising effect was noted in tuberculous glands. The number of tubercle bacilli gradually diminished and finally disappeared entirely. An extract of pig's spleen was used, in 5 c.c. ampules, for the injections, or was given in syrup by the mouth. The oral route was used in prophylaxis or as adjuvant to the injections. Adults are given daily four tablespoonfuls, each representing 25 gm. of spleen tissue, taken with the meals. Children under 3 years are given daily one teaspoonful for four days during the week; under 5 years, two; under 7, one tablespoonful; under 10, two; under 14, three. Adults and children above 10 are given the syrup for three weeks; then a pause for a week or two. One or two injections, each of 5 c.c., are given daily to adults. The dose of 1 c.c. is injected per year of age, in children under 5. The injections are made subcutaneously, in the abdomen, or intramuscularly, in the thigh; they are not accompanied by fever or anaphylactic phenomena. The treatment should be continued for a few months after apparent recovery. He claims 100 per cent. of recoveries in tuberculosis of the first degree and 75 per cent. in all. This splenic organotherapy, he adds, is absolutely harmless. It is being used in a number of French hospitals.

Etiology and Pathogenesis of Measles.—After a circumstantial review of the research work on measles, Pollitzer summarizes Caronia's experiments leading, he says, to the discovery of the specific micro-organism in 1923.

The Dual Innervation of Striped Muscle.—Oury emphasizes that the voluntary or reflex contraction lasts only as long as the excitation in striated muscle fibers, innervated by the cerebrospinal nerve terminals. These fibers possess the "contractile tone" and command the voluntary movements. Muscle fibers innervated by the sympathetic, become longer or shorter during excitation, and the induced condition still persists after the stimulus ceases. These fibers possess the "plastic tone." The existence of both "movement muscles and fixing muscles" is manifest in vertebrates and in man. Lesions of fibers with sympathetic innervation are responsible for decerebrate rigidity or extrapyramidal contracture in which the "plastic tone" predominates. Affections of fibers with cerebrospinal innervation may induce muscular atrophy or dystrophy, also myasthenia. Oury recalls that Royle and Hunter suggested section of the sympathetic for exaggerated "plastic tonus" in Parkinson's disease, encephalitis sequelae and decerebrate rigidity.

Metabolism and Skin Diseases. W. Lutz.—p. 885.
Curvatures of the Spine. M. Dubois.—p. 890. C'cn.
*The Blood Pressure in Children. Thomas.—p. 896.
*Vaccine Encephalitis. F. Lucksch.—p. 897.
*Prevention of Thrombosis. M. Walthard.—p. 898.

The Blood Pressure in Children.—Thomas measured the blood pressure in 627 children (7-14 years of age). The systolic pressure in boys between the ages of 7 and 11 was 98, the diastolic, 61 mm. of mercury; in girls of the same age. 93 and 58. In boys from 11-14, the systolic pressure averaged 107, the diastolic 71 mm.; in girls, 106 and 63, respectively. The pressure was lower in tuberculous children but only in the older group. The amplitude of the blood pressure is 5 to 10 mm. greater in children than in adults.

Vaccination Encephalitis.—Lucksch observed three cases of encephalitis following vaccination against smallpox. He advises to vaccinate only perfectly healthy children, and to defer the vaccination at times of an epidemic of encephalitis or poliomyelitis.

Prevention of Thrombosis.—Walthard endeavors to ward off thrombosis and embolism by systematic exercises of the women, beginning on the first day after labor or a gynecologic operation. The foot end of the bed is raised 50 cm. above the floor for women with varicose veins. He describes the simple, progressive movements of the arms and legs and deep breathing which he advocates while the women are confined to bed.

Specific Prevention of Scarlet Fever and Measles. G. Caronia.—p. 1357.
Limits of Quinin Prophylaxis. A. Lusignoli.—p. 1359.

Periaterial Sympathectomy.—Durante points out that an approximately complete interruption of the sympathetic fibers can be accomplished only by removing the adventitia nearer the periphery of the extremity. This method has the further advantage of avoiding the untoward possibilities of an intervention on the large arteries. His six patients recovered. Among them was one with a mal perforant; sympathectomy on the femoral artery had failed, but the decortication of the posterior tibial was successful. This patient, however, had a relapse ten months later.

Gonococcus Ophthalmia. E. Campos.—p. 33.
*Malarial Coma. Clinio de Jesus.—p. 34.

Exaggeration of the Second Aortic Sound in Syphilis.—Martagão Gesteira did not find in adults this sign to which Rubião Meira called attention in 1916 as a new sign of syphilis. But he discovered it almost constantly in children with congenital syphilis, and he relates some case histories to show its importance in the differential diagnosis, and as revealing a surprising amount of aorta disease in apparently healthy children. The course of the cases, however, confirmed the reliability of this early warning sign. It confirms Beretervide's discovery of an abnormally wide aorta in 99 per cent. of 200 children with congenital syphilis.

Malarial Coma.—A youth was brought into the hospital in a comatose condition for which no cause was apparent until the malarial parasite was found in the blood. The absence of mononuclears was ascribed to the intensity of the infection.

*Primary Infantile Acidosis. C. Torres Umaña.—p. 268.
Stoll Method for Estimating Hookworm Infestation. Wilson.—p. 301.
History of Leprosy in Colombia; Carrasquilla. Rico.—p. 304. C'tn.

Primary Acidosis in Children.—Torres Umaña thinks we must distinguish this primary infantile acidosis from acidosis in adults, and that secondary to febrile conditions, inanition, diabetes, etc. He says it is frequently observed at Bogota, and is often grave, appearing in the form of periodical uncontrollable vomiting, a meningeal form, and a form with similar headache, pallor and acetonuria, but, as the vomiting ceases, the temperature and the general condition grow rapidly worse, with air hunger and enlargement of the liver, dysphagia and increasing prostration. The pulse may keep good throughout. Recovery is slower than in the other forms. About 50 per cent. of the children are between 7 and 12 months old. In the extremely toxic cases, he never witnessed any benefit from transfusion of blood. The main reliance is on alkalies, and dieting to restrict production of acids. Two of four small infants recovered after injection in the longitudinal sinus of a solution of sodium bicarbonate treated with carbon dioxid.

Case of Influenzal Meningism. L. A. Forero Rubio.—p. 335.
*Creatinin in the Blood. R. Saravia Gallo.—p. 337.

Creatinin in the Blood in Colombia.—Saravia Gallo reviews the present status of our knowledge of creatinin, and states that his research on 113 persons at Bogota demonstrated that the normal average is much below that in Europe (2.5 mg.). At Bogota the average for healthy men is 1.7 mg. per hundred cubic centimeters of blood, and, for women, from 1.3 to 1.5. He found the creatinin level high in chronic parenchymatous nephritis and uremia, and wherever there was much tissue destruction. The level rose a little during the onset of pneumonia, malaria, typhoid fever and other febrile conditions, but not in the first stage of syphilis or diabetes. The creatinin is below the normal average in the debilitated and in convalescents, and also as term approaches in pregnancy. Experiments on rabbits showed the same creatinin content after severe exercise as before, thus confirming that the creatinin is endogenous and does not proceed from muscle tissue waste.

*Epinephrin in Treatment of Gas Gangrene. S. Uribe Rivera.—p. 905.
Necessity for Teaching Individual Prophylaxis to Supplement the Present Fight Against Venereal Disease. I. Chávez.—p. 910.

Fetus Shot in the Thorax.—The woman died from hemorrhage after the viable child had been extracted by cesarean section, after she had received a gunshot wound in the abdomen. The bullet had passed through the thorax of the fetus, entering in the tenth left interspace and emerging in the suprascapular region above. Blood escaped from the child's mouth when it was suspended by the feet. The child has survived in good condition; there was not even an appreciable pleural effusion, and the wounds healed by primary intention.

Epinephrin in Infected Wounds.—Uribe Rivera injected 0.5 c.c. of the official solution of epinephrin in the vein at the elbow in a case of gas gangrene of the leg that had required amputation and an emergency exarticulation at the hip joint. The man was apparently moribund, but he recuperated by the next day, when a second injection, 0.25 c.c., was given, with complete recovery. Similar success was realized in two other cases of gas gangrene, of the arm or hand. The third case was in an intern who had been contaminated during the operation on the second case. All recovered under the epinephrin injections.

*Acute Scarlatinal Polyarthritis. F. de P. Rivas Maza.—p. 91.
The Sedimentation Test in Pulmonary Tuberculosis. Fenstermann and Baldó.—p. 95.

Acute Polyarthritis of Scarlatinal Origin.—Rivas Maza reports a case of severe involvement of nearly all the joints, large and small, seven days after the development of the principal eruption in a case of retrospectively diagnosed scarlet fever in a young woman. Syphilitic rheumatism had been assumed by the attending physician and he had sent the patient to the hospital for neo-arsphenamin treatment. The urine was practically normal, and the arthritis subsided completely in a week under simple diuretics and disinfectants for the kidneys, including sodium benzoate. Rivas Maza comments on the harmless and prompt recovery in such cases of scarlatinal polyarthritis which has no need for heroic measures or the usual treatment for articular rheumatism. In three cases in 1924 scarlet fever developed in parturients, and streptococci, staphylococci, pneumococci, the colon bacillus and saprophytes were cultivated from the throat but there was no puerperal infection.

*Decomposition and Congenital Syphilis. J. Medeiros.—p. 322.
Case of Double Hearing of Certain Sounds from Relaxation of Left Drum Membrane. V. Ribón.—p. 324.

Sporadic Cases of Plague.—Paso describes a case of plague with primary and secondary plague carbuncles and fatal septicemia. Two other fatal cases of plague had preceded it in the same district in the three years before, but no connection between the cases could be discovered. Unusual numbers of rats had infested the stable where the man had worked, and some were sick. The rats migrated soon after, but no further cases of plague have developed during the nearly three years since.

Cancer of the Tongue.—Finochietto states that in the case described ligation and severing of the lingual arteries on both sides reduced the large cancer on the tongue to a fifth of its former size in a very few days. With invasion of the tonsils, he ligates the inferior pharyngeal arteries also. He relates some typical instances to show the advantages of preliminary ligation before operating on the tongue, or as a palliative measure in inoperable cases.

Abstention in Tubal Abortion.—Chueco's practice is to give morphin first, to combat the shock. If the tube is permeable, the fetus dies, and there is tubal abortion. If the openings are obstructed, the fetus does not die, and the tube bursts. In either condition the tube may be empty when palpated. The rupture requires an emergency operation, but he always refrains until the diagnosis is certain. He reiterates that complete tubal abortion does not require an operation. There is not much extravasation of blood, and resorption of this is promoted by diathermy. The indications are merely to combat the shock; this is more pronounced when there have been no preceding symptoms. In operating, when the tumor can be reduced and brought outside, he extirpates it through the anterior vagina, with a supplementary posterior colpotomy when drainage is needed. He demonstrated a case of this kind. The signs and symptoms had indicated a tubal pregnancy of two and a half months. The tube was found obstructed, with rupture impending, but it was safely removed by anterior colpotomy, and the woman was up and about in six days.

Malnutrition and Congenital Syphilis.—Medeiros reports two cases in which what seemed to be typical malnutrition in young infants, of the Finkelstein decomposition type, yielded promptly to tentative treatment for congenital syphilis.

*Arterial Tension in General Practice. J. B. de Quirós.—p. 436.
*Syphilis of the Prostate. J. Salleras.—p. 450.

Experimental Labyrinthitis.—Podestá's nineteen photomicrographs confirm that the bone lesions in the internal ear are always preceded by necrosis or purulent destruction of the mucosa of the middle ear, acute or chronic, of various origins.

Detachment of the Epiphysis of the Neck of the Femur.—Lagos Garcia presents evidence to show that one of the features of the adiposogenital syndrome is a peculiar fragility of the tissues forming the junction of the shaft of the femur with the epiphysis. The epiphysis is liable to separate in girls of this type. In the three cases described the girls were all 12 years old, and no trauma was known. This detachment of the epiphysis is often mistaken for fracture of the cervix or a sprain of the hip joint. Stout girls at this age should be supervised with care—including frequent roentgen-ray examination when they complain of slight pains in this region, and the joint should be relieved of strain, and organotherapy be applied until this critical age of extra fragility of the epiphysis is past. The pains may be slight, with very little limping, but these disturbances are tenacious. There is seldom spontaneous pain when reclining.

The Blood Pressure in the Tuberculous.—De Quirós tabulates the findings in regard to arterial pressure and viscosity of the blood in 100 patients with pulmonary tuberculosis, calling attention to the ratio between them characteristic of different phases of the tuberculosis.

Syphilis of the Prostate.—Salleras relates the case history of a man, aged 55, who for about a year had had pollakiuria in the second half of the night, with dysuria and pains after micturition. These disturbances had been transient until the last three months when they became more severe and tenacious, and micturition was imperative every half hour during the day, and extremely difficult. He had been treated for gonorrhea and syphilis in his youth but had never noted a chancre. The prostate was enlarged, the bladder irritable, with retention of 20 c.c. of urine; and cancer seemed certain, but under tentative treatment for syphilis all the symptoms subsided. Nothing of the former clinical picture was left by the end of two months except slight initial dysuria, and this was gradually disappearing. In twenty-eight such cases on record, the spirochete was found in the prostate in two. The ages ranged from 18 to 73. In some cases there were continual pains, spreading to the legs, and in some there was complete retention. There may be hematuria or hemaspermia, a sensation of a foreign body in the rectum, pain in the perineum, or difficulty in defecation. The good general condition is also instructive, and the long course.

Familial and Constitutional Factor in Pernicious Anemia.—Neuburger finds no evidence in favor of a hereditary factor in pernicious anemia: Four of his sixty-five patients believed that the disease had occurred in their family. His investigations showed that they were mistaken. He also examined the gastric secretion in twenty-nine relatives of fourteen patients. Only one of these subjects had achylia.

Metabolism After Resection of Intestine.—Wildegans resected parts of the small intestine in dogs. Proteins and fats were not well digested in the first four weeks after resection of two thirds of the small intestine, but the animals recovered later. They died from inanition when seven or eight tenths of the small intestine was removed. The jejunum and the ileum can compensate for each other.

Cocainism and Homosexuality.—Joël and Fränkel find that cocain addiction usually removes only the inhibition in a bisexual man. In heterosexual men the loss of potency without diminishing of the libido, together with the craving for new sensations, accounts for the inversion.

Acetylene Anesthesia.—Mallebrein and Maier report the results of 2,000 anesthesias made with acetylene at the gynecologic clinic at Würzburg. No death occurred; postoperative pneumonia was observed only in 0.3 per cent. and bronchitis in 0.3 per cent. of the women. The method surpassed in obstetrics all the classical types of anesthesia.

Treatment of Laryngeal Diphtheria.—Ochsenius believes that tracheotomy and intubation could be rendered superfluous by sufficiently large and early administered doses of antitoxin. At least 10,000 units are advisable even in infants, and reinjection is indicated six hours later if the improvement is not distinct.

The Blood Pressure During Local Anesthesia.—Andrejew ascribes to the emotional condition the drop in blood pressure often observed just before an operation, but the lowering of the blood pressure during the operation is due to the operative trauma and the length of the operation. The more sensitive the tissues or the organs, the lower the pressure will drop. Even after the operation, the blood pressure may be low or drop, but this speedily returns to normal as a rule. His research on fifty women and thirty-four men during operations under local anesthesia demonstrated the value of supervising the blood pressure during the operation as it is possible by this means to detect the first sign of impending collapse or shock, and ward it off in time. He suggests the advisability of supplementing the local anesthesia with a few whiffs of ether at the moment of the greatest injury of the tissues when it is not absolutely certain that all the centripetal nerve tracts have been blocked.

Furuncle on the Face.—Morian asserts that the malignant furuncle with sepsis from the start is doomed, whatever treatment is applied. In the 103 cases of furuncles on the face in Payr's service, 1913-1924, 10.7 per cent. were of this fatal type. The others all healed under conservative measures, salve, protecting bandage and fluid food. The results were equally good in former years under incision, but no better, and the disfigurement is less.

*Desiccated Milk for Infants. J. Schoedel.—p. 58.
"Goat's Milk Anemia." Ockel.—p. 62. Reply. Opitz.—p. 68.

Surgical Treatment of Otitis.—Brühl discusses the treatment of acute otitis media in children. A paracentesis should be made without much hesitation. Antrotomy is frequently necessary (grave symptoms, protracted suppuration) but it should not be done unnecessarily. A radical operation should be performed in a child only for a vital indication.

Genuine Nephrosis and Idiopathic Edema. — Fanconi observed recovery from genuine nephrosis with extensive edema in a child after pneumococcus peritonitis. He suggests vaccine treatment. The child's blood contained less chlorids during the edematous stage than later.

Treatment of Typhoid with Caronia's Vaccine.—Tüdös reports good results with the use of this vaccine. It consists of typhoid cultures dissolved by serum from typhoid patients and sterilized by phenol.

Desiccated Milk for Infants.—Schoedel considers dried milk superior to condensed milk. Yet it should not be used for children for more than one to three months, and should not be older than 2 or 3 months. It may be preferable to unsafe fresh milk in summer and while traveling. Other food containing a sufficient quantity of vitamins should be added.

Local Anesthesia. F. Rost.—p. 1779.

Experimental Vaccination Against Tuberculosis.—Dold tested the immunity of guinea-pigs immunized according to Langer's method (heat-killed tubercle bacilli), and according to Seiffert's method (defatted bacilli). He found that these "immunized" animals were no more resistant to a tuberculous infection than normal guinea-pigs.

Phosphates in Insulin Hypoglycemia.—Abelin and Goldener found that the oral administration of phosphates prevented or greatly diminished the hypoglycemia caused by insulin injection into normal animals.

*Spasmodic Yelling in Parkinsonism. J. Schuster.—p. 1824.
Orbital Complications of Sinus Infections. A. Esch.—p. 1826.
Immunization Against Tumors. N. Waterman.—p. 1829.

Vibration of Diseased Heart.—Kaufmann draws attention to a vibration of the heart which may be felt with the lightly applied hand. It indicates a bad prognosis, especially in patients with angina pectoris. It may be transitory in exophthalmic goiter and in acute endocarditis.

The p_H of the Stomach Contents.—Kalk and Kugelmann had practically identical results with dimethylamido-azobenzol titration and the estimation of the hydrogen ions in the gastric contents. Both methods should be used only when a test meal containing much proteins has been given, or when there is much blood, mucus or lactic acid present.

Serum Sickness and Tetany.—Hopmann observed a case of tetany and another case of a spasmophilic tendency in the incubation period of serum sickness. The alkalosis changed into acidosis during the eruption of the urticarial rash.

The Predisposition and the Incubation Period.—Abels reviews the facts which speak for a regular prolongation of the incubation period whenever the relation between the virus and the organism is shifted in favor of the organism. This applies especially to measles.

Extraction of Cataract.—Braunstein removes the senile cataract without iridectomy after dilating the pupil by an injection of epinephrin under the conjunctiva.

Antagonism of Insulin and Epinephrin. — Boden and Wankell noted an apparent antagonism of the action of insulin and epinephrin on isolated intestine. Both preparations seem to have a constricting action on the Laeven-Trendelenburg frog preparation.

Incubation Period in Passive Anaphylaxis.—Friedberger and Seidenberg obtained an immediate passive sensitization of guinea-pigs by an injection of the serum of sensitized animals of the same species. The incubation period after passive sensitization with serum from rabbits is due merely to the nonspecific inhibiting action of the foreign serum.

Spasmodic Yelling in Parkinsonism.—Schuster's patient suffered from daily attacks of spasmodic yelling due to previous encephalitis. The attacks stopped after lumbar puncture and filling of the ventricles of the brain with air.

Cancer and Its Treatment. O. Strauss.—p. 1432. C'td.
The Rockefeller Institute and Its Research on Filtrable Viruses. W. Levinthal.—p. 1441.

Iodin Treatment of Hyperthyroidism.—Biedl and Redisch confirm good results of administration of iodin only in the typical cases of exophthalmic goiter. Hyperthyroid symptoms occurring in patients with a goiter of long standing did not improve.

Pyloric Ulcers.—Bársony points out that the majority of alleged pyloric ulcers are situated in the duodenum. Consequently the mechanical lesions due to the pressure of the gastric contents at this narrowest point of passage cannot have much pathogenetic influence in the origin of ulcers.

Tuberculous Infants and Congenital Syphilis.—Epstein observed among 11,600 infants nine cases of tuberculosis complicating congenital syphilis. He had the impression that the tuberculosis infection was rather milder in these infants.

Early Diagnosis and Treatment of Congenital Dislocation of the Hip Joint.—Hilgenreiner requires an early diagnosis and treatment. He has designed a splint which is applied only to the extensor surface of the thighs, and keeps clean, therefore, even in infants. It is light, and allows free access to the region of the joint.

The Future of Pediatricians. E. Liefmann.—p. 1608.
Treatment in Tuberculosis Sanatorium. J. Ritter.—p. 1609.

Rickets and Irradiation of Cholesterol.—Beumer irradiated cholesterol or its alcoholic solution with ultraviolet rays. He determined with the digitonin method the loss of cholesterol. It averaged 8.1 per cent. after two hours of irradiation and 9.5 per cent. after twenty hours.

Cure or Seeming Cure of Choked Disk.—Heine admits recovery only in two of his seventeen patients with choked disk in whom the symptom disappeared without decompressive trephining. The longer the time of observation after the alleged recovery, the less favorable are the statistics.

Fat Embolism in Eye.—Bernhard describes the ophthalmoscopic changes in a case of fat embolism. He claims that his is the first case observed intra vitam.

Culture of Tubercle Bacilli from the Sputum.—Pesch and Simchowitz had excellent results with the Löwenstein-Sumiyoshi method of cultivation of tubercle bacilli from the sputum. The culture was positive in three of nineteen cases with negative microscopic findings.

Nursing in Austria. H. Sternberg.—p. 1068.
Therapeutic Use of Hebra's Water Bed. L. Arzt. Supplement.—pp. 1-16.

Surface Tension of Body Fluids.—Adlersberg determined with his associates the surface tension of single fractions of urine and found the curves instructive. There are large variations in health, usually in the opposite sense to the specific gravity. Disease of the liver causes a low level of the surface tension and less variations (isostalaguria). Exophthalmic goiter is also associated with a low surface tension of the urine. Cachectic cancer and tuberculosis patients had a low surface tension of the serum—similar to that encountered in diseases of the liver. Blood diseases showed high figures—perhaps due to the low cholesterol content of the blood. Extremely acid stomach contents showed a high surface tension. Admixture of bile lowered it considerably.

Pathogenesis of Melena of the New-Born.—Högler reports on fifty-nine cases of melena among 31,500 childbirths. Erosions or ulcers of the gastro-intestinal tract were found in the five infants who died from it. He confirms Raisz' observation on occult bleeding in about one half of otherwise normal new-born infants. The cause of the melena may be the change in the circulation of the fetus, and perhaps the toxic products accumulating in a prolonged labor: delivery had been difficult in fourteen of his cases. Gelatin, injections of horse serum or of the mother's serum, and especially roentgen-ray irradiation of the spleen are recommended.

Administration of Testis Extracts.—Zoth believes that the only rational way of testing the efficiency of any method endeavoring to prevent senility is to start using it before old age sets in. Every summer for the last thirty years (since he was 30) he has been taking a series of injections of a testis extract prepared by Brown-Séquard's technic. The intervals between the courses should be at least nine months, he says, if one wants to avoid disturbances of the heart. He is inclined to attribute his muscular efficiency and easy recovery from various infections to this treatment. He is unable to assert any striking result in the sexual sphere. He recommends the same prolonged experiment to others in order to find out if his impression of a delayed senility is correct.

Alkali Treatment of Gastric and Duodenal Ulcers.—Porges had devised independently of Sippy a similar method. He uses, however, only calcium carbonate and magnesium oxid. He objects to sodium bicarbonate because it may produce a transitory alkaline reaction in the stomach, as well as too high an osmotic pressure if taken with too little water. The calcium and magnesium are taken separately. The latter serves chiefly to prevent constipation. Therefore he advises to take it once or twice a day, and more often if there is constipation. Usually the patient is advised to take a heaped teaspoonful of one or the other powder every two hours, in grave cases every hour. He does not need to stay in bed or restrict his diet much except with hemorrhages. All other patients may work and avoid only strong spices, strong liquor, fresh bread and too cold drinks. Persistence of subjective disturbances in spite of the treatment speaks against uncomplicated ulcers.

Properitoneal Hernia. H. Heinlein.—p. 2172.
A Cylinder Saw. A. Nussbaum.—p. 2176.
*Emergency Disinfection. Haas.—p. 2178.

Hygiene of the Operating Room.—Kirschner thinks that the surgeon and his aides suffer from too long standing, too much glare in the operating rooms, and from the overheating. He suggests that the surgeon might sit for certain interventions or certain phases of his activity. The white uniforms add to the glare, and the absence of shadows is a distinct drawback which might be prevented by having the light on a portable stand that could be moved around the room. The overheating and inhalation of anesthetic fumes he combats with small electric fans arranged to play on the operating personnel and the air above the table and at the washstands.

Pain in the Psoas with Spondylitis.—Gregory has noted that tenderness of the psoas may be the first manifestation of spondylitis. This is particularly likely in adults. The stiff attitude and the pains in the back or leg may be mistaken for lumbago or sciatica but palpation of the psoas will correct the diagnosis. The pain on pressure of the psoas spreads down the leg on that side. The most tender point is where the psoas passes the brim of the pelvis. In one of two cases described, the spinous processes were not tender to explain the pains in the back and left leg. Pain on deep palpation and pressure to the left of the spinous process of the first lumbar vertebra and pain on deep gliding pressure of the left psoas confirmed the diagnosis of spondylitis. Eighteen months later a gravity abscess in the left thigh, with sequesters, was cleared out, and in six months the man was clinically cured. There had been no curvature at any time.

Emergency Disinfection Without Gas, Fire or Hot Water.—Haas used three pans of alcohol. In one he placed sheets and towels, in the second his instruments, and the third he used for his hands. By this means he saved three women in grave eclampsia, all recovering smoothly after the cesarean section or decapsulation of the kidneys in the remote farmhouse.

Toxic Psychopathic Conditions in Pregnancy. S. A. Selitzky.—p. 2070.
Thyroid Treatment of Temporary Edema in the New-Born. Waltner.—p. 2073.

Evidence for Pregnancies of Subnormal Duration.—Rissmann emphasizes the medicolegal importance of this subject, and the undependability of the guiding points hitherto listed. He says that a fully developed child born from a pregnancy of 229 or 230 days has not been authentically established to date, as the methods of measurement and calculation are faulty. He urges the German Gynecologic Society to take the initiative in correcting the present lack of authoritative criteria.

*Treatment of Tears of the Cervix. H. Baumm.—p. 2141.
*Early Diagnosis of Pregnancy. A. Timofeew.—p. 2143.

Blood Cholesterol and Jaundice in the New-Born.—Hornung found in the new-born, with Simmel's method, an increased osmotic resistance of the erythrocytes. This was especially pronounced in jaundice. He believes that this testifies against a hemolytic origin of the jaundice. The blood cholesterol was low in almost every new-born child, and remained low longer in the infants with jaundice than in the others.

Treatment of Tears of the Cervix.—Baumm did not find a single instance of a profusely bleeding laceration of the cervix among 7,551 cases of spontaneous delivery. A slight tear does not need to be sutured and large tears should be sutured only in the clinic, except when Henkel's compression of the parametria is used.

Early Diagnosis of Pregnancy.—Timofeew applied Dienst's method (estimation of antithrombin) with good results: Negative findings excluded pregnancy with 90 per cent. of probability.

Actinomycosis of Tongue. V. Hlaváček.—p. 1335.
Cause of Death of Composer Smetana. A. Heveroch.—p. 1338.

Chronic Nephritis with Tuberculosis of Suprarenals.—Ortynský describes a case of chronic nephritis associated with an extensive destruction of the suprarenals by tuberculosis, and with tuberculosis of the genito-urinary apparatus. The heart was not enlarged, the systolic pressure only 155 mm. mercury, and the pigmentation slight. He points to Bauer's theory on the change of retained nitrogenous products into epinephrin. He obtained a positive Meirowski reaction (pigmentation) with pieces of skin from patients with contracted kidneys. The reaction was negative in lipoid nephrosis.

4: 1-192 (Aug.) 1925. Partial Index

*Action of Alkaloids on Antibody Production. P. Butiagin.—p. 11.

Influence of Drugs on Formation of Agglutinins.—Butiagin, who made his experiments on rabbits with various alkaloids, says that he is not aware of any previous experiments in this line with eserin, cocain or pituitary extract. He used a typhoid bacillus culture for the antigen. Repeated injections of pilocarpin and antigen increased the formation of agglutinins by five or sixfold. Eserin, atropin and pituitary extract appeared to be without effect. Morphin inhibited the formation of agglutinins; as also repeated injections of epinephrin. With cocain, the amount of agglutinins was augmented twelve or fifteenfold.

Russkaia Klinika, Moscow

3: 483-672 (April) 1925. Partial Index

*Leukocytosis in Man and Dog. A. Voronoff and J. Riskin.—p. 483.
*The Leukocyte Picture in Various Diseases. N. Zolotareva.—p. 513.
Drug Treatment of Apepsia. V. Vinogradoff et al.—p. 526.
Palpation of Gastro-Intestinal Tract. J. Flekel.—p. 556.

*Carcinoid of the Appendix. V. Prebsting.—p. 606.
Improved Plastic Technic for Correction of Prolapse of Uterus. N. Markoff.—p. 620.

Digestive Leukocytosis as a Conditional Reflex.—Voronoff and Riskin's research was made on five healthy men and ten dogs during fasting and absolute rest. The number of leukocytes varied during the day, the changes being different in different persons. The number increased at the usual meal hour, thus showing a "habitual" leukocytosis. An exaggerated leukocytosis appeared in dogs under certain external stimuli associated with sham feeding. This leukocytosis was thus proved to be the result of a conditional reflex. The alleged digestive leukocytosis is evidently not a constant reaction from absorption of products of digestion and secretion, but is a conditional reflex reaction, in this same way.

The Leukocyte Picture in Different Affections.—Zolotareva made 610 examinations of blood from 406 patients, using Schilling's simplification of the Arneth classification, and records the findings.

Four Cases of Carcinoid of the Appendix.—Prebsting describes four cases in patients, aged from 17 to 34. On microscopic examination the tumors showed glandlike formations, confirming the embryonal origin of carcinoid, and the connection with the entodermal epithelium of Lieberkühn's glands.

Nederlandsch Maandschr. v. Geneesk., Amsterdam

13: 141-247, 1925

*The Bacteriophage in Children's Pyelitis. F. N. Sickenga.—p. 141.

The Bacteriophage in Children's Pyelitis.—Sickenga found a bacteriophage constantly in the urine in four of twenty-six cases of colon bacillus pyelitis in children from 5 weeks to 3½ years old. The bacteriophage was found occasionally in twelve others, but not at all in ten others. The course of the pyelitis did not seem to be modified by the presence or absence of the bacteriophage, and none was ever found in urine or feces that was strong enough for complete lysis of the corresponding bacillus in bouillon culture. An autogenous vaccine had little if any influence on the bacteriophage findings, but the presence of the bacteriophage seemed to detract from the action of the vaccine. Sodium citrate was the only drug that seemed to modify the course of the disease, and this only in the acute phase. The article is a complete study of the subject, with illustrations.

Folklore Treatment of Enuresis. C. Bakker.—p. 1123.
Hippocrates' Visit to Democritus. J. B. van Gils.—p. 1132.

Bacteriophage in Blood.—Wolff's research has demonstrated that addition of blood or serum to bacteriophage cultures does not impede the bacteriophage action.

Monosymptomatic Intense Pains in the Legs.—In two of Wortman's three cases, the pains in the legs were finally traced to a tumor in the pituitary or spinal cord. The pains in the third case suggested acute polyarticular rheumatism except the onset with chills, the involvement of three large joints with the connected muscles, the continuous fever, and the lack of benefit from the salicylates. The assumption, by exclusion, of the gonococcal nature of the acute infection was confirmed by discovery that the husband had recently been operated on for urethral stenosis. The operation may have roused latent gonococci to virulence. Anything in the line of an acute articular affection in women should suggest the gonococcus unless definitely explained otherwise.

Finska Läkaresällskapets Handlingar, Helsingfors

67: 691-761 (Aug.) 1925

*Cytology of Pyuria. F. Stenius.—p. 691.
Operative Invagination Cases. G. Snellman.—p. 711.
Movement of Endolymph in Semicircular Canals. F. Leiri.—p. 729.
Tuberculosis in the Curriculum. A. v. Bonsdorff.—p. 734.

Differential Diagnosis of Pyuria.—Stenius confirmed on fifty patients the dependability of Colombino's sign of tuberculosis, namely, the characteristic irregular outlines of the leukocytes in the sediment. Nearly all the leukocytes were thus deformed in all the twenty-two pure tuberculous cases, while they were smoothly round in twenty-two streptococcus, staphylococcus or colon bacillus cases. The cytology of the urine thus throws light on the etiology.

Hospitalstidende, Copenhagen

68: 721-744 (Aug. 6) 1925

*Microtest for Protein in Serum. S. Holm and H. Tómasson.—p. 721.
*Pathogenesis of Myopia. E. Holm.—p. 729.

Microtest for Protein in Serum.—Holm and Tómasson dilute 0.1 c.c. of serum with Ringer's solution, and pipet nitric acid to the bottom of the glass. A white precipitate at the line of junction always paralleled positive findings with other tests. By varying the dilution, it is possible to estimate the protein content quantitatively. In twenty-three normal persons the average range was from 5.55 to 8.77 per cent.

Etiology of Myopia.—Holm ascribes to the effort for accommodation in near reading, during the period of active growth, the development of myopia in persons congenitally predisposed as a recessive hereditary condition. Myopia is common among printers, he has noticed, while it is rare in watchmakers. Printers have to do a great deal of reading while watchmakers use a magnifying glass for their work. They thus are saved the strain of accommodation, although their work requires much bending over, while printers' copy is placed high before them.

*Total Heart Block with Full Earning Capacity. E. Zander.—p. 657.
*Myeloma with Uremia. B. Frykberg.—p. 667. Begun, p. 618.

Unimpaired Earning Capacity with Total Heart Block.—Zander examined this patient first, as a boy, aged 7. His bradycardia had attracted attention and the heart block was total. At 20, the young man had passed through several infectious diseases, but the general condition had kept constantly good, and Zander does not regard the prognosis as grave. There is no progressive tendency, and the heart seems able to cope with any strain. This was tested with graduated exertion.

Case of Myeloma with Uremia.—Frykberg's patient was a man, aged 69, who twenty-two years before had been successfully treated for chronic nephritis. With regulation of the diet the urine was kept free from sugar and albumin until 1924, when symptoms of nephrosis with uremia developed accompanying symptoms explained by a myeloma in the first lumbar vertebra. Bence-Jones albumin was present in the urine, with anemia of a special type: 1,600,000 erythrocyte and hemoglobin 32 per cent.; 48 per cent. neutrophil leukocytes; 37 per cent. small lymphocytes, and from 4 to 6 per cent myelocytes—the total leukocyte figure being 4,500 to 8,600. Th kidneys showed proliferation of connective tissue and hyalin glomeruli. The multiple myeloma had invaded ribs, kidney and liver as well as the spine. The case seems to confirr the formation of Bence-Jones albumin in the kidneys, anc that the process is of the nephrosis type. The kidneys reac in a specific manner to the specific toxin.

*Human Thoracopagic Monsters. F. Ysander.—p. 319.
*The Endocrine System in the Human Fetus. J. A. Hammar.—p. 375.

Thoracopagic Monsters.—Ysander's study of human diploterata is devoted to the thoracopagic type and is profusely illustrated, with eleven double plates. The youngest of the seven specimens examined measured only 14 mm.; most of the cases published to date have been full term deliveries. The article is in English. The importance of teratology for the study of embryology in general is emphasized.

The Endocrine System from Embryologic Standpoint.—Hammar discusses the question as to when the first signs of endocrine activity become apparent in the fetus. The article is in French, with twenty photomicrographs.

CHRONIC HUMAN AMEBIASIS

A REVIEW OF THE DIAGNOSIS AND TREATMENT ON THE BASIS OF ENCYSTMENT IN THE LIVER AREA

LUTHER M. BOYERS, M.D.
CHARLES A. KOFOID, PH.D., Sc.D.
AND
OLIVE SWEZY, PH.D.
BERKELEY, CALIF.

It is a common statement in or inference from the literature of amebiasis that encystment of *Endameba dysenteriae* occurs only in the colon. It is also generally supposed that the cysts of *E. dysenteriae* are not vulnerable to emetin hydrochlorid. During six years' experience in the diagnosis and treatment of human amebiasis, and especially in the last three and a half years in observing and treating those persons with amebiasis who have at the same time chronic hypertrophic arthritis, clinical features have appeared that do not seem susceptible of satisfactory explanation, if one is restricted to the concept that encystment of the amebas is confined to the colon alone. In chronic amebiasis, one is often struck by the appearance of partial improvement under specific therapy, followed by a neutral period, and then often by retrogression. Retrogression is quite often associated with the advent of colds, influenza, chilling, etc.

On attempting to visualize the disease process, the following questions arise: Does partial improvement or incomplete recovery mean that the patient's illness has other factors in its causation, in addition to the amebiasis, or does it mean that something occurs in the life cycle of the ameba which can explain the clinical behavior? The first question can be answered in the negative in numerous instances, by careful examination of the patient and elimination of possible factors other than amebiasis. The second question may possibly be answered in time with certainty in the affirmative. It is interesting that these retrogressions partake of the characteristics of the original syndrome and often appear out of proportion to the severity of the intercurrent infection. One is then led to the conception of depression of the host's resistance by the intercurrent cold or other factor, and a prompt lighting up of the original amebic infection, which may have been encysted, and which has not been actually eradicated. That is, on analysis, one is led to conclude on clinical evidence that arrested improvement during the course of specific therapy and the initiation of a retrogression that is typical of the original syndrome quite possibly mean that specific treatment was successful in eradicating only the motile phase, but not the hardy phase of the infection; i. e., that in which encystment may have occurred.

In this connection one recalls that cysts of *E. dysenteriae* are invulnerable to emetin hydrochlorid. Are they possibly also resistant in the presence of emetin bismuth iodid? Whatever is the ultimate answer to this question, one can arrive, by clinical reasoning, at a concept of encystment occurring in the host, outside of the feces in the colon. This encystment may be conceived as coinciding in time with, or perhaps persisting throughout, the neutral period so often seen in the course of treatment of human amebiasis by specific therapy, with emetin in some form or other. The lull of arrested development in the patient continues until circumstances adverse to the ameba are removed, and until circumstances adverse to the host arise. That is, the neutral period occurs when the patient's intolerance to specific therapy has been reached, and one must desist out of regard for safety to merge into actual retrogression on the advent of depressing factors, such as colds, influenza, worry, fatigue, chilling and constipation.

In analyzing cases of human amebiasis, it is remarkable how often a mild colitis is found as a characteristic sign. In a list of several hundred cases extending over a period of several years, only one case has been found in which there was no colitis demonstrable by sigmoidoscopy. In this instance there may have been a mild typhlitis. Bearing in mind this mild colitis, and observing that a high percentage of cases also showed apparent enlargement of the right lobe of the liver with a sensitive liver edge, the medical author was forced to the concept of early mild hepatitis occuring in the majority of cases. This view, of course, has had added support in the protozoological findings of *Endameba dysenteriae* in the invaded capillaries of the colon.[1]

As shown in Figures 1 and 2, from a section of the colon adjacent to an amebic ulcer in a fatal case of human amebiasis, one finds, outside of the muscularis in the capillaries and small blood vessels of the serosa, abundant evidence that the amebas have entered the blood stream and are thus in a position to find their way in the hepatic portal stream to the liver. The hematogenic mode of distribution of amebas from colonic infections is thus provided for by this invasion of the blood stream into other organs of the body, such as bone, lymph glands and skin.

M., and Swezy, Olive: Systemic Infections by Endameba Dysenteriae, Proceedings of the International Conference on Health Problems in Tropical America, held at Kingston, Jamaica, B. W. I., July 22 to Aug. 1, 1924, by invitation of the Medical Department, United Fruit Company (Boston, United Fruit Company), pp. 381-399.

PREVIOUS CONCEPTS

To recapitulate, the sequence of concepts has been as follows:

The cysts of *E. dysenteriae* are not vulnerable to emetin hydrochlorid. Although this statement may not be absolutely true, the relative resistance of these cysts is so high that no case of amebiasis can be completely eradicated by the use of emetin hydrochlorid alone. This is indicated in the experimental results of the British Medical Research Council.

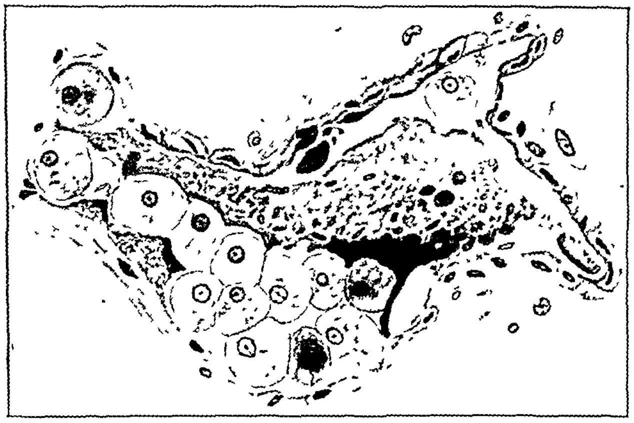

Fig 1.—Cross section of small vein in the wall of the colon immediately outside the muscularis near the margin of an amebic ulcer, showing fifteen amebas in a single section; × 460; after Kofoid (Amoeba and Man, University of California Chronicle, April and July, 1923, Plate 4, Figure 42).

In the treatment of chronic amebiasis, one does get improvement by specific therapy, but in many cases, especially in those of chronic hypertrophic arthritis and in those with apparent involvement of the liver area, this improvement does not lead to complete recovery. The case is oftener arrested, the patient entering a neutral phase in which there is neither progression nor retrogression. In watching numbers of these cases, one is constantly tantalized by this more or less neutral period, and is led irresistibly to the concept that it coincides with the existence of encysted stages of the parasite, with only slight returns to activity. Since the medical author has come to treat amebiasis entirely on the basis of the patient's tolerance for specific therapy, and since the neutral periods may have occurred after quite intensive treatment—the actual reaching of the limit of the patient's tolerance—one is again led to the concept of encystment of the parasite occurring after a period of treatment and bringing to a halt the process of eradication. Whether or not this is a protective reaction on the part of the parasite is not known. As one observes these neutral periods, little of moment is seen in the course of the disease until the patient is subjected to some assault, such as chilling, fatigue, worry, colds or influenza. Then one usually sees an end to the neutral period and the beginning of actual retrogression. Apparently excystment is under way, and the original syndrome appears with the lighting up of the disease process. The same rise and fall can be followed in the colitis and the hepatitis, each tissue apparently telling the same story of partial eradication, encystment, excystment, and renewed activity of the infection.

This train of thought was followed for several years before added observation brought to light cases presenting not only mild chronic appendicitis and typhlitis, but, as often observed at celiotomy, perityphlitis, pericolitis and pericholecystitis, occurring concurrently with clinical amebiasis with proved laboratory confirmation of the diagnosis.

These observations were made during the use of surgery, combined with the clinical concept of general mild hepatitis, and the reasoning of encystment and specific therapy heretofore outlined led the medical author to take two steps. First, some ten or twelve months ago a statement was made to the protozoologists that encystment must occur outside the colon, if one is to account rationally for the clinical behavior of cases. Secondly, some six months ago routine duodenal drainage was instituted, to secure a check on the liver area, and examinations paralleling fecal examinations were made; both of these procedures took place under the stimulation of bile salts and salines by mouth.

PRESENT CONCEPT

Before proceeding further with our revision, it may be helpful to indicate our present concept of clinical amebiasis. It has been possible for the last two years to say that there is a definite disease entity that can be recognized by clinical means as chronic amebiasis. According to our own records, this is so definite that fully 95 per cent. of cases can be diagnosed clinically, before laboratory confirmation is obtained.

The process of arriving at a clinical diagnosis of amebiasis involves a complete history, taken with more than usual care, because of the great need of particular attention being paid to vague symptoms and their sequence. It is hardly possible to be too careful in eliciting this history. All the minor and major illnesses of the individual, as well as his physical and mental peculiarities, are recorded against a background of heredity and environment. The question of environment is elaborated to make a record of the individual's residence during life, as to state or country. Certain well known areas containing endemic foci contribute largely to the chance of infection with protozoan parasites. The fruitful way of dealing with these cases is to attack them with a desire to find every factor and every disease process involved in the case whether or

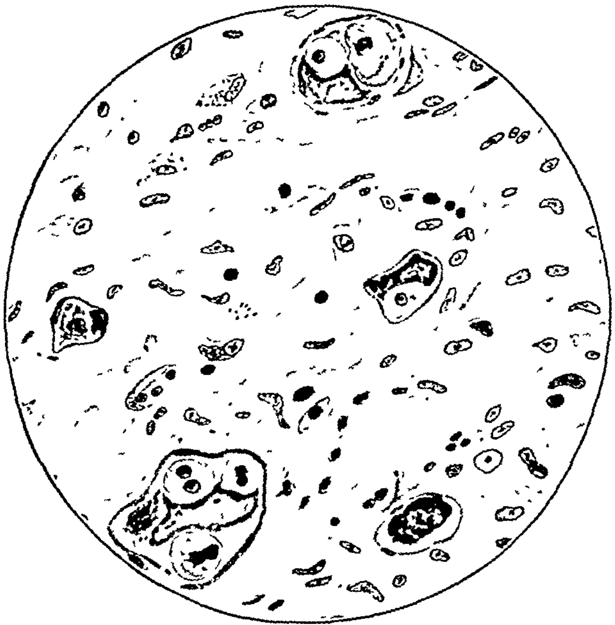

Fig 2.—From the same section as in Figure 1, showing amebas in several small vessels; × 380.

not it interacts with the amebiasis. Amebic infection is of long duration in the host, and the way to arrive at a just estimate of its prevalence and its importance to human welfare is to seek to define accurately the limits of its invasion, both in human tissue and in the social body.

Nearly all individuals of the white race seem to be susceptible to chronic amebiasis. The two sexes seem equally vulnerable, although certain tissues are possibly more easily invaded in one sex than in the other. In the Caucasian race no sufficient observation has been made to indicate increased susceptibility of blond over brunette, or vice versa. There is a well defined feeling, however, that some of the dark peoples, such as the negro, the East Indian, the Chinese, the Japanese and the Filipino, show more tolerance of *E. dysenteriae* in the bowel than does the white man. However, this is merely an impression.[2]

In this connection, one is reminded of the question of carriers. Over a period of years, constant search has been made for a true carrier, but as yet only one individual has been found by the medical author in more than 500 cases who showed no visible tissue damage attributable to *E. dysenteriae*. The behavior of cases in the temperate zone suggests that *E. dysenteriae* meets with a number of adverse conditions that help to create a subtle picture of chronicity. Whether this tendency to chronicity in large numbers of persons in the temperature zone means an actual relative immunity is not known. One is only able to say that, to date, but one individual has been found with no visible tissue damage, and he may have had considerable damage in areas not open to the eye. This particular individual, it may be worth noting, died later of arteriosclerosis.

SYMPTOMS

In symptomatology, one of the salient facts is that persons with amebiasis commonly complain of fatigability. They go to bed tired, and arise in the morning tired; they are tired whether they work or rest; many of them are so tired that they are in actual anguish; others merely say they have lost their "pep." Very commonly associated with fatigability is constipation, or constipation interspersed with evanescent diarrheas. Occasionally one will elicit the passing of considerable quantities of mucus or blood. A normal man knows hunger and the desire for evacuation; otherwise his bowel does not obtrude on his consciousness. In amebiasis the patient often has no actual pain. On the other hand, he is not comfortable in the abdominal region. He is, as we say, "bowel conscious." He may have considerable flatulence. He may or may not complain of definite soreness in the right lower quadrant, in the right upper quadrant, or in the region of the splenic flexure. He may complain of neuritic symptoms, pain along the course of some particular nerve or nerves. He may complain of basal headache, or of pain and aching in the region of joints. He may have considerable digestive disturbance, referable to the upper abdomen, that leads to the clinical suspicion of hyperacidity, hypo-acidity, gastric and duodenal ulcers, chronic pancreatitis, chronic cholecystitis, chronic duodenitis or chronic hepatitis. He may complain of cough and expectoration, with bloody sputum. He may complain of rapid pulse, and one may see mild tachycardias. He may complain of much nervousness, and one may find in him symptoms of a subacute or chronic thyroiditis. He may complain of defective vision, and one may find greatly impaired vision with or without definite iritis. Some may complain of disabling loss of memory, while others show various neuroses. One may find also the grosser lesions of liver abscess, lung abscess, brain abscess, skin ulcers, etc. The matter can be summed up by saying that in chronic amebiasis we are dealing with a disease entity as protean as syphilis.

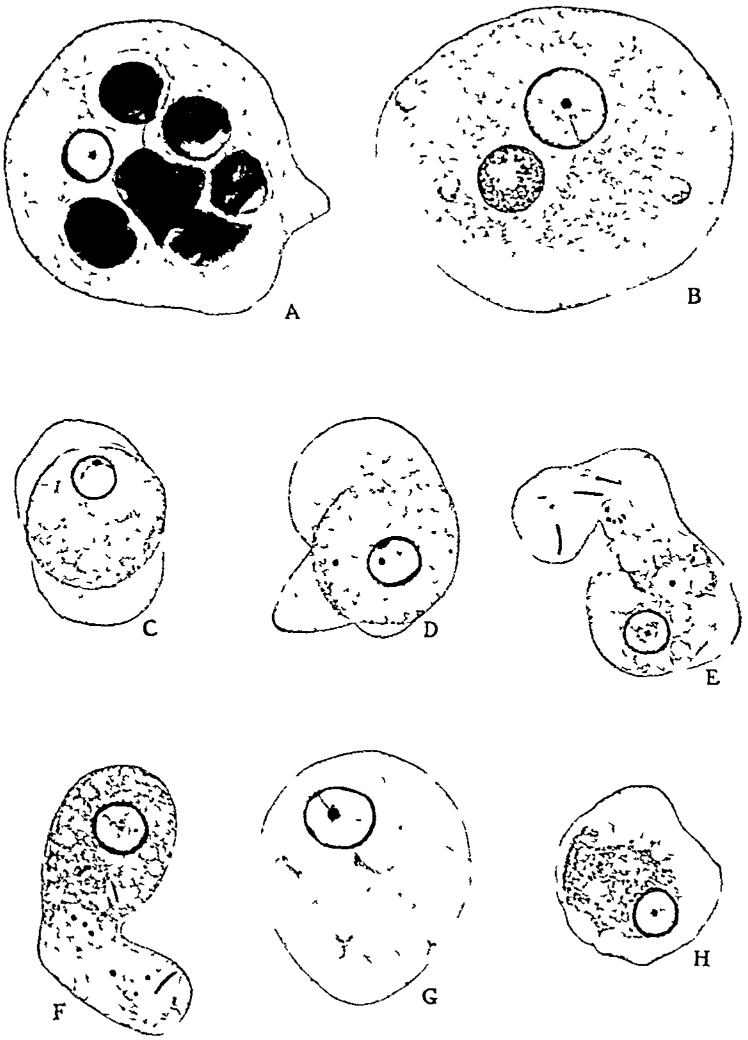

Fig 3—Motile Endamebae dysenteriae from the detritus of duodenal drainage: *A, B, E* and *F* are from Flask 2, and *C, D, G* and *H* from Flask 4 *A* contains partially digested leukocytes, and *B* a red blood corpuscle Structures resembling bacteria appear in *E* and *F*, slightly reduced from a drawing with a magnification of 2,500 diameters

In discussing with the patient his past history, it is important to note such quoted diagnoses as nervous breakdown, neurasthenia, incipient tuberculosis, tuberculosis without the actual finding of tubercle bacilli, constipation, diarrhea, the passing of mucus, the passing of blood, hemorrhoids without the actual demonstration of hemorrhoids, neuritis or chronic rheumatism.

---

[2] Since the foregoing was written, the authors, through the courtesy of the United Fruit Company, have had the opportunity to observe the incidence and severity of amebiasis in both acute and chronic phases among negroes and varying race mixtures among the coastal peoples at Santa Marta, Colombia and also at Panama We are less impressed than we formerly were as to the existence of a difference in tolerance to human amebiasis between the Caucasian and the darker races, at least so far as this pertains to these negroid and Indian admixtures

Human amebiasis is a definite disease entity, protean in character as is syphilis, undramatic in behavior, subtle in its onset, and definitely nonbacterial in type. We have been highly trained in thinking from the bacterial point of view since the days of Pasteur, and, on the whole, poorly trained in thinking from the point of view of protozoan infection. One commonly associates with the bacterial point of view such findings as fever, redness, swelling, acute pain, and more or less characteristic blood and urinary pictures. From the protozoan point of view, the very absence of these old guides may be highly significant. It is suggestive to recall that the bacteria are minute plant forms, and are often intolerantly regarded by human tissue cells. Protozoa are minute animal forms, and are often tolerantly regarded by human tissues for considerable periods of time. From this point of view one comes to realize that when bacterial infection is not demonstrable, one is not necessarily justified in a diagnosis of functional disturbance, or of normality, but very often may be dealing with a chronic amebic infection.

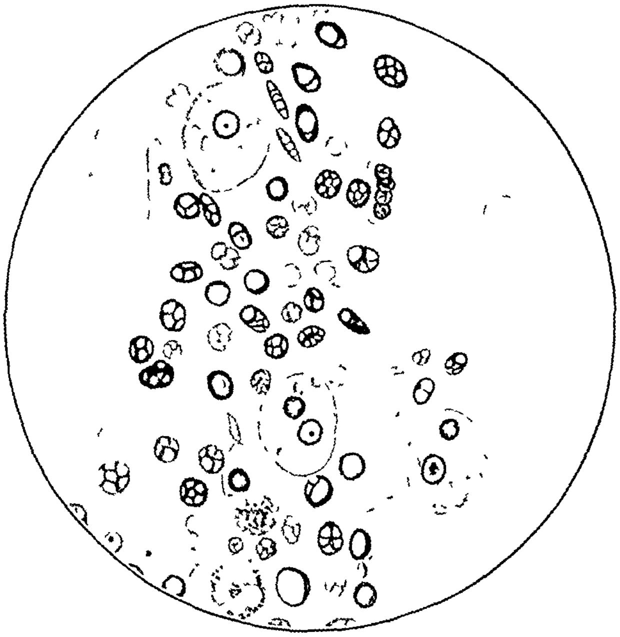

Fig 4—A shred of mucus from duodenal drainage with contents and three recognizable amebas in situ in the mucus and remnants (?) of two others; reduced from a drawing with a magnification of 730 diameters

It is worth a strenuous effort to try to eliminate other possible factors before arriving at a clinical diagnosis of amebiasis. The dearth of the usual findings to account for the patient's symptoms should make one suspicious of an amebic infection, especially if the symptoms are vague in character. One should not be content with the ready estimate that there is nothing really wrong physically, or that the disturbance is "functional." Such relatively insignificant findings as sensitiveness in the region of the cecum, a slightly enlarged right lobe of the liver with sensitive liver edge, sensitive splenic flexure, vague nerve and joint pains, and a general air of depression, may in the end be accounted for by the demonstration of chronic intestinal infection. The physician needs to become very sensitive to the picture of toxemia, no matter through what tissue or organ it presents itself.

Sigmoidoscopy in chronic amebiasis is necessary. Patients commonly believe that bleeding from the anus is due to hemorrhoids; this cannot be demonstrated on examination, the bleeding having been due to a mild colitis. One of the most valuable findings by sigmoidoscopy is this chronic colitis, which often is mild in grade and is characterized by the appearance in the mucosa of dilated vessels, pinpoint hemorrhagic areas, larger hemorrhagic areas, often granular mucosa, and occasionally free blood and abnormal amounts of mucus. It is surprising how often this mild colitis is interpreted as of no consequence, or overlooked entirely. In reality, it may be of the first significance, especially when considered in relation to symptomatology, past history, physical findings and the occurrence of cysts of *E. dysenteriae* detected by stool examination.

When identification of *Endameba dysenteriae* by cytologic criteria of the encysted stage was substituted for the older method of identification by the motile phase, a much more reliable method came into being. Further improvement in diagnostic methods ensued, when serial examinations of the feces were substituted for haphazard examination. Salines have proved useful in bringing to light amebic cysts or motile forms that might otherwise escape detection, but, with the routine use of bile salts as a cholagogue, an even better method has been substituted as a matter of routine. In fact, the use of bile salts has proved so effective in making demonstrable obscure infections with amebas that it has aroused suspicion that large numbers of amebas may be found commonly in the liver area, in chronic amebiasis, and this suspicion has led to our observations on the size of the liver, the sensitiveness of the liver edge and the frequency of accompanying gallbladder symptoms. Certainly in the light of our present knowledge, no fecal examination or duodenal examination is complete without the use of bile salts, with or without a saline.

POSSIBILITY OF CURE

For many years, tried and competent workers in the therapy of parasitic infections have been divided between two points of view, one group considering amebiasis insusceptible of cure; the other group considering it amenable to modern methods of treatment. This division in point of view is a challenge, and arouses curiosity as to why one often sees incomplete eradication of amebiasis.

Considerable light seems to have been thrown on this problem of incomplete eradication by our results on duodenal drainage. Amebas, both motile and encysted, have been found by us in the liver area. By analogy the question is raised as to whether or not they may also occur in other areas, such as about the joints and wherever either the intestinal stream or the circulatory stream tends to slow down.

In this connection it is well to bear in mind that encystment in protozoa generally is often regarded as a protective procedure providing for their resistance to desiccative or other adverse conditions. From this point of view, one would not predict encystment in the liver region, or elsewhere in the tissues. There is, however, another point of view; namely, that encystment is related to the metabolism of the protozoan. It often occurs among free-living protozoa in cultures in which food is abundant and no adverse conditions appear to be present. There is a possibility that encystment may follow a period of abundant feeding and thus have a metabolic aspect, or that it may be a resultant of the interaction of some factor in the life cycle of the protozoan. There is as yet no satisfactory evidence that sexual reproduction occurs in any ameba, certainly not in any ameba parasitic in man, or that encystment follows syngamy. In any event there is no sound biologic evidence that encystment is primarily a protective device or that it might not occur in the case of *Endameba dysenteriae* in loci in the human host other than the lumen of the colon.

Whenever they do occur, they may not be entirely eradicated, perhaps because the encysted stage is hardy and possibly invulnerable to our present medicaments, and perhaps because one cannot quickly enough reach all parasites with a dose of sufficient concentration to kill. As in the old problem of syphilis, one may be tempted to search for a drug that will permit of a sterilizing dose. Perhaps, as in syphilis, such a drug will not be found, and one must, perforce, utilize his whole armamentarium, both medically and surgically, realizing that no one medicament is adequate and that only by the greatest resourcefulness can the actual cure of amebiasis be achieved.

TREATMENT

In the present position of the diagnosis and treatment of chronic amebiasis, patients should be impressed with the fact that treatment partakes of the nature of a campaign and not of a "cure," that is, patients with chronic amebiasis can be definitely bettered in health because of treatment, but the word "cure" carries with it too many implied promises, and may well be barred from the language of those who deal with amebiasis, for the present at least. It is wiser to tell patients with chronic amebiasis that, no matter how mild the infection appears, observation and treatment, including periodic examination, may easily occupy even as much as two years before the question of cure can be considered. Actual cure may be achieved in less time, but it should not be pronounced by the physician, without long and careful checking of both feces and duodenal contents. In the more severe cases, such as those with accompanying chronic hypertrophic arthritis, a combination of treatment, observation and checking may easily extend over a period of from three to five years. It may be well to note here that many cases of chronic hypertrophic arthritis do not appear to have so simple a causation as amebiasis alone. In many of these cases the factors are complex, including not only amebiasis, but also bacterial infections, seriously impaired metabolism, etc.

Duodenal drainage is done in the following manner:

The patient appears at the hospital or convalescent home in the morning without breakfast. The ordinary duodenal tube of the Rehfuss type is passed, and the patient is placed on the couch on his right side. A group of four flasks is made ready. Into Flasks 2 and 4 is put approximately 50 c.c. of Bouin's solution. The end of the duodenal tube is put into Flask 1 and left there until fluid begins to siphon away. When the fluid in Flask 1 begins to show a tinge of bile, the tube is passed into Flask 2, and the bile-stained fluid is allowed to run into the Bouin's solution, which acts as a fixative for the cellular material. When this drainage has continued for the matter of an hour, 125 c.c. of a warm, nearly saturated solution of magnesium sulphate is passed through the tube with the aid of a glass syringe. As much as possible of the magnesium sulphate solution is thereafter withdrawn by suction. Then the end of the tube is passed into Flask 3 and allowed to drain until all the magnesium sulphate solution is passed and the dark cystic bile begins to flow. With the appearance of the dark cystic bile, the tube is inserted into Flask 4, and the material is again thrown into contact with the fixative. Frequently one will wish to use a fifth flask containing Bouin's solution, in which to collect the so-called hepatic bile. The collected material in the flask is then centrifugalized and sent to the laboratory, where it may be stained and studied directly in the sediment, or infiltrated with paraffin, sectioned, stained and then studied.

Since duodenal drainage has been instituted as a check, 120 drainages on a total of fifty patients have been done by us. The patients furnishing the drainages, with the two exceptions noted below, have had a clinical diagnosis of pathogenic amebiasis confirmed by laboratory diagnosis. As a rule, in this series, they have been selected for duodenal drainage because each one has shown some refractory feature, either during or after specific therapy. Eleven of these persons, that is, eleven of the fifty, show positive duodenal findings of *E. dysenteriae,* either motile or encysted, or both, either in Flask 2, Flask 4, or both, and amebas have been found in one case in the duodenal drainage with six negative stools examined serially.

An analysis of these cases shows symptoms grouped as follows: one case with eye and colon symptoms predominating; thirty cases with stomach, liver, gallbladder and colon symptoms predominating; fourteen cases with joint, nerve and colon symptoms predominating. The remaining six cases include a group in which infections of *Craigia hominis* and *Councilmania lafleuri* had been found, but no *Endameba dysenteriae* to date.

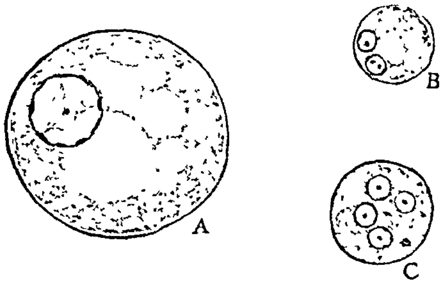

Fig. 5.—Cysts of Endameba dysenteriae from contents of Flask 4 in Case 50, with one, two and four nuclei, respectively; slightly reduced from a drawing with a magnification of 2,500 diameters.

TYPICAL CASES

It will be of interest to summarize very briefly our experience with typical cases out of this group.

Case 1, referred to the medical member by Dr. Milton Shutes of Oakland, presented a most interesting symptom complex. The chief complaint was due to a chronic iritis with cataract.[3] The colon showed a high degree of inflammation, the visible mucosa being almost beefy in color. No free blood was seen. Since treatment, no further attacks of iritis have occurred, and the mucosa is much improved, the color being nearly normal. Two duodenal checks after treatment yielded negative results.

Case 6 illustrated the picture of gallbladder involvement. This patient came in complaining of a "kink in the back" that had endured two weeks, much discomfort in the region of the stomach, and much flatulence. His symptoms were worse from two to three hours after eating, and he complained definitely of weakness. Roentgen-ray observation showed a pathologic gallbladder, probable cholelithiasis, a chronic pathologic appendix, with adhesions, signs of colitis, and possible diverticula of the ascending colon. Specific therapy caused the disappearance of symptoms within four weeks, though an attack of influenza kept the patient uncomfortable for another month. He is at work and has had no further symptoms referable to bowel, appendix or gallbladder to date.

---

[3] Mills, L.: Amebic Iritis Occurring in the Course of Non-Dysenteric Amebiasis, Arch. Ophth. **52**: 525-545 (Nov.) 1923.

Case 22 illustrates disturbance in the liver area, with epileptiform seizures. When this young matron came under observation, she was suffering from great irritability and from two to four attacks a week. These attacks were preceded by a definite aura, and a violent headache accompanied by vomiting, both preceding and succeeding the attacks. Following specific therapy, which was given in three different courses, she has been free from these attacks for six months. Duodenal drainage itself has kept her improving. It has been repeated on the slightest hint of headache or aura, at lengthening intervals, until now the schedule indicates drainage every ten days. Recently *E. dysenteriae* was found in Flask 4 in concentrated cystic bile.

Case 10 was that of a person with chronic hypertrophic arthritis. This patient, a physician, suffered much and had to accept limited activity because of pain and increasing weakness, associated with a "toxic feeling." Under specific therapy, the joints receded in size and became more supple. Pain was much decreased. The patient commented on feeling better than in several years, having lost a sense of depression. On checking with duodenal drainage, *E. dysenteriae* was found in Flask 4, and vigorous treatment was again instituted.

Case 34 was another chronic hypertrophic arthritis. This patient had been confined to bed and wheel chair for about three years She had much pain and disability, with atrophy of the joint structures. Roentgenray observation, however, showed thin disks of cartilage persisting in the joints. On specific treatment, she lost much of her pain, found her joints more supple, and has recently been able to stand and to take two steps, the first in more than three years. Duodenal drainage has recently shown *E. dysenteriae* in Flask 2.

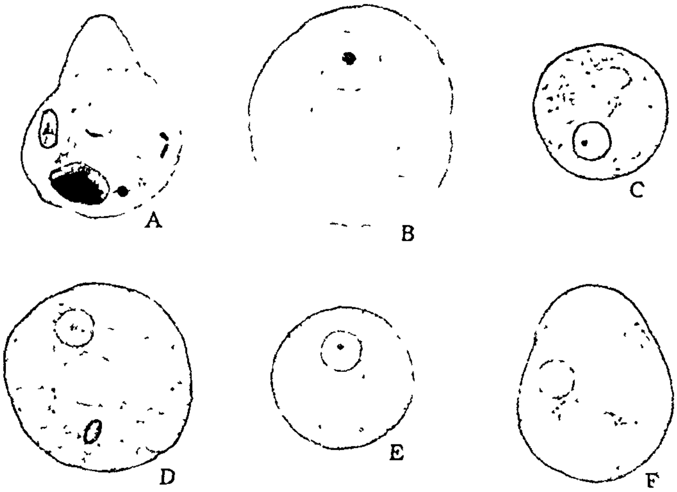

Fig. 6—Moribund Endameba dysenteriae from duodenal drainage with signs of disorganization, from four different patients *A*, *B* and *E* are from Flask 2, and *C*, *D* and *F* from Flask 4; slightly reduced from a drawing with a magnification of 2,500 diameters.

In the duodenal drainage the amebas are fixed by the Bouin's fluid immediately on their arrival in the flask. The condition in which they arrive in the flask is presumably preserved by the fixation, and will be indicative to an unknown degree of the condition in which they are found in the liver region. Three types are present in the detritus of the duodenal drainage, (1) motile amebas (Figs. 3 and 4), encysted amebas (Fig. 5), and moribund amebas (Fig. 6).

The motile amebas have been preserved with pseudopodia still extended (Fig. 3 *C*, *D*, *E*, *F*), with ingested leukocytes (Fig. 3 *A*) and erythrocytes (Fig. 3 *B*) in their cytoplasm, and with bacteria (Fig. 3 *E* and *F*) in vacuoles. These evidences are indicative of the presence of a normal motile feeding phase in the region from which the duodenal drainage is derived.

The cysts of *Endameba dysenteriae* were found in the duodenal drainage of Patient 50 two years after specific therapy, and four months after removal of the appendix and digital examination of an apparently normal gallbladder. The cysts occurred in Flask 4 only. They were few and appeared to be normal in cytologic detail. Two of them (Fig. 5 *A* and *B*) contained characteristic glycogen vacuoles. One (Fig. 5 *C*) had the characteristic terminal remnants of the chromatoid bodies. This is significantly a four nucleate cyst. Cysts in the one, two and four nucleated stages have been found, but those with one nucleus were most frequently seen. The three cysts shown in Figure 5 all came from Case 50 and exhibit a considerable range in diameter, being 14, 5 and 7 microns, respectively. This suggests the occurrence of both large and small amebas, a condition sometimes seen in amebas from active ulcers and in our cultures in vitro.

Moribund amebas from the duodenal drainages of three different patients (18, 28 and 50) are shown in Figure 6. They intergrade with the normal motile amebas. They exhibit varying degrees of loss of chromatin from the nucleus, disappearance of the spoke radii and karyosome, a tendency to vacuolation of the cytoplasm and a general lack of stainability. It is probable that Figure 3 *G* and *H* represents early stages in this process. The cause of this condition is unknown. Similar amebas are sometimes found in stools and in our cultures in vitro. It is possible that the bile with which they have been in contact may be deleterious to them.

According to the work of Kofoid and Wagener,[4] a 1 : 10 dilution of human or cat bile will cause lysis within from twenty to thirty minutes in *Endameba dysenteriae* from our cultures in vitro on the slide, treated with petrolatum, on the warm stage. This strength inhibits the growth of the ameba when added to the mediums used in vitro. Conditions in vitro are not those of the liver region. The remarkable powers of acclimatization exhibited by certain protozoa to toxic substances should be remembered in this connection. It is quite possible that amebas transported to the liver might become in time acclimatized to a much higher concentration of bile than are culture amebas derived from discharges of ulcers of the colon and suddenly exposed to bile.

The presence of the moribund amebas in the duodenal drainage may, in the light of our experiments, indicate a progressively destructive action of the bile on them. It may thus be that the gallbladder region in a case of amebic hepatitis is one into which the contents of amebic cytoplasm are released to a greater or less extent, whenever the amebas escape from the liver by way of the biliary system.

It is apparent, however, that not all of them are thus destroyed, for seemingly normal motile amebas escape in the duodenal drainage, and some of them have assumed the cystic condition before they reach the fixing fluid of the duodenal flask. Kofoid and Wagener[4] have been unable, however, to induce encystment in vitro in culture amebas by forty-eight hours' exposure to varying dilutions of bile.

The evidence for concluding that the amebas of the duodenal drainage are derived from the liver area is as follows: (1) the clinical signs in the hepatic area; (2) the coincidence of regression with amebas in the duodenal content, following treatment; (3) the inclusion of amebas (Fig. 4) together with typical gallbladder débris in mucous strands; (4) the increased facility in finding amebas in stools following the administration of bile salts, and (5) the absence of any evidence from clinical examination or necropsy, of infection of the jejunum or ileum, above its lowermost part, by *Endameba dysenteriae*. Amebic hepatitis may, therefore, be hematogenous in origin and attend many, perhaps all, cases of chronic amebiasis.

"SPECIFIC" THERAPY

The term specific therapy in our papers refers to the use in combination of emetin hydrochlorid and either emetin periodid or rarely bismuth emetin iodid plus either neo-arsphenamin or stovarsol. In addition, under this term are included also bismuth subnitrate and an organic iodin preparation (iodo-oxybenzenepyridin sulphonate). The use of these medicinal agents in our hands, with emphasis on such precautions as are observed regularly against both overdosage and insufficient medication, will be discussed in a subsequent paper.

Combinations of the above mentioned drugs are used because each has been tested singly and the results obtained are inferior to those resulting from their combined use.

A word of caution should be said regarding the necessity of keeping a very close supervision of the patient during specific therapy, in which period all symptoms are generally exacerbated, and even more especially, of being watchful during the post-treatment period. Persons with amebiasis are often subject to profound depression, mentally and physically, are prone to circulatory disturbances, such as palpitation and mild tachycardia, and often emerge from a bout with specific medication with definite secondary anemia. Commonly, patients have a troublesome colitis, which is often accompanied by hemorrhoids. It is obvious that all patients must be followed till normal.

Relation of Social Service to Other Social Agencies.—Social work in dispensaries is a form of treatment that may include a variety of activities. Its chief aim is to speed up the processes that make for the patient's recovery. The social worker may herself carry out the necessary steps in removing obstacles and in making adjustments or she may act as intermediary between the patient and the agency especially qualified to carry out this procedure. Because of the variety of tasks that fall to her lot, she needs to maintain a nice balance between the work that is peculiarly hers and that which should be delegated to other agencies.—*Hosp. Social Service* **12**:137 (Sept.) 1925.

GLANDULAR BLOCK DISSECTIONS FOR METASTATIC CANCER

REPORT OF ONE HUNDRED AND SIXTY CASES DONE EXCLUSIVELY WITH THE CAUTERY *

A. C. SCOTT, SR., M.D.
TEMPLE, TEXAS

It is my purpose, not to review the history of cancer or of the cautery, but first to point out that surgery or surgical technic has not reached its maximum efficiency in the treatment of cancer and later to show that the cautery as a therapeutic agent has undreamed of possibilities.

Until the cause of cancer is positively known, no one will be justified in believing that surgery will be of any real value beyond certain local and regional limitations.

According to Crile's[1] investigation of 4,500 necropsies on subjects who had had cancer of the head, face and neck, in which 99 per cent. had no metastasis below the base of the neck, one must conclude that the fatal results of those dying from cancer in this group were attributable to extension of the original growth by local infiltration of important tissues adjacent to it and to neck metastasis only, and one cannot escape the further conclusion that, in the cases in which operations were performed, the operation stopped short of completion, failing to include some of the growth, infiltrated tissues or metastasized glands, or that the wound was contaminated with live cancer cells during the operation.

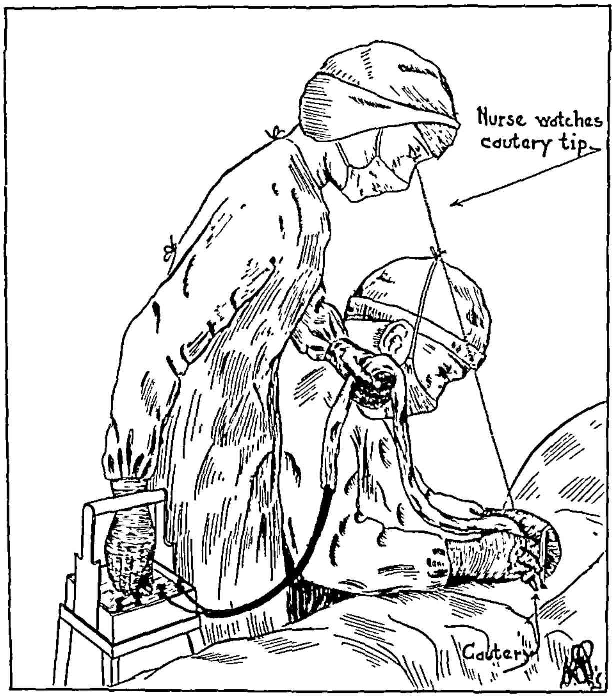

Fig. 1.—The nurse standing on a tall stool, watches the cautery tip in the hand of the operator, and controls the heat by means of the rheostat mounted on a stand.

In 1921, Sistrunk[2] reported a series of cases, with no metastasis at the time of operation, which showed 10.5 per cent. local recurrence of the disease. He also reported that in forty-six cases of local recurrences 80.4 per cent. showed involvement of the lymph glands at the time of operation.

When one considers that during the excision of cancerous masses and during glandular block dissections it is difficult to avoid cutting into infiltrated tissues near the growth or into infected lymph chains or glands before completion of the operation, thus contaminating the knife, scissors or gauze sponges with live cancer cells, and when one further considers the numerous open lymph chains and capillary blood vessels exposed attack of influenza kept the patient uncomfortable for another month. He is at work and has had no further symptoms referable to bowel, appendix or gallbladder to date.

Case 22 illustrates disturbance in the liver area, with epileptiform seizures. When this young matron came under observation, she was suffering from great irritability and from two to four attacks a week. These attacks were preceded by a definite aura, and a violent headache accompanied by vomiting, both preceding and succeeding the attacks. Following specific therapy, which was given in three different courses, she has been free from these attacks for six months. Duodenal drainage itself has kept her improving. It has been repeated on the slightest hint of headache or aura, at lengthening intervals, until now the schedule indicates drainage every ten days. Recently *E. dysenteriae* was found in Flask 4 in concentrated cystic bile.

Case 10 was that of a person with chronic hypertrophic arthritis. This patient, a physician, suffered much and had to accept limited activity because of pain and increasing weakness, associated with a "toxic feeling." Under specific therapy, the joints receded in size and became more supple. Pain was much decreased. The patient commented on feeling better *than in several years, having lost a sense of depression.* On checking with duodenal drainage, *E. dysenteriae* was found in Flask 4, and vigorous treatment was again instituted.

Case 34 was another chronic hypertrophic arthritis. This patient had been confined to bed and wheel chair for about three years. She had much pain and disability, with atrophy of the joint structures. Roentgen-ray observation, however, showed thin disks of cartilage persisting in the joints. On specific treatment, she lost much of her pain, found her joints more supple, and has recently been able to stand and to take two steps, the first in more than three years. Duodenal drainage has recently shown *E. dysenteriae* in Flask 2.

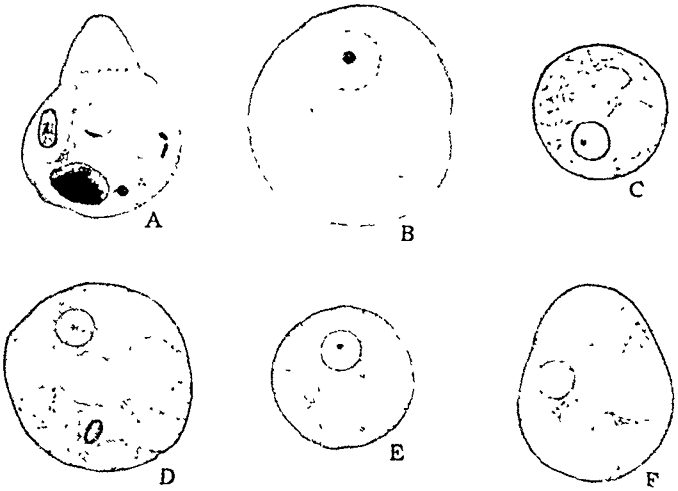

Fig. 6.—Moribund Endameba dysenteriae from duodenal drainage with signs of disorganization, from four different patients. *A, B* and *E* are from Flask 2, and *C, D* and *F* from Flask 4; slightly reduced from a drawing with a magnification of 2,500 diameters.

In the duodenal drainage the amebas are fixed by the Bouin's fluid immediately on their arrival in the flask. The condition in which they arrive in the flask is presumably preserved by the fixation, and will be indicative to an unknown degree of the condition in which they are found in the liver region. Three types are present in the detritus of the duodenal drainage, (1) motile amebas (Figs. 3 and 4), encysted amebas (Fig. 5), and moribund amebas (Fig. 6).

The motile amebas have been preserved with pseudopodia still extended (Fig. 3 *C, D, E, F*), with ingested leukocytes (Fig. 3 *A*) and erythrocytes (Fig. 3 *B*) in their cytoplasm, and with bacteria (Fig. 3 *E* and *F*) in vacuoles. These evidences are indicative of the presence of a normal motile feeding phase in the region from which the duodenal drainage is derived.

The cysts of *Endameba dysenteriae* were found in the duodenal drainage of Patient 50 two years after specific therapy, and four months after removal of the appendix and digital examination of an apparently normal gallbladder. The cysts occurred in Flask 4 only. They were few and appeared to be normal in cytologic detail. Two of them (Fig. 5 *A* and *B*) contained characteristic glycogen vacuoles. One (Fig. 5 *C*) had the characteristic terminal remnants of the chromatoid bodies. This is significantly a four nucleate cyst. Cysts in the one, two and four nucleated stages have been found, but those with one nucleus were most frequently seen. The three cysts shown in Figure 5 all came from Case 50 and exhibit a considerable range in diameter, being 14, 5 and 7 microns, respectively. This suggests the occurrence of both large and small amebas, a condition sometimes seen in amebas from active ulcers and in our cultures in vitro.

Moribund amebas from the duodenal drainages of three different patients (18, 28 and 50) are shown in Figure 6. They intergrade with the normal motile amebas. They exhibit varying degrees of loss of chromatin from the nucleus, disappearance of the spoke radii and karyosome, a tendency to vacuolation of the cytoplasm and a general lack of stainability. It is probable that Figure 3 *G* and *H* represents early stages in this process. The cause of this condition is unknown. Similar amebas are sometimes found in stools *and in our cultures in vitro. It is possible that the bile* with which they have been in contact may be deleterious to them.

According to the work of Kofoid and Wagener,[4] a 1 : 10 dilution of human or cat bile will cause lysis within from twenty to thirty minutes in *Endameba dysenteriae* from our cultures in vitro on the slide, treated with *petrolatum, on the warm* stage. This strength inhibits the growth of the ameba when added to the mediums used in vitro. Conditions in vitro are not those of the liver region. The remarkable powers of acclimatization exhibited by certain protozoa to toxic substances should be remembered in this connection. It is quite possible that amebas transported to the liver might become in time acclimatized to a much higher concentration of bile than are culture amebas derived from discharges of ulcers of the colon and suddenly exposed to bile.

The presence of the moribund amebas in the duodenal drainage may, in the light of our experiments, indicate a progressively destructive action of the bile on them. It may thus be that the gallbladder region in a case of amebic hepatitis is one into which the contents of amebic cytoplasm are released to a greater or less extent, whenever the amebas escape from the liver by way of the biliary system.

It is apparent, however, that not all of them are thus destroyed, for seemingly normal motile amebas escape in the duodenal drainage, and some of them have assumed the cystic condition before they reach the fixing fluid of the duodenal flask. Kofoid and Wagener[4] have been unable, however, to induce encystment in vitro in culture amebas by forty-eight hours' exposure to varying dilutions of bile.

The evidence for concluding that the amebas of the duodenal drainage are derived from the liver area is as follows: (1) the clinical signs in the hepatic area; (2) the coincidence of regression with amebas in the duodenal content, following treatment; (3) the inclusion of amebas (Fig. 4) together with typical gallbladder débris in mucous strands; (4) the increased facility in finding amebas in stools following the administration of bile salts, and (5) the absence of any evidence from clinical examination or necropsy, of infection of the jejunum or ileum, above its lowermost part, by *Endameba dysenteriae*. Amebic hepatitis may, therefore, be hematogenous in origin and attend many, perhaps all, cases of chronic amebiasis.

GLANDULAR BLOCK DISSECTIONS FOR METASTATIC CANCER

REPORT OF ONE HUNDRED AND SIXTY CASES DONE EXCLUSIVELY WITH THE CAUTERY *

A. C. SCOTT, Sr., M.D.
TEMPLE, TEXAS

It is my purpose, not to review the history of cancer or of the cautery, but first to point out that surgery or surgical technic has not reached its maximum efficiency in the treatment of cancer and later to show that the cautery as a therapeutic agent has undreamed of possibilities.

Until the cause of cancer is positively known, no one will be justified in believing that surgery will be of any real value beyond certain local and regional limitations.

According to Crile's[1] investigation of 4,500 necropsies on subjects who had had cancer of the head, face and neck, in which 99 per cent. had no metastasis below the base of the neck, one must conclude that the fatal results of those dying from cancer in this group were attributable to extension of the original growth by local infiltration of important tissues adjacent to it and to neck metastasis only, and one cannot escape the further conclusion that, in the cases in which operations were performed, the operation stopped short of completion, failing to include some of the growth, infiltrated tissues or metastasized glands, or that the wound was contaminated with live cancer cells during the operation.

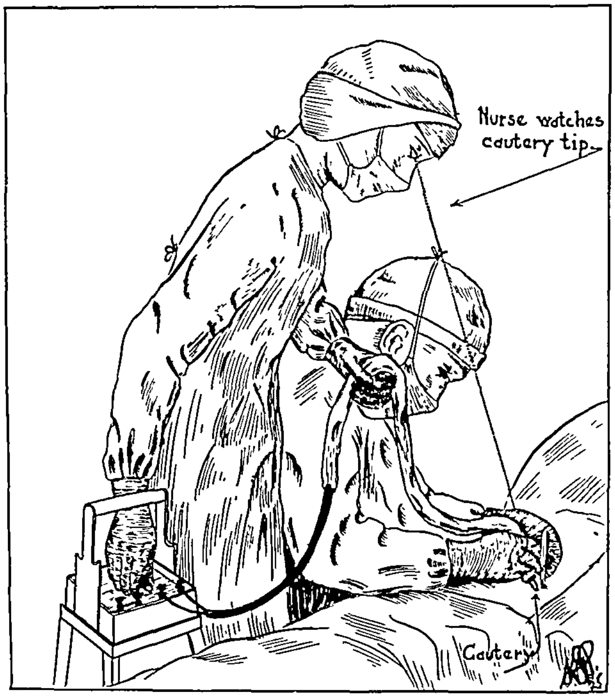

Fig. 1.—The nurse standing on a tall stool, watches the cautery tip in the hand of the operator, and controls the heat by means of the rheostat mounted on a stand.

In 1921, Sistrunk[2] reported a series of cases, with no metastasis at the time of operation, which showed 10.5 per cent. local recurrence of the disease. He also reported that in forty-six cases of local recurrences 80.4 per cent. showed involvement of the lymph glands at the time of operation.

When one considers that during the excision of cancerous masses and during glandular block dissections it is difficult to avoid cutting into infiltrated tissues near the growth or into infected lymph chains or glands before completion of the operation, thus contaminating the knife, scissors or gauze sponges with live cancer cells, and when one further considers the numerous open lymph chains and capillary blood vessels exposed to such contamination, it is not at all strange that local recurrences following surgical operations on patients of proved susceptibility are still quite common.

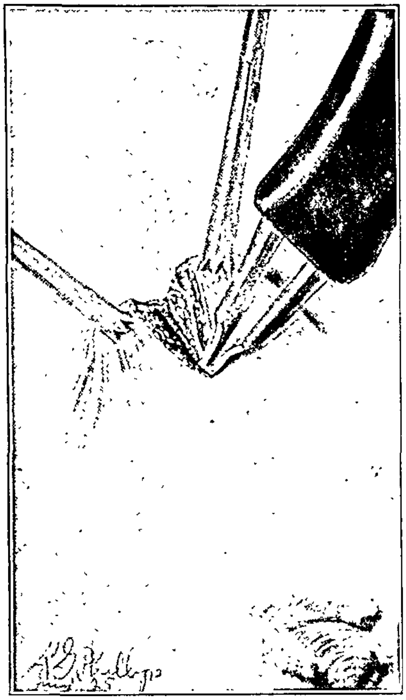

Fig. 2.—Beginning skin incision: Holding the skin on tension is one essential for a successful cautery incision.

It is not conceivable that a red hot cautery which might touch cancer cells during a surgical procedure could possibly be the means of spreading such cells into tissues through which it passed, and it could hardly be doubted that the cautery closes lymph and capillary blood vessels the instant it touches them.

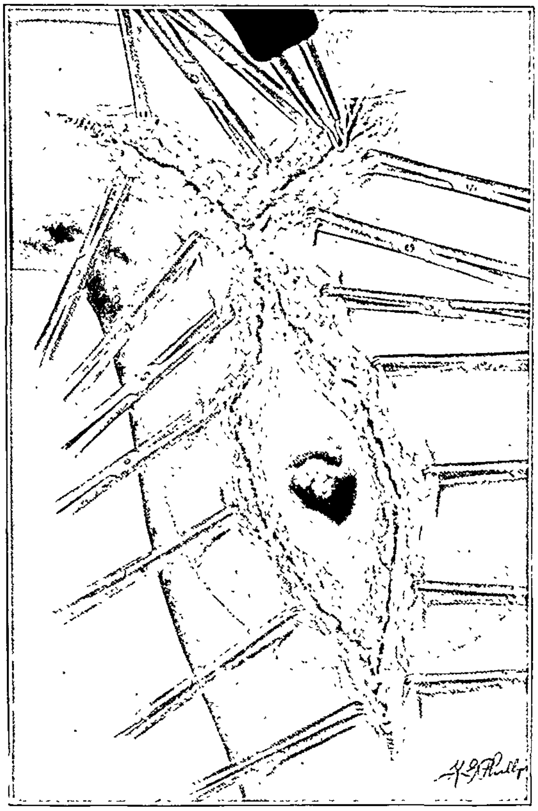

Fig. 3.—Completion of skin incision and beginning of flap dissection.

It should be made clear just here that the cauterization of cancer as practiced by the ancients with heated blunt instruments and popularized in recent times by the use of the soldering irons, and various instruments heated by electricity, in the hands of John Byrne, Percy, Bloodgood, Ochsner and others, is distinctly different from the use of the beveled edge cautery heated especially to suit various tissues involved and used like a knife for radical excision of cancerous masses, the reflection of skin flaps and block dissections. While the former may be used for making excisions, it destroys tissues in mass and leaves great areas of charred tissue, the operators depending on heat radiation for varying and uncertain distances into apparently healthy tissue in the blind hope that it may reach any cancer cells that may have escaped destruction with the deeply charred tissues.

In 1920, I[3] described much of the technic here given, showing the possibility of making skin incisions and flap reflections with the cautery in a manner to secure primary union of wounds. I also showed the possibility of removing lymph gland bearing tissues from accessible areas by dissection with the cautery alone.

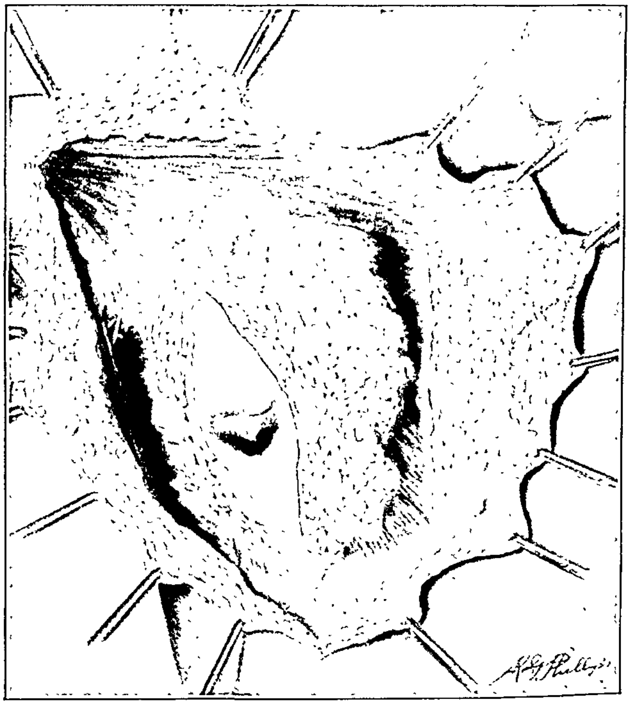

Fig. 4.—Skin flaps completed, ready for amputation, which includes pectoralis major muscle.

Space forbids giving the details of the technic in full. It is sufficient to say that the entire operation is done with the bevel edge cautery as the instrument of incision and dissection, and that observance of certain principles are absolutely essential for success. They are as follows:

1. All tissues must be held on tension as the cautery approaches them; i. e., perfect retraction is absolutely essential.
2. The cautery must be applied in strokes that are short and quick.
3. Perfect control of the cautery heat is best attained by a trained assistant who has no other duty to perform.
4. The cautery must be heated to suit the different tissues involved.
5. Three distinct differences in heat are essential:

(*a*) White heat for incising skin when primary union of skin is desired and for cutting large sensory nerves.

(*b*) Bright cherry red for reflecting skin flaps, cutting muscles and for dissections in general.

(*c*) Dark red for working close to large blood vessels and nerve trunks. With this low degree of heat the cautery tip may safely pass within one-sixteenth inch of a large vessel, loosening the areolar attachment of its sheath without damage to its wall.

---

[3] Scott, A. C.: Radical Excision and Sterilization of Certain Local and Glandular Infections, Texas State J. Med. **16**: 250 (Oct.) 1920.

The three and five year tests for cure of cancer are unquestionably valuable in determining the actual results that follow operation for cancer, but they do not determine with accuracy the real value of the technic employed. Their greatest significance probably relates to the degree of malignancy, to the period of the disease, and to the state of metastasis existing at the time operation was performed.

In attempting to arrive at the merit of an operation, it is obvious that, if performed after metastasis has advanced beyond the field of operation, no surgical procedure will have any value so far as the final outcome is concerned.

We should, then, keep clearly in mind that the most perfect technic will fail in almost every case if metastasis has progressed beyond the field of operation prior to the time of operation. Regardless, then, of how good the technic may be, the surgeon's three and five year cures may show a high or low percentage of mortality, according to how careful he has been in eliminating cases that have progressed beyond hope of improvement

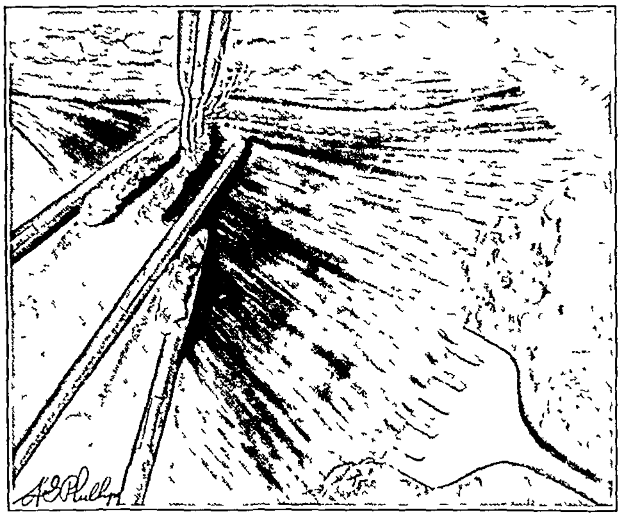

Fig 5.—Pectoralis major muscle being severed and excised with breast.

Most local recurrences are within the three year limit and most of the reported deaths after the three year limit are due to remote metastases, which evidently existed at the time of operation. In our own cases, all the local recurrences appeared in less than one year after operation, the average time being five months.

With these facts in mind and also remembering that most local recurrences are found within three years, it seems to me only rational to return to Volkmann's period of three years to determine, *not* the percentage of final cures, but rather the value of the surgical technic used in the elimination of the local disease and accessible metastasized glands.

Since patients suffering from cancer come for operation at a time when we have no means of ascertaining the limits of metastasis and no power to check metastasis beyond the first group of glands, it occurs to me that the statistical calculations which are designed to determine the value of any procedure should lay greatest emphasis on local recurrences to determine two things: 1. Thoroughness of technic in eradicating the local lesion and the accessible lymph nodes most likely to be involved. 2. The ability of the operator to remove all demonstrable lesions, and include tissues most likely to be invaded by disease, without leaving the wound contaminated with cancer cells, set free by cutting into infected areas or tearing through infected lymph nodes or chains.

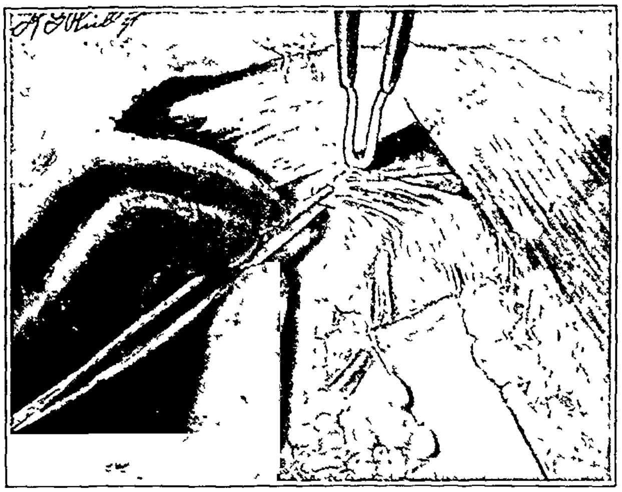

Fig. 6—Exposure of axillary vessels by removal of fascia below margins of pectoralis minor and coracobrachialis.

Therefore, I believe that the most uniform test of a therapeutic agent should be the freedom from recurrence in or about the site of operation for a period of three years.

LOCAL RECURRENCES

In this series of 145 patients traced, there were five local recurrences in or near the site of operation. Considering only seventy-eight patients operated on three years or longer, we have local recurrences of 6.4 per cent. Three of these with local recurrences would ordinarily have been considered inoperable on account of extensive infiltration and probably should not have been operated on. If these cases were not counted, the percentage of local recurrences would be 2.3.

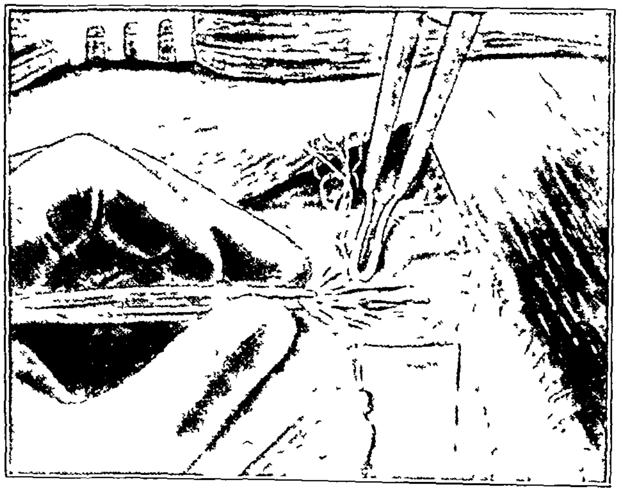

Fig 7—Easy separation of fascia from vessels by means of tension on axillary fascia, with light touches of dark red cautery.

There was not a single local recurrence in the group of thirty breast cases operated on three years or longer. As a matter of fact, up to this time there have been no local recurrences in any of the sixty-five breast cases.

The 160 cases referred to in the title of this paper were drawn from more than 700 cases of cancer in which the cautery was used for excision. Twelve of them will be disregarded in this report because of incomplete pathologic reports and because part of them were not done with the cautery alone. We are concerned with the 160 cases only because of the operative mortality, which consisted of four cases, representing 2.5 per cent. There were 148 cases which have complete pathologic reports and were done with the cautery alone, distributed as shown in the accompanying tables.

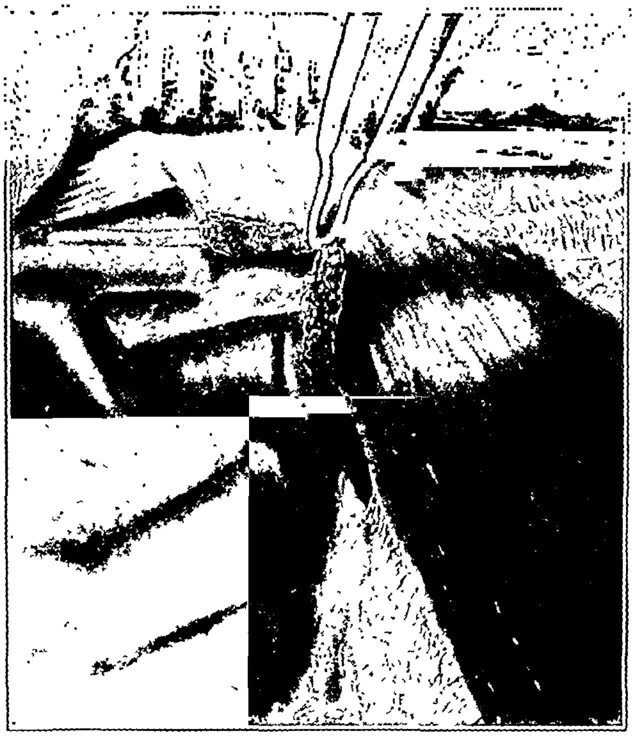

Fig. 8.—Cutting of pectoralis minor with cautery above vessels while it is being lifted with the finger.

* In review of literature, 1,866 traced cases.

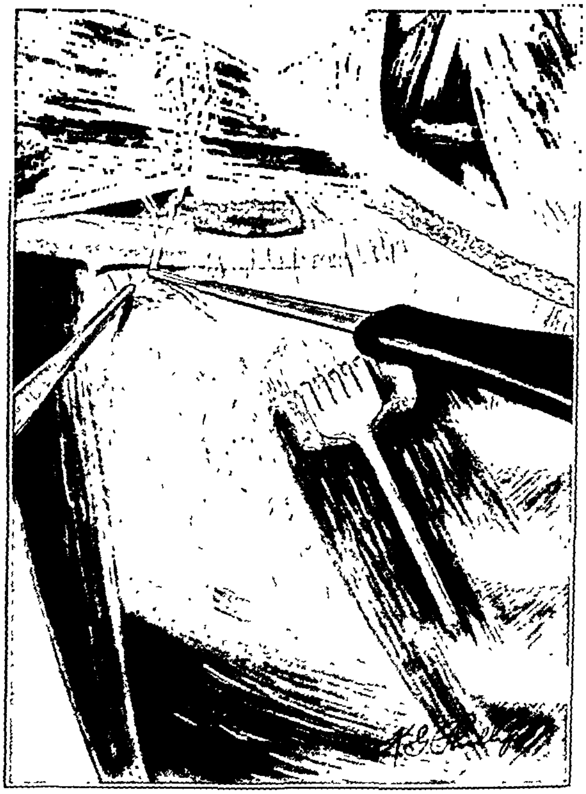

Fig. 9.—With pectoralis minor turned down, fascia covering vessels is gently placed on tension and loosened by light touches of cautery.

CONCLUSIONS

1. Block dissection of the neck, axilla and groin for metastatic cancer can be done with an electrically heated bevel edged cautery with the following results:
   - (*a*) Marked reduction in the amount of blood lost during the operation.
   - (*b*) Marked decrease in postoperative pain.

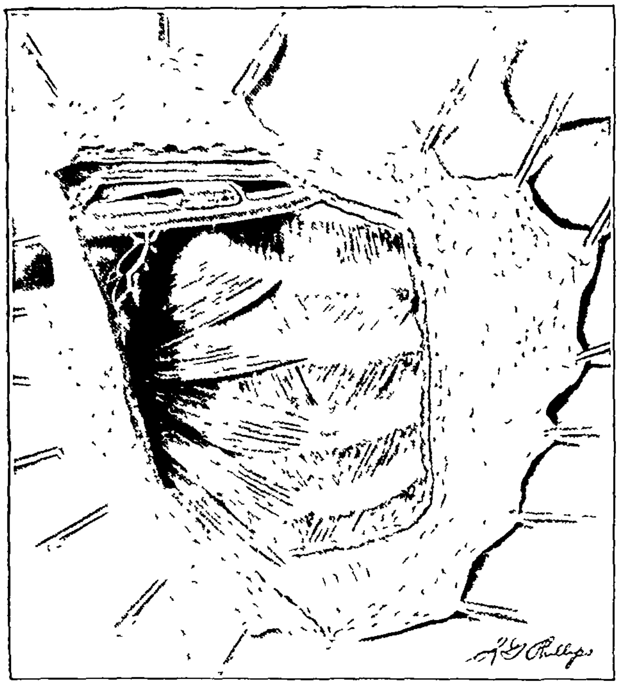

Fig. 10.—After completion of dissection, wound is ready for closure.

   - (*c*) Marked decrease in the number of patients showing any operative shock whatever.
   - (*d*) Primary union of skin flaps.

2. Operations done with the technic described, as compared with cauterization as commonly practiced, result in less pain, less shock and much shorter convalescence.

3. Operations done by this method, as compared with operations done with the knife, scissors or gauze dissection method result in:
   - (*a*) Fewer local recurrences in or near the site of operation, and therefore:
   - (*b*) A greater percentage of three and five year cures.

4. Since the groups of cases here reported contain many that would ordinarily fall in the inoperable group, I feel justified in believing that if this type of technic should be used in only the operable group, the percentage of three and five year cures would be still further increased.

ABSTRACT OF DISCUSSION

Dr. Frank E. Adair, New York: Any new method of surgically attacking breast cancer is valuable. There are so many types and clinical manifestations of the disease, each differing so vastly, that a routine surgical removal is not always the best method for a particular patient. Dr. Scott not only gives us a new method, but a complete series of traced cases treated by a method not heretofore employed. Why his percentage of five-year cures in cases having axillary involvement runs so high, I am at a loss to explain. I see no reason why those cases should have a better opportunity for cure with the cautery than with a painstaking dissection with scalpel or scissors. As a matter of fact, a microscopic study of the tissues remaining behind, treated by Dr. Scott's method, will show a very narrow zone of heat coagulation necrosis where touched by the cautery; outside this is a zone of small, mononuclear infiltration of mild degree. The tissue reaction is not intense. This is to be anticipated, because part of Dr. Scott's technic is to have the assistant forcefully retract the tissues in such a way that the cautery comes in contact with a particular portion of tissue for only a fraction of a second; otherwise, there would not be primary union. Dr. Scott has emphasized a new point of great importance to surgeons; namely, the application of the Lane technic principle to cancer surgery. I believe he is correct in making it the rule never to put into the wound a gauze sponge that he has been using before; this is particularly important when operating in an axilla that obviously is involved. Unquestionably, many cancer transplants are due to not observing this principle After all, many factors enter into breast surgery, such as the age of the patient, the type of carcinoma, lactation, rapidity of growth and distribution of the disease; these factors are, to a large extent, those that will eventually determine the future result of a particular case Unfortunately, to cope with these factors is entirely beyond the power of the surgeon.

Dr. J. F. Percy, Los Angeles: On the basis of results, Dr. Scott's paper is ideal. I believe that he could improve them still further if he made use of a knife of greater bulk. This would insure an even flow of a more penetrating degree of heat, something that cannot easily be accomplished with the type of cautery knife shown. A knife that will give a constant and adequate degree of temperature, regardless of how wet or how dry the tissues may be, can be regulated to a nicety, especially about the blood vessels. This cannot be true of the thin platinum blades that are sold for cautery purposes A knife that has bulk will feed heat into the tissues and thus destroy more cancer cells with less damage to normal cells than can the knife without bulk One cannot get heat penetration with the short, quick strokes spoken of by Dr. Scott. But with a larger knife, in which the heat is more easily regulated, fat can safely be melted on the surface of the carotid artery or jugular vein. The cancer cell is quickly destroyed by a temperature that will melt fat. With a sufficient and steady flow of heat, the outer coat of the carotid artery with its sympathetic nerve fibers can be dissected free, without permanent damage to the underlying vessel structures. I want to

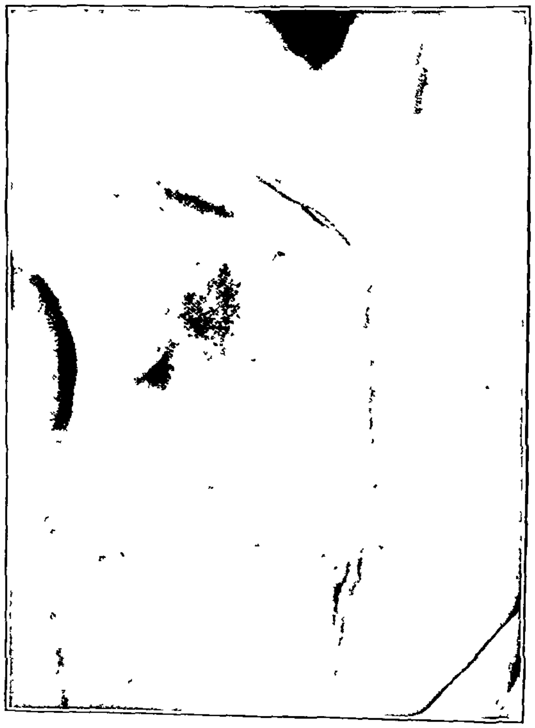

Fig. 11.—Primary union may be obtained in most cases.

take exception to a statement made by Dr. Adair that in cases in which metastasis develops we cannot hope for any results from further treatment. If the metastatic focus is accessible and is treated as actively as was the primary condition, a surprising number of these otherwise doomed patients will remain well for years. We have too many preconceived ideas regarding cancer that are not true clinically. Many of them have come down to the present time merely as traditional lore from the fathers of medicine. The appearance of a mass of cancer, great or small, ulcerating or intact, primary or metastatic, gives absolutely no clue as to the degree of either its malignancy or benignity. Untreated, patients practically all die. But if managed along modern lines, a large percentage will make a good recovery, as has so well been pointed out in the paper that we have just heard.

SPIROCHETAL PULMONARY GANGRENE TREATED WITH ARSPHENAMINS *

B. S. KLINE, M.D.
AND
S. S. BERGER, M.D.
CLEVELAND

In a previous article,[1] it was stated that "evidence is accumulating that pulmonary gangrene may be caused by spirochetes and fusiform bacilli aspirated from an unclean mouth, and that it may be prevented by proper oral hygienic measures. Furthermore, when the condition is once established a diagnosis can be made early by finding the organisms in the washed sputum, thus offering an opportunity for successful specific treatment with the arsphenamins."

The etiologic relationship of spirochetes and fusiform bacilli to pulmonary gangrene is evidenced not only by the predominance of these organisms in early gangrenous areas but also by the fact that gangrene with death in a few days was produced in guinea-pigs [2] by the injection into traumatized tissues of material from pyorrhea alveolaris, dental caries, pulmonary gangrene and Vincent's angina containing innumerable Vincent spirochetes and fusiform bacilli. The organisms in the material from four cases of Vincent's angina that produced gangrene in guinea-pigs were almost solely the characteristic spirochetes and fusiform bacilli.

The relationship of oral spirochetosis to pulmonary gangrene is emphasized by the production in a rabbit of pleuropulmonary gangrene following the intrabronchial injection of material from dental caries containing innumerable Vincent spirochetes and fusiform bacilli.

Many cases of bronchopulmonary spirochetosis have been reported from Europe and the tropics since the publications of Rona (Hungary, 1905) and Castellani (India, 1906), but in the United States, including sixteen cases observed during the course of the last two years at Mount Sinai Hospital, Cleveland, only fifty-two cases [3] of this condition have been reported. Some of these fifty-two cases were at first confused with tuberculosis, abscess, bronchopneumonia or lobar pneumonia. The disease was observed somewhat more frequently in males, the patients ranging in age from 4 to 76 years. The sputum in some of these cases was jelly-like and blood tinged, in some frankly hemorrhagic, in some purulent and in others thin, brown and foul smelling. In only two of these cases did the washed sputum show tubercule bacilli. It always contained, however, numerous spirochetes varying considerably in morphology, frequently associated with fusiform bacilli.

CASES OBSERVED AT MOUNT SINAI HOSPITAL

Case 1.—W. R., a man, aged 30, a physician, admitted, March 1, 1924, had not felt well for some time. For the past two weeks he had been coughing and expectorating incessantly and he had substernal pain and an afternoon rise in temperature. In August, 1921, he had Vincent's angina, which apparently cleared up after several injections of neo-arsphenamin.

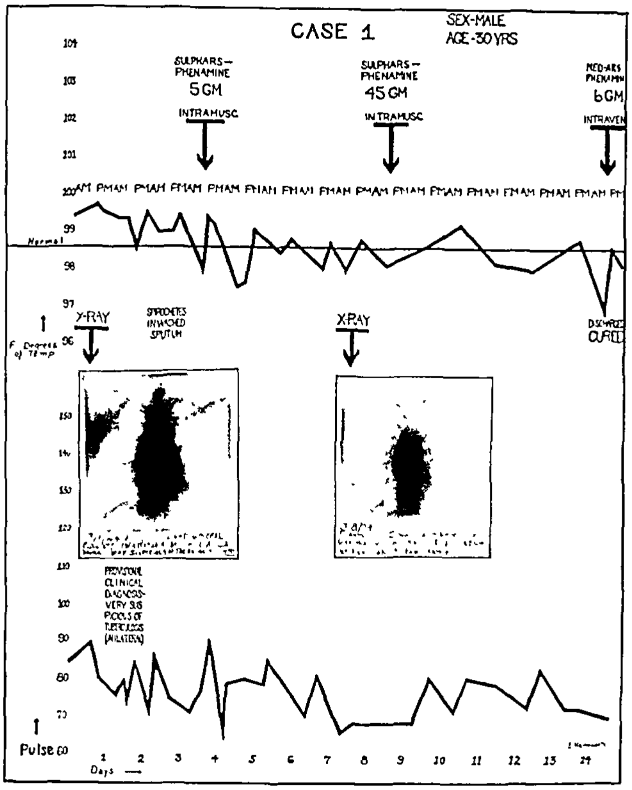

Fig. 1 (Case 1).—Course of temperature and pulse.

The examination showed a patient with asthenic habitus and a general appearance suggestive of tuberculosis. There was slight lateral curvature of the spine. There was some impairment posteriorly in the right upper chest.

March 1, the leukocytes numbered 7,200. The examination of the sputum (yellowish, purulent) was negative for tubercle bacilli. The roentgen-ray diagnosis was "very suggestive of tuberculosis of the right base and infraclavicular region."

March 3, the sputum (well washed) showed no acid-fast bacilli. Many spirochetes of Vincent type were found in Fontana stained slides. This finding, with the history of Vincent's infection in the mouth, decided us, March 4, to give 0.5 gm. of sulpharsphenamin intramuscularly.

March 8, the sputum (after treatment) showed fewer spirochetes than on March 3. The roentgen-ray examination revealed slight mottling at the base and cloudiness in the upper right chest. *This was much less than on the previous examination.*

March 9, 0.45 gm. of sulpharsphenamin was given intramuscularly.

---

* From the Departments of Pathology and of Medicine of Mount Sinai Hospital.

* Read before the Section on Practice of Medicine at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

Sc. **155**: 742 (May) 1918, three cases. Pilot, I.; Davis, D. J., and Shapiro, I. J.: Am. Rev. Tuberc. **8**: 249 (Nov.) 1923, five cases. Rawson, Vance: Spirochetal Abscesses of the Lung, J. A. M. A. **82**: 545 (Feb. 16) 1924, one case. McNeill, C.: Bull. Johns Hopkins Hosp. **35**: 368 (Nov.) 1924, one case. Jackson, Chevalier: Ulcerative Bronchitis Due to Vincent's Organisms, J. A. M. A. **83**: 1845 (Dec. 6) 1924, two cases.

March 14, the roentgen-ray examination, after two injections of sulpharsphenamin, showed that practically all infiltration had disappeared.

All signs and symptoms rapidly disappeared. The temperature and pulse reached normal. The cough and expectoration ceased. The patient was discharged free from all symptoms, March 15, two weeks after admission.

CASE 2.—J. A., a man, aged 29, a patient of Dr. Harold Feil, admitted, July 28, 1924, six days before admission began having fever, headache, cough and some pain in the chest. He was apathetic, cyanotic and acutely ill. The temperature was 100.2 F.; the pulse, 115, and the respirations, 30. The patient coughed frequently, bringing up abundant purulent sputum. The teeth showed several fillings and crowns. There were signs of consolidation of the lungs at both bases, more marked over the right base. Crepitant râles were present. Anteriorly there were signs of diffuse bronchitis. The clinical impression was diffuse bronchitis and bronchopneumonia.

July 28, the leukocytes numbered 15,000. The roentgen-ray examination showed moderate thickening of the hilum and marked fine and coarse mottling throughout the right side of the chest. In the left side of the chest there were several small areas of increased density throughout; also some fine mottling, less marked than on the right side.

July 29, the sputum showed no tubercle bacilli. There were a moderate number of Vincent spirochetes and fusiform bacilli present.

July 31, the leukocytes totaled 16,200.

From July 29 to August 6, daily sputum examination showed no tubercle bacilli.

August 2, the patient received 0.4 gm. of neo-arsphenamin intravenously. The following day he was much improved. The temperature was normal; the coughing and expectoration were diminished.

August 6, the patient was given 0.6 gm. of neo-arsphenamin intravenously and discharged from the hospital, greatly improved.

Beginning August 8, the patient was given four weekly intravenous injections of neo-arsphenamin followed by complete recovery. He has been working since.

May 5, 1925, the roentgen-ray examination showed the lungs to be clear.

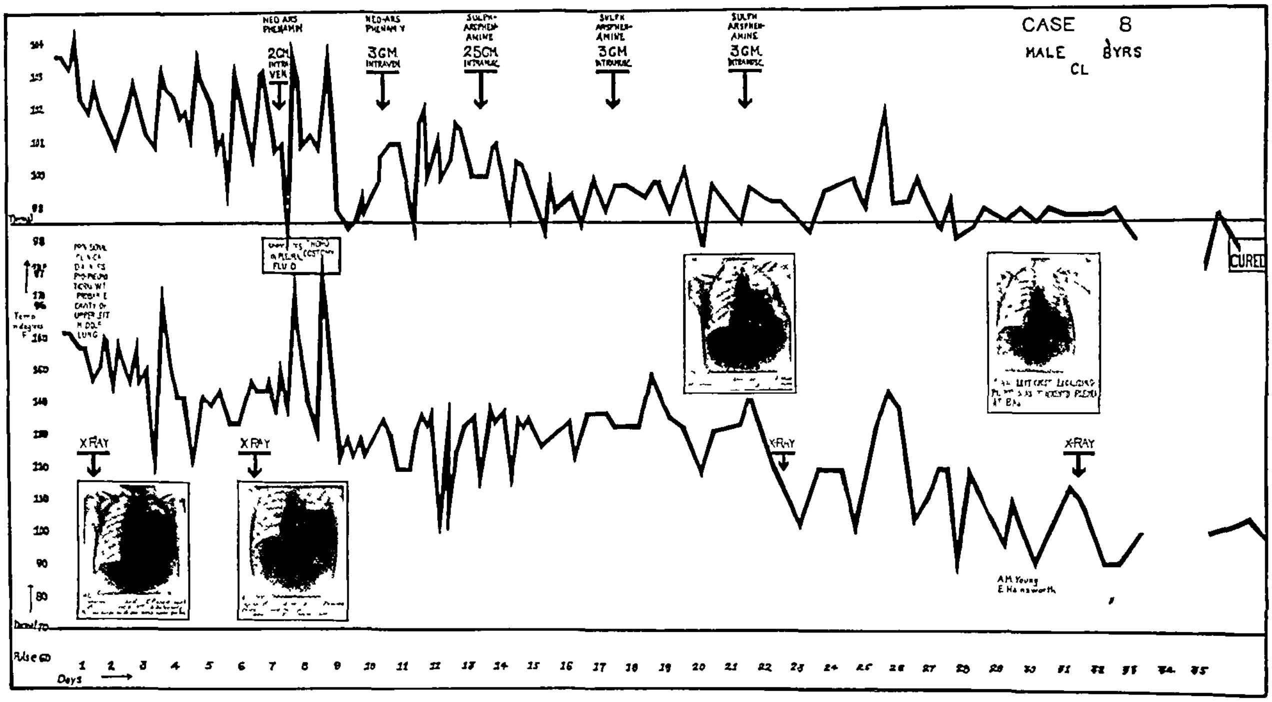

Fig 2 (Case 2) —Course of temperature and pulse.

CASE 3.—O. F., a man, aged 58, on admission, Feb. 1, 1924, stated that he had bronchitis for seven years with moderate cough. A week before, he developed fever and was obliged to remain in bed. The night before admission, after a severe coughing spell, he noticed that the sputum was bloody. February 1, following a coughing spell, a large amount of bright red blood gushed from his mouth. He was brought to the emergency room and admitted to the hospital.

The examination revealed a dark cherry hue to the patient's lips, marked oral sepsis, marked general arteriosclerosis, and barrel chest with signs of chronic bronchitis and emphysema. The blood pressure was: systolic, 138; diastolic, 80. The spleen was felt about a hand's breadth below the costal border, the edge firm, smooth and not tender. The liver was palpable, the edge firm, not tender. The reflexes were normal.

The clinical diagnosis was emphysema; chronic bronchitis; Vincent infection of mouth and lung; polycythemia vera.

November 3, the roentgen-ray examination showed generalized peribronchial thickening, slight mottling of the infraclavicular areas, and moderate infiltration at the left base.

The red blood count ranged from 7,100,000 to 13,500,000; the leukocytes, from 16,800 to 24,000. The hemoglobin was 130 per cent. The blood Wassermann reaction was negative. Daily examinations of the sputum were negative for tubercle bacilli. Numerous fusiform bacilli and spirochetes were found in direct smears from the mouth and also on three occasions from the washed sputum.

November 7, 0.3 gm., and November 10 and 13, 0.4 gm. of sulpharsphenamin was given intramuscularly. The acute pulmonary condition cleared up completely. Phenylhydrazin was given for the Vaquez disease until the red blood count was down to about 5,000,000. Since then the patient has been receiving it intermittently when his blood count rises.

The patient was discharged, improved, November 13.

December 2, he received 0.4 gm. of sulpharsphenamin intramuscularly.

May 5, 1925, roentgen-ray examination showed generalized peribronchial thickening but no infiltration.

CASE 4.—V. C., a man, aged 29, who came to the dispensary, March 28, 1924, stated that he began to have rheumatism with painful and swollen joints while in the army. Since his discharge in 1919, he had not felt well because of recurring attacks of rheumatic pains. For the last two years he had been spitting blood every morning. Eight months before coming, he was treated for rheumatism at the Marine Hospital.

The examination revealed signs and symptoms suggesting tuberculosis of both upper lobes, with activity in the left upper lobe. During an examination in the ear, nose and throat department, blood was seen coming from the trachea.

March 29, the roentgen-ray examination was suggestive of tuberculosis of the upper part of the chest on both sides.

April 10, the sputum showed many fusiform bacilli and spirochetes of Vincent's and the macrodentium type.

April 11, the sputum (washed) was negative for tubercle bacilli. It showed innumerable Vincent spirochetes.

April 30, 0.2 gm. of arsphenamin, and May 14, 0.5 gm. of arsphenamin were given intravenously.

May 22, the sputum was negative for tubercle bacilli.

May 28, the sputum still showed Vincent organisms. The patient was given 0.5 gm. of arsphenamin intravenously. The patient felt much better. All joint pains had disappeared.

June 4, neo-arsphenamin, 0.5 gm., was given intravenously.

June 11, sulpharsphenamin, 0 5 gm., was given intramuscularly. The patient, much improved, did not return for further treatment.

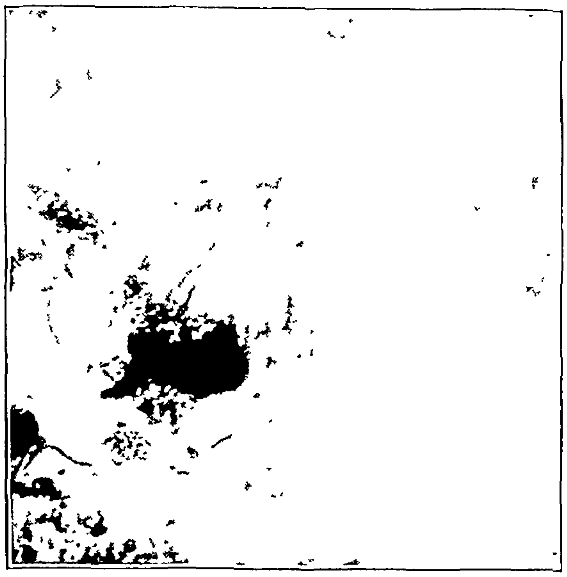

Fig 3 (Case 8).—Carious tooth: spirochetes (Vincent and macro dentium types).

Case 5—L. G., a man, aged 55, admitted, Nov. 26, 1924, had a cold a year before admission which never cleared up. About two weeks before admission, he noticed blood in the sputum. He had been short of breath for a long time and had had cough and precordial distress. There had been some loss of weight.

On examination, the patient appeared cachectic, apparently quite ill and markedly prostrated. There was icteroid discoloration of the skin and conjunctivae. The lips were cyanotic. There was marked oral sepsis. The fingers were clubbed. Marked generalized arteriosclerosis was noted. There was flattening of the left side of the chest, with diminished respiratory excursions in the upper part. The breath sounds and fremitus were absent. Similar physical signs were made out posteriorly over the left apex. They were much more marked anteriorly. A soft systolic murmur, probably inorganic, was heard over the apex and the base of the heart. The liver and spleen were palpable. The clinical diagnosis was lung abscess.

The appearance of the mouth and the characteristic foul odor of the sputum suggested the possibility of spirochetal infection of the lung. Smears from the mouth and the washed sputum, November 26 to November 30, showed the presence of a few Vincent spirochetes. On the latter date, 0 45 gm. of neo-arsphenamin was given intravenously.

November 28, the blood Wassermann reaction was four plus.

Repeated sputum examinations showed the presence of fusiform bacilli until December 18. December 6, 12 and 18, the patient was given 0.6 gm. of neo-arsphenamin intravenously.

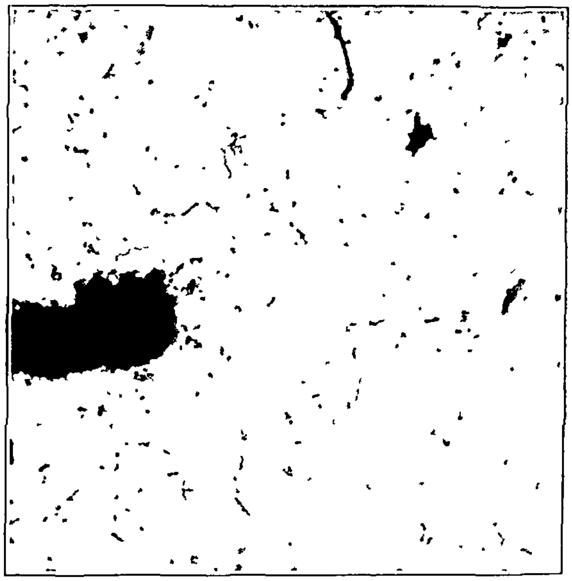

Fig. 4 (Case 8).—Washed sputum: Vincent spirochetes.

Some improvement was shown. The temperature gradually came down, but there was a slight daily elevation, apparently due to the presence of a tuberculous infection. The tubercle bacilli were found in the sputum, December 30. As the patient required additional observation and care, he was sent to the City Hospital.

Case 6.—W. P., a man, aged 27, admitted, Sept. 9, 1924, had been confined in a Chicago hospital five months before, with a condition diagnosed pneumonia of the left upper lobe. At the end of three weeks he was discharged with a diagnosis of unresolved pneumonia. He later went to New York, where a diagnosis of pulmonary abscess was made. The patient's mother died from tuberculosis. One sister had tuberculosis.

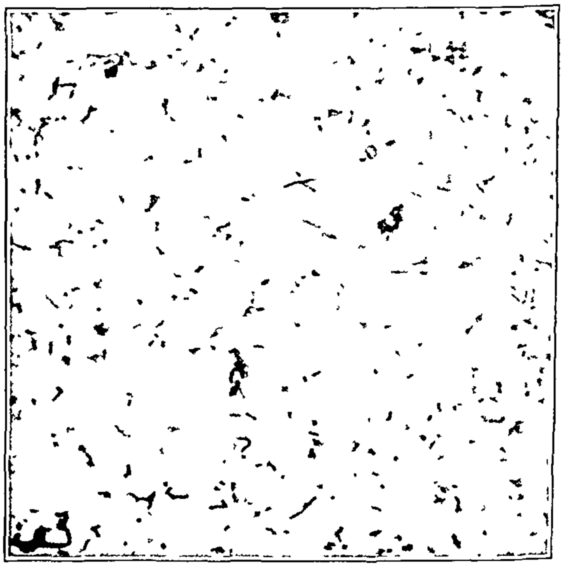

Fig. 5 (Case 8).—Pleural fluid: Vincent spirochetes.

The patient had marked oral sepsis. He coughed and expectorated large quantities of foul smelling sputum. Slight clubbing of the fingers was noted. There were signs of thickened pleura, with some infiltration and cavity formation of the left upper lobe. The leukocytes numbered 14,000. The clinical diagnosis was pulmonary abscess of the left upper lobe. This was confirmed by the roentgen-ray examination, September 21.

The patient's temperature ranged between 99 and 103 F. Repeated daily sputum examinations were negative for tubercle bacilli. September 11, the sputum had a slightly foul odor and contained Vincent spirochetes and fusiform bacilli, and on the 12th, the patient received 0.4 gm. of sulpharsphenamin intramuscularly.

October 10, the patient had not improved appreciably since admission, so operation was decided on. A thoracostomy under local anesthesia was performed. The pleura was opened and a good sized pus pocket, well walled off with adhesions, was encountered. The lung abscess in the left upper lobe was drained. A smear of this material showed innumerable Vincent spirochetes and fusiform bacilli. October 15 and 18, the patient received 0.6 gm. of neo-arsphenamin intravenously. The temperature dropped to normal. The general condition improved markedly.

December 20, the sputum was brown and foul smelling. It was negative for tubercle bacilli.

December 24, the material draining from the thoracostomy wound contained a moderate number of fusiform bacilli and spirochetes of Vincent type.

December 26, in medical consultation, Dr. Berger recorded the following: "The finding of fusiform bacilli and spirochetes in the drainage from the thoracostomy wound should not go unheeded. It would be well, therefore, to give the patient neo-arsphenamin. The odor of the discharge from the wound is characteristic of gangrene."

December 27, 0.4 gm. of neo-arsphenamin, and Jan. 4, 1924, and January 10, 0.6 gm. of neo-arsphenamin was given intravenously.

January 1, the blood Wassermann reaction was plus-minus.

January 1, during the pleural irrigation, the patient stated that he could taste the surgical solution of chlorinated soda.

January 17, the roentgen-ray examination showed a large partial pneumothorax on the left side extending from the base along the axillary line to the apex. There was no evidence of fluid in the chest.

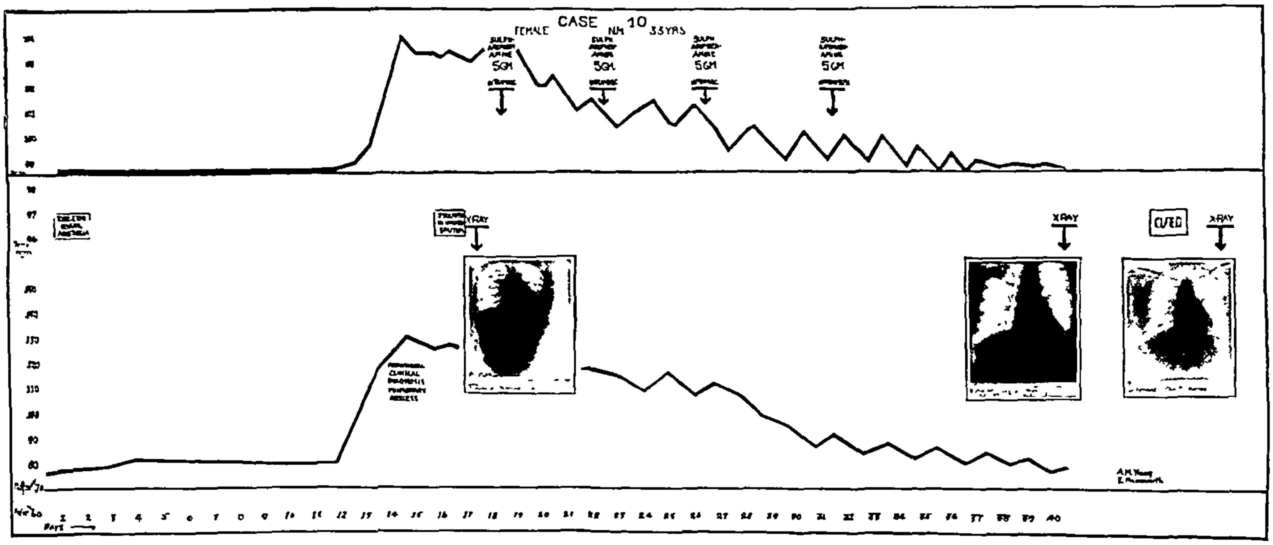

Fig. 6 (Case 10).—Course of temperature and pulse.

October 27, the wound was practically closed and there was only a small amount of drainage; 0.6 gm. of neo-arsphenamin was given intravenously.

November 3, the wound was entirely closed. There was no discharge. The examination of the chest showed practically normal signs except for sharpened breathing at the left upper lobe. All signs of infection had abated. There had been no elevation of temperature for ten days. Neo-arsphenamin, 0.6 gm., was given intravenously.

November 15, the patient was discharged, improved.

Case 7.—H. D., a man, aged 32, admitted, Nov. 10, 1923, with a gunshot wound in the third left interspace 0.5 cm. above the left nipple, was critically ill. The point of exit was opposite the wound of entrance in the fifth interspace in the midscapular line posteriorly. There was evidence of a hemothorax of the left chest.

November 11, 600 c.c. of whole blood, uncitrated, was given intravenously.

November 12, the leukocytes numbered 11,000.

November 13, November 20 and December 8, thoracentesis was performed, and from 300 to 1,100 c.c. of thick, sanguineous fluid was obtained.

November 19, the sputum contained blood. It was negative for tubercle bacilli.

December 14, a resection of a portion of the ninth rib was performed. No fluid was encountered in the pleural cavity. Tubes were inserted, and the cavity was irrigated with surgical solution of chlorinated soda (Dakin solution).

February 3, the patient was discharged improved.

April 28, 1925, he had regained his weight and had returned to police duty. His mouth still contained spirochetes. The roentgen-ray examination of the lungs was negative except for thickened pleura on the left side.

Case 8.—C. L., a boy, aged 8, referred by Dr. J. W. Epstein, admitted, April 21, 1925, with a diagnosis of pneumonia, began having pain on the left side with difficulty in breathing, cough and fever, five days before. He had a tonsillectomy under general anesthesia two weeks before admission.

The physical signs and symptoms on admission suggested lung abscess and open pyopneumothorax. The sputum was foul smelling. The leukocytes numbered 28,000. The patient's condition was very grave.

April 22, the roentgen-ray examination showed the costophrenic angle obliterated, a fluid level to the third rib anteriorly on the left side, and a pneumothorax above this point.

April 27, the roentgen-ray examination showed a fluid level at the third rib with a pneumothorax above this point. The diagnosis was pyopneumothorax on the left side. The sputum (washed) showed many Vincent spirochetes and fusiform bacilli.

April 28, a smear from a carious tooth showed numerous Vincent spirochetes and fusiform bacilli; 110 c.c. of foul smelling thin pus was obtained from the left side of the chest, a smear of which showed innumerable Vincent spirochetes and a moderate number of fusiform bacilli. The patient was given 0.2 gm. of neo-arsphenamin intravenously.

April 29, a thoracostomy was performed under local anesthesia on the left side. A large amount of foul smelling pus containing innumerable Vincent spirochetes was obtained. The washed sputum likewise contained many Vincent spirochetes and fusiform bacilli.

May 1, 0.3 gm. of neo-arsphenamin was given intravenously. The patient was still critically ill.

May 4, 0 25 gm. of neo-arsphenamin was given intravenously. The child was much improved. The discharge was still profuse but odorless.

May 8, 0.3 gm. of sulpharsphenamin was given intramuscularly. The child was practically well. The temperature and pulse were around the normal level.

Fig 7 (Case 15).—Tooth caries (spirochetal).

May 12, 0.3 gm. of neo-arsphenamin was given intramuscularly.

May 13, the roentgen-ray examination showed the costophrenic angle obliterated on the left side, moderate cloudiness at the base, and a partial pneumothorax at the base to the third rib.

June 17, the patient was discharged cured.

Case 9.—L J., a woman, aged 37, was admitted, Sept. 30, 1923, for a study of the genito-urinary tract. Tonsillectomy, adenoidectomy and teeth extraction were performed under general anesthesia, October 10.

The examination was essentially negative except for tenderness in the region of the left flank. The roentgen-ray examination of the teeth showed several abscesses. The tonsils were cryptic and greatly hypertrophied.

October 11, a rise in temperature was noted. October 13, the patient complained of pain in the right side of the chest and back. October 14, the patient had severe coughing spells and sweats, was restless, exhausted, delirious and refused nourishment. The respirations were short and gasping. October 15, the temperature reached 103 F. The leukocytes numbered 12,500. Seven days after operation, the patient expectorated a considerable amount of very offensive, blood-streaked sputum. The sputum examination was negative for tubercle bacilli.

October 26, the clinical diagnosis was lung abscess. The roentgen-ray examination was very suggestive of lung abscess at the right base.

The patient's condition steadily grew worse. There was expectoration of large quantities of foul smelling sputum, which directed a search for spirochetes, and they were recovered in large numbers from the washed sputum (November 16). The same day, the patient received neo-arsphenamin intravenously, and prompt improvement in all signs and symptoms was noted.

November 23, 0 6 gm. of neo-arsphenamin was given intravenously. The temperature, pulse and respirations gradually approached normal and the patient was discharged much improved, December 2 (seventeen days after the first antisyphilitic treatment).

April 28, 1925 (twenty months later), she was in good health The roentgen-ray examination showed very slight cloudiness in the right upper chest, but otherwise was negative.

Case 10—M. M., a woman, aged 33, a patient of Dr. Mahrer, was seen at home. She had had a tonsillectomy under general anesthesia, Sept. 2, 1924, with an apparently good recovery until September 13. On this day the patient became ill with a sharp pain in the right side with cough and fever. On the 15th, when seen in consultation, she showed well marked signs of infiltration of the right upper lobe The temperature ranged up to 104 F. There was marked prostration. The sputum had a foul odor, of which the patient was conscious and complained. A tentative diagnosis of lung abscess following tonsillectomy was made. Because of the characteristic odor of the sputum, spirochetal infection was suspected and smears of the mouth and washed sputum were made, September 18, and showed numerous Vincent spirochetes and fusiform bacilli.

September 18, the roentgen-ray examination of the chest with a portable apparatus showed marked density in the upper right part of the chest, with a small cavity in the infraclavicular area.

Four intramuscular injections of sulpharsphenamin (each 0.5 gm.) were given at intervals of five days, beginning September 18. The patient made an uneventful recovery, and at the end of four weeks was able to leave her bed. The patient has been well since and is teaching school as before.

October 10, the roentgen-ray examination revealed much less density and infiltration of the right chest than on the first examination. The diagnosis was pulmonary abscess.

April 25, 1925, the roentgen-ray examination revealed that the chest was normal.

Case 11.—T. S., a man, aged 39, admitted, Nov. 26, 1924, had had pleurisy, and rheumatic fever with mitral valvulitis, in 1915. Later a mitral stenosis developed. In July, 1924, there was infarction of the kidney, with hematuria.

Two years before admission, the patient began having some pain in the chest, with difficulty in breathing, and since then had been incapacitated a good part of the time. About two weeks before admission, his condition became worse, with coughing and expectoration of yellowish, bloody sputum with some odor.

The examination showed signs of emphysema with chronic bronchitis and superimposed acute infection of the bronchi causing marked respiratory embarrassment. There was no evidence of cardiac failure.

November 26, a smear from the teeth showed a moderate number of fusiform bacilli. No spirochetes were seen.

November 27, the roentgen-ray examination of the right side of the chest showed the hilum enlarged, with much vascular congestion extending into the lung. There was cloudiness in the midportion of the lung. The left lung showed the diaphragm and the costophrenic angle slightly clouded. There was haziness of the entire lung from a thickened pleura. The orthodiagram showed a typical configuration of mitral stenosis. The leukocytes numbered 11,000. The blood Wassermann reaction was negative.

From November 27 to December 4, daily examinations of the washed sputum revealed the presence of a moderate number to innumerable Vincent spirochetes and fusiform bacilli. No tubercle bacilli were found.

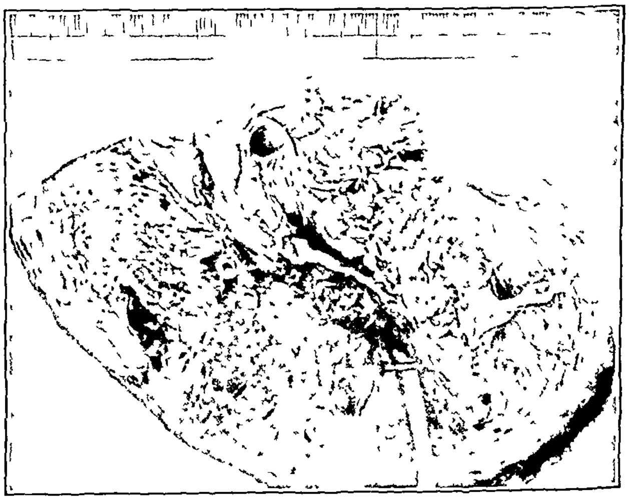

Fig. 8 (Case 15).—Spirochetal pulmonary gangrene.

Since the Vincent organisms were repeatedly recovered from the washed sputum, the condition was considered a spirochetosis superimposed on a chronic bronchitis. December 4, the patient received 0.6 gm. of neo-arsphenamin intravenously. The next day he left the hospital improved and did not return to the outpatient department for observation.

Case 12.—G. K., a man, aged 42, was admitted to the hospital, May 24, 1924, in a dying condition. His eyes were hollow and sunken. The malar bones were prominent. He was stuporous. The respirations were rapid and shallow. There was coughing, with occasional expectoration of very foul smelling, greenish gray sputum. The mouth showed marked oral sepsis. The posterior pharyngeal wall was covered with a thick, foul, greenish, purulent discharge. The tonsils were moderately enlarged. The cervical glands were palpable, about the size of almonds. The chest showed signs of abscess of the right lung. The clinical impression was pulmonary abscess with gangrene.

May 25, the sputum contained numerous Vincent spirochetes; there were no tubercle bacilli. On this day and the 27th, the patient received 0.6 gm. of neo-arsphenamin intravenously. The temperature ranged from 100 to 103 F., the pulse from 120 to 140, the respirations from 30 to 60. Roentgen-ray examination (May 19, before admission to the hospital) showed a marked area of infiltration in the region of the middle lobe, with two distinct abscess cavities in the middle of this infiltration. There was slight mottling in the apex.

The patient died, May 28, four days after admission.

Case 13.—J. S., a man, aged 29, overweight, with diabetes, admitted, March 1, 1925, complained of pain in the abdomen. There were signs of acute appendicitis. The leukocytes numbered 18,000. The patient was operated on the same day. The diagnosis of the surgical specimen was acute suppurative appendicitis, with areas of gangrenous necrosis.

About the fifth day after the operation, the patient experienced pain in the left side of the chest, followed by hemoptysis. There was also some elevation of temperature.

March 9, an examination revealed signs of pleurisy on the left side. Later there were signs of effusion.

March 18, the chest was aspirated and 400 c.c. of foul smelling, purulent material was obtained, a smear of which showed innumerable fusiform bacilli and few Vincent spirochetes. No tubercle bacilli were found.

March 20, the patient was given 0.6 gm. of neo-arsphenamin intravenously.

March 21, a smear from the teeth showed many Vincent spirochetes and fusiform bacilli.

Three examinations of the sputum, March 21 to March 26, were negative for tubercle bacilli. Roentgen-ray examination on the latter date showed the costophrenic angle on the left side obliterated, and slight cloudiness throughout the chest, less marked in the upper part. The diagnosis was: thickened pleura with a small amount of fluid in the left chest. On the same day, the patient was given 0.6 gm. of neo-arsphenamin intravenously.

March 28, the patient complained of pain in the chest and abdomen. He was perspiring a great deal. His temperature was 99.5 F. At his request he was transferred to the Charity Hospital, improved but still quite ill.

Case 14.—J. V., a man, aged 38, admitted Sept. 24, 1923, had had blood poisoning, Nov. 28, 1922, which followed a cut in the hand. December 3, bronchitis developed, followed by pneumonia. This lasted for about five weeks. He was in bed from Dec. 2, 1922, to Jan. 7, 1923. He improved but did not fully recover. In April and again in May the cough, expectoration and pain in the chest became aggravated. About a week previous to admisison there was intense pain in the right chest, dyspnea and cough. The chest was aspirated at the dispensary and fluid was obtained.

The examination in the hospital showed signs of fluid in the right side of the chest. The teeth showed erosions and cavities, with foul smelling contents. The tonsils were large and cryptic. The cervical glands were palpable.

September 24, the roentgen-ray examination showed fluid in the right pleural cavity, with infiltration very suggestive of tuberculosis. A smear of the pleural exudate obtained was negative for tubercle bacilli. The leukocytes numbered 21,600.

September 29, a thoracostomy was performed, with resection of a portion of the right ninth rib. Foul smelling pus was found in the pleural cavity. This continued to drain for a month. The general condition of the patient steadily became worse.

October 27, the pus from the pleural cavity, whitish yellow, foul smelling, showed innumerable Vincent spirochetes and fusiform bacilli. The condition of the patient was extremely poor, and 0.6 gm. of neo-arsphenamin was given intravenously.

October 29, the washed sputum showed innumerable Vincent spirochetes and fusiform bacilli. The patient died at 1:40 p. m.

Case 15.—J. H., a man, aged 68, was admitted Jan. 15, 1924, for a prostatectomy.

January 29, the day following the prostatectomy, the chest examination revealed impairment of resonance at the right base, with showers of râles at both bases, more especially the right.

February 2, the patient coughed considerably and expectorated yellowish sputum. The right side of the chest showed definite patches of pneumonic infiltration.

From February 2 to February 23, the course of the disease continued like a pneumonic process with elevation of temperature, the general condition growing steadily worse.

February 23, the patient's lung condition never cleared up. It was noted that the odor of the breath was foul. There was an abrupt change in his general condition. He became restless and delirious, and he died in a few hours.

The necropsy (February 24) showed a number of teeth absent from the lower jaw, a few missing from the upper jaw. Some of those remaining showed fillings. Others showed erosions and cavities filled with foul smelling viscid greenish material. This was especially true of the last molar in the upper jaw on the left side. The gums showed some injection and were overlaid in a few places by thin, viscid material. The pyorrhea was much less marked than the caries. A smear of the material from a carious tooth showed innumerable spirochetes of Vincent and macrodentium types, fusiform bacilli, large curved gram-negative bacilli, gram positive cocci and other organisms.

When the thorax was opened, the lower half of the right pleural cavity laterally and posteriorly contained between adherent thickened visceral and parietal pleura a few hundred cubic centimeters of thin, turbid, faintly green tinged yellowish, somewhat foul smelling fluid.

The right upper lobe of the lung showed in the posterior and dependent portions patches of reddish gray consolidation varying in size up to several centimeters, in some of which there was cavity formation. The inner wall was necrotic, faintly green tinged, yellowish. In the lumen there were masses of necrotic tissue débris apparently and exudate with a foul odor, weak but penetrating. These gangrenous areas communicated with bronchial branches which showed marked swelling and injection of the mucosa, with necrotic material and mucopus in the lumen. There was no consolidation or cavitation in the right middle lobe. On section of the lower lobe, a striking picture presented similar to that in the posterior and dependent portion of the upper lobe. The consolidation and gangrenous ulceration were somewhat more marked here. There was one solid patch in the center of the left upper lobe toward the anterior surface several centimeters in diameter. The lower lobe on section was similar to the right upper lobe, with patches of consolidation in the posterior and dependent portions, with areas of gangrenous necrosis, the cavities varying in size up to several centimeters. In one portion the process reached practically to the pleura, over which there were the adhesions mentioned above.

A smear from an area of gangrenous necrosis of the lung showed organisms indistinguishable from those observed in the smear of the material from the carious tooth.

Histologically, the picture in the lungs was similar to that described in previous cases of spirochetal pulmonary gangrene.

Case 16.—J. H., a man, aged 26, was admitted. Oct. 6, 1924, with signs of an acute appendicitis for which he was operated on the same day. A gangrenous appendix was removed.

October 8, the patient's condition was alarming, the temperature 102 F., the pulse 130, and the respirations 30.

October 12, the patient was seen in consultation by Dr. Berger, who noted marked oral sepsis suggestive of Vincent's infection. There were signs of consolidation and fluid in the right side of the chest. October 13, the roentgen-ray examination confirmed this diagnosis.

October 16, thoracentesis was done. No fluid was obtained. The pus was thought to be encapsulated.

October 23, a smear from the mouth showed Vincent spirochetes and fusiform bacilli.

October 24, the leukocytes numbered 22,400. The right side of the chest was again aspirated, but no fluid was obtained and it was thought that the pus was probably encapsulated. The presence of spirochetes in smears from the mouth made us suspicious of their presence in the lungs. The patient was very ill.

October 25, a smear from the mouth again showed Vincent organisms. Arsphenamin therapy was instituted, and 0.4 gm. was given intravenously, but the patient died the same day.

The necropsy (October 26) disclosed the teeth in fair condition. A number, however, showed erosions. The gums, especially anteriorly, showed numerous areas of ulceration and discoloration. A smear from an area of ulceration showed innumerable spirochetes of Vincent, macrodentium and larger types, the first type predominating; innumerable fusiform bacilli, and innumerable other mouth organisms.

The right pleural cavity contained a few hundred cubic centimeters of serosanguineofibrinopurulent fluid. There were apparently organizing adhesions between the chest wall and the lung, especially laterally and posteriorly in the lower two thirds. There were organizing adhesions also to the diaphragm and to the pericardium. Between the middle and the lower lobes, about 40 c.c. of clear yellow fluid was found. The left pleural cavity contained about 60 c.c. of blood-tinged fluid. There were some friable adhesions about the lower lobe, especially along the inferior border and posteriorly.

On section of the right upper lobe of the lung, a considerable area of the inferior fourth of the lobe appeared consolidated. Four patches varying in size from 1 cm. to several centimeters showed central ulceration, the cavities varying in size up to 1 cm. in diameter. Three contained thin, slightly viscid, greenish brown, foul smelling fluid. No consolidation was observed anywhere in the middle lobe. Along the inferior border of the lower lobe, there were two wedge shaped sharply demarcated solid areas each about 4 cm. in diameter, apparently infarcts. Along the inferior border of the left lower lobe anteriorly there was a wedge shaped area 6 by 3 by 3 cm., sharply demarcated and apparently an infarct.

A smear made from one of the gangrenous cavities showed innumerable spirochetes and fusiform bacilli, together with innumerable other mouth organisms. The spirochetes were of Vincent, macrodentium and larger types, the first type predominating.

Histologically, the picture in the lung was similar to that described in previous cases of spirochetal pulmonary gangrene, and in places showed changes characteristic of pulmonary embolism and infarction.

CONCLUSIONS

1. At Mount Sinai Hospital, Cleveland, in the course of two years, sixteen cases of pulmonary or pleuropulmonary spirochetosis have been observed. This number gives a better idea of the incidence of this condition than the fact that only fifty-two cases have thus far been recorded in the literature of the United States.

2. In five of our cases in which definite gangrenous necrosis with cavitation was present, arsphenamin treatment apparently prevented death and resulted in practically complete disappearance of all symptoms referable to this condition. Five cases in which there was extensive pulmonary or pleuropulmonary gangrene, and in which no treatment was given or treatment when the patients were moribund, resulted unfavorably. In five of six cases in which there were less severe acute pulmonary lesions, arsphenamin treatment resulted in prompt cure. The sixth patient left the hospital after one injection of arsphenamin.

3. The onset of pulmonary gangrene in the course of any respiratory condition should be suspected when the sputum becomes brown and foul smelling and there is an increase in the severity of the existing signs and symptoms.

4. A diagnosis before any appreciable pulmonary destruction has occurred may be made by the finding of Vincent spirochetes and fusiform bacilli in the sputum (after careful washing).

5. Spirochetal pulmonary or pleuropulmonary gangrene can be prevented by eradicating the primary oral focus.

6. Spirochetal pulmonary gangrene is a distinct entity. It apparently develops as a result of the aspiration of spirochetes and fusiform bacilli from the oral cavity. It may be engrafted on any acute or chronic pulmonary condition, but is usually unrecognized, principally because its symptoms, although characteristic, are attributed to the primary disease. It is a grave complication, and if untreated is frequently the cause of death. Arsphenamin therapy is apparently as specific in this as in other spirochetal infections.

ABSTRACT OF DISCUSSION

Dr. Joseph Sailer, Philadelphia: The beginning of all treatment is diagnosis. Diagnosis involves etiology. When the etiology of the condition is known, we are aware at once, or at a later time, by experiments, whether or not any specific treatment exists. If it does, we apply it and the patient gets well; if it does not, we make an effort to discover the specific treatment. The diagnosis of pulmonary gangrene is not difficult to make in the majority of cases. We may be aided by physical signs, by roentgen-ray studies and by examination of the sputum; examination of the sputum is of prime importance. The specific agent having been discovered (Vincent's spirillum), rational treatment is readily employed. During the war, I had no recognized case of gangrene of the lung, but there were always in the base hospital a large number of cases of Vincent's angina, which we had no difficulty in curing with arsphenamin or similar preparations. Vincent's angina is not unknown among the wealthier class of patients. I have, to the surprise of dentists, found it in the mouths of persons in whom it would never have been suspected. It has occasioned cases of persistent, chronic sore mouth for which there was no previous explanation. I believe that Vincent's angina is not uncommon among all classes, and that probably under certain conditions, such as previous infection or injury, it may develop gangrenous pulmonary conditions. The earlier the diagnosis is made, the greater is the possibility of cure, when the proper treatment is employed. Dr. Berger's paper is interesting and valuable from another standpoint, for it shows how a well known organism may become very serious in some of its manifestations. Entirely apart from the spirochetes of syphilis, we have spirochetal organisms capable of producing a variety of diseases, some of which can be very serious. I have seen two cases of infection with *Leptospira icterohemorragiae*, the organism of infectious jaundice, which experimental workers have found to be a worldwide disease. This has been recently added to the group of spirochetal diseases. It differs from the others in this group in that it is not amenable to treatment by arsphenamin. It is exceedingly important that a more thorough study of the morbidity occasioned by the organisms of the spirochete group should be undertaken, not only to gain information on gangrene of the lung and other serious conditions produced by the spirochetes, but also to discover new forms of disease produced by them.

Dr. Albert E. Roussel, Philadelphia: It is quite possible that cases of spirochetal pneumonias may be more numerous than we think. I have reported two cases that occurred in my service at the Polyclinic Hospital. They were treated in the wards of the hospital in which were kept influenza and bronchopneumonia patients. The physical signs were those seen in the last epidemic of influenza. The sputum was suggestive of bronchopneumonia or influenza. There was a "cranberry" rather than a pink type of pulmonary congestion. The use of neo-arsphenamin resulted in recovery. In both cases the spirochetes were recognized. I think it is possible that a larger number of these cases would be found if we made a systematic search in respiratory cases, particularly if dark field examination was made. On the other hand, it is interesting to note that in my ten years' service at the Eagleville Sanitarium for Tuberculosis, no such cases have come under my observation. In every case a microscopic examination of the sputum should be done to rule out this condition.

Dr. B. S. Kline, Cleveland: In these cases, there is usually pyorrhea or an active lesion in the mouth, with the Vincent organism. In one case, at necropsy, a molar tooth was found filled with a greenish deposit that contained many spirochetes. The organism is best stained by the Fontaine silver impregnation method. It is a gram-negative organism. The majority of the organisms in early pulmonary lesions are of the Vincent type. On a slide they show bronchial and peribronchial infiltration. The lung has a moth eaten appearance. It is mottled with gray-green, foul-smelling masses, containing the Vincent organism. These lesions are scattered throughout the lung, and are often apical, so that they are very easily confused with tuberculosis of the lung, both clinically and roentgenographically. There are no ridges or bridges, as in tuberculosis. The cavities are hollow spheres. The organisms spare nothing, and only a few shreds of tissue are left hanging to the lumen of the vessels. The lung tissue will often show healed, healing and actually gangrenous lesions. An interesting complication in one case was brain abscess; the abscess had the peculiar brownish-greenish-grayish look of the lung lesions, and had a number of spirochetal organisms.

CONTROL OF UTERINE HEMORRHAGE BY THE ROENTGEN RAY *

WILLIAM S. NEWCOMET, M.D.
PHILADELPHIA

The sensibility of the organs of generation to irradiation has been proved by a number of experimenters, and, while exact figures may differ to some degree as to the amount of irradiation required and the results produced, the fact remains that generative cellular elements are the most susceptible of all the cells of the body. It may be safely stated that they undergo a retrograde change from the influence of about one half the amount of irradiation tolerated by other cells. These experimental facts are based on the normal cell and not on cells influenced by local inflammatory or general systemic changes that are usually observed in cases of metrorrhagia or menorrhagia. The question now arises as to what extent irradiation influences cellular elements under these altered conditions.

In the last decade, radium has been employed by many operators for the control of hemorrhage in certain benign diseases of the uterus, with success in many instances, and very few poor results. The usual procedure has been to introduce from 50 to 100 mg. with proper filtration, into the uterine cavity and leave it for from four to eight hours. Any one familiar with the action of radium knows that if the same amount is placed on the skin or mucous surface, there will follow a reaction, which will result in an ulceration of several weeks' duration, and the subsequent formation of a certain amount of scar tissue, and, in some instances, after primary healing has taken place, a secondary ulceration may follow. This secondary ulceration is often troublesome in surface cases, and when produced on mucous surfaces of the vagina or uterus, may be the cause of bleeding that is occasionally observed several months after the application of radium. In some instances following these intra-uterine applications, there has also been considerable general disturbance, which, at times, has been alarming.

With these facts in view, the question of treating a certain number of these cases with the roentgen rays was presented to Dr. Girvin and his staff at the Presbyterian Hospital about four years ago, and they supplied a number of carefully selected cases. Those first treated were women about the time of the menopause with an enlarged uterus, having excessive and prolonged bleeding at their natural menstrual periods. The success in this class led to the selection of patients having small fibroids on whom operations were not advisable. The field was gradually extended until patients suffering from other causes, such as excessive bleeding in anemia, cardiovascular disease and pulmonary tuberculosis, were included. At the same time, the age limit was lowered and it was surprising to note that bleeding in women of from 30 to 35 years was controlled almost with the same ease as those near the age of 50 years, or the natural menopause.

It is recognized that there is nothing new in the treatment of benign uterine conditions with the roentgen rays. Their use was recommended by many authorities fifteen or twenty years ago, but the scarring and skin changes observed after the application of the dosage usually employed deterred most practitioners from recommending their general use. The patients in this group were given extremely mild treatments, and the results produced by this method were equal to those in which heavy dosages had been previously employed. It also appeared possible to obtain rather surprising results in checking bleeding without the usual unpleasant after-effects. In a series of sixty selected patients, only three failed to respond to treatment. In these three, there was absolutely no control of the bleeding, and similar failures have also been observed when a heavy dosage of roentgen ray and radium was employed. In a number, the influence was only partial; in some, lasting for only a few months, while in most of the cases treated, the amount of bleeding was less, usually controlled in proportion to the amount of irradiation given, the idea being to administer that amount of irradiation which would control the bleeding without checking the natural menstrual period. It must be stated, however, that so far we have not been able to produce this result every time it was desired.

The mild character of the treatments is well illustrated by the fact that in the whole series, the pubic hair was retained, but in a few, there was a slight tanning of the skin, which naturally was observed in those cases in which the treatment was repeated several times.

METHOD OF APPLICATION

The body of the patient was covered completely with a leaded rubber sheet or thin lead plates, and four areas over anterior portions of the pelvis, each 2 inches square, were exposed for four minutes, at a 10-inch focal distance, to rays produced by a current of 4 milliamperes, 8 inch spark gap, and filtered by 3 mm. of aluminum. The future applications depended largely on the effect accomplished by the first séance. If there had been very little effect and the hemorrhage was severe, a second application on the back was given at the end of three weeks, provided the condition of the patient warranted it. In making the posterior application, the same technic was used as that employed in the application anteriorly, except that five areas were exposed, three in the center line over the sacrum, and two on the buttocks, in the form of a cross. The next application was repeated in six weeks or two months, if needed, and certain modifications were made according to the requirements of the individual case. If there was the slightest evidence of tanning of the skin over the pelvis, further treatment was withheld, but, in cases in which irradiation was required, the anterior and posterior areas were avoided and four areas were selected on the right and left sides, cross-firing the pelvic organs.

---

* Read before the meeting on radiology in the Section on Miscellaneous Topics at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

While there was no observable dermal change in most of these patients, it seemed strange that a number were more or less nauseated for several days after treatment. This nausea was not the result of the effect of the nitrogen gas poisoning, as the air in the rooms in which the treatment was given was not bad, but appeared to be the local effect of the treatment on the pelvic organs. In one instance, a patient with a fibroid with marked endocardial involvement showed a general reaction after each treatment, suffering from intense nausea and vomiting for a week afterward, so that it was necessary to confine her to bed, and yet there was absolutely not the least sign of any local disturbance on the skin. In fact, a patient treated with radium also complained of the same effect, the details of which will be mentioned later.

Roentgen-Ray Treatment of Uterine Hemorrhage in Sixty Women

Total number of patients treated		60
Metritis local pelvic inflammation	40	
Fibroid tumors	10	
Fibroid tumors, complicated with cardiac conditions	3	
Fibroid tumors, complicated with renal disease	2	
Fibroid tumors, complicated with anemia	2	
Pulmonary tuberculosis, pelvis normal	1	
Pulmonary tuberculosis, endometritis	1	
Renal disease, pelvis normal	1	

NUMBER OF TREATMENTS REQUIRED TO CONTROL HEMORRHAGE

Treatments	1	2	3	4	5 or over
Cases	7	25	10	8	6
Not controlled cases			1		3

Ages of patients	30	40	45	50	55	60	Not given
	4	10	10	14	3	1	18

Hemorrhage controlled, but continued to menstruate	6
Hemorrhage controlled, subsequent roentgen ray	4

The usual phenomena incident to the change of life was observed in many in whom the menses were suppressed, also in several in whom there was only a temporary suppression of menstruation. A few thought the symptoms were unusually severe, and they naturally placed the blame on the irradiation. However, from observation, they did not seem to suffer more than is usual with women undergoing the same change in normal life.

ADVANTAGES OF ROENTGEN RAYS

The advantages of the roentgen rays compared with radium for the control of hemorrhage in these benign uterine conditions appear to be many, with very few disadvantages. They can be easily applied and cause no discomfort, a factor to be considered in the treatment of elderly single women. The treatment consumes less time, the patient is not incapacitated, but can follow her usual vocation, and, while the periods between treatments may be longer, the dosage is more easily controlled, as there is no extensive preparation, the patient is not confined to bed, and she can be more readily induced to submit to treatment. From a physiologic standpoint, it appears to be more rational. The trauma on the uterus is decidedly less, and the intense local reaction usual to radium is avoided, the effect of the roentgen rays being more generally on the pelvic organs.

One patient, not included in this group, was treated with radium applied on the abdomen to simulate the manner of radiation given by the roentgen ray. It required a long time of exposure, as only a small amount was applied in a number of different positions over the lower part of the abdomen. Its routine use is not warranted, except under conditions in which the roentgen rays cannot be conveniently employed. In this instance, 100 mg. was applied over the anterior portion of the abdomen for twenty-four hours. It was moved every two hours and was filtered by 1 mm. of lead and 2 cm. of wood. When it is possible to command large quantities of radium, the time of exposure will be materially lessened.

In two instances, the roentgen ray was used to control bleeding in very large fibroids, in which radium could not be used internally as the os could not be found, and operation was impossible because of the profound anemia. It was necessary in these cases to use many more areas on the abdomen, back and flanks, but the dosage was the same and there was no local disturbance of the skin After the hemorrhage was controlled, the uterus contracted to such a degree that the os could be easily located and radium was then employed within the uterus.

Two patients who failed to respond to treatment suffered from a polypod endometritis, and, as these patients had purely a local endometrial disease, it is evident the amount of irradiation on the uterine body was not sufficient to control the bleeding.

The younger the women, the greater the tendency toward the reestablishment of the menstral function; and, in some of these patients, there was a reestablishment of function without hemorrhage. In others, there was a tendency toward free bleeding, and, in those patients who had a second series of treatments, bleeding was again controlled. There were six patients who continued to menstruate regularly after treatment although the bleeding was checked. In four others, it recurred from one year to three years after treatment.

It may be safely stated that in 75 per cent. all bleeding was checked from the effect of the first series of treatments, but it can easily be seen that more time will be required before exact figures can be obtained on this point.

It is of interest to note that in the majority of these patients, the hemorrhage stopped after a few treatments. Of the sixty patients, in seven, bleeding stopped after one treatment; in twenty-five, after two treatments; in twelve, after three; in eight, after four, and eight required five or more. The majority of those requiring five or more treatments had fibroids. However, one patient, a very small, thin woman, aged 45, suffering from chronic pulmonary tuberculosis, with very free and profuse bleeding at the menstrual period sometimes lasting a whole month, required four treatments. A year later, menses recurred, and, fearing further trouble, a fifth treatment was given, thus placing her in the five-treatment class. Four others were retreatment patients under similar conditions.

The majority of those treated suffered from a metritis modified with more or less ovarian or tubal inflammation. This group numbered forty. There were ten who suffered from fibroid tumors uncomplicated, while three others had severe cardiac complications, two had kidney complications and two, a profound anemia. In the three remaining patients, no local disease could be demonstrated, and bleeding was supposedly the result of a general systemic condition; there was pulmonary tuberculosis in two and a chronic nephritis in the other.

It was surprising to find that many of the patients who complained of pelvic pain and backache were relieved by treatment, no doubt incident to the subsidence of the low-grade inflammatory condition that previously existed in the pelvis. Yet, from the fact that many others expressed themselves as being free from headaches, digestive disturbance and other symptoms complicating these pelvic disorders, one is led to think that there is also a psychologic influence that must be considered.

CONCLUSION

I wish to emphasize the fact that uterine hemorrhage from general systemic or local benign origin, of many different forms, can be controlled by a rather mild roentgen irradiation of such dosage as to leave no perceptible change of the skin over the pelvis, which is used as the port of entrance. In those cases in which a larger amount of irradiation is desired, a larger number of ports of entrance should be used. If this mild irradiation fails, I feel that heavy irradiation will also fail. In some instances, it is possible to control the bleeding without causing a cessation of menstruation. This result, however, is not always obtainable, and in women nearing the menopause, the control of bleeding is likely to lead to a permanent cessation of menstruation.

ABSTRACT OF DISCUSSION

Dr. John Girvin, Philadelphia: I took up some years ago with Dr. Newcomet the possibility of controlling by mild roentgen-ray irradiation cases in which we wanted to retain the menstrual function if possible, or to lose it with as little systemic effect as possible; and secondly, with the hope that in cases of excessive bleeding we might control or stop the bleeding and still retain the child-bearing function. We have not had as yet any case in which we have been able to check the bleeding and yet have a return of menstruation and pregnancy take place. The type of cases that are most effective are those approaching the menopause. In many cases bleeding is excessive at that time, and it is not due to any very distinct pathologic finding. One may find a little symmetrical enlargement of the uterus, or a slight displacement. These cases seem to respond very well. In subinvolution of the uterus when medication has not seemed to affect it, the roentgen ray has had a rather remarkable effect in causing contraction. We have had two or three cases in which menstruation ceased for several months and then returned. In a few fibroid cases, those in which one finds small nodules subperitoneally, we have had some very good results. In cases in which the mucous membrane was particularly affected, such as polypoid endometritis or submucous fibroids, we have had our worst results. I do not think that we can say really that we have had any result in that class of cases. The great advantage in most of these cases is the fact that we get results without the trauma that comes from using radium, and if an operation becomes necessary, as it has in two or three of our cases, it does not complicate the operation. In fact, those cases in which we have operated after the use of the roentgen ray have done unusually well.

Dr. G. M. Laws, Philadelphia: This small dosage irradiation seems to meet the indication for radium without trauma and without hospitalization. To estimate its value from the standpoint of efficiency and safety, I reviewed the records of thirty-seven patients that Dr. Newcomet has treated for the gynecologic staff. They were proved to be benign by curettage or other operation in 70 per cent. of cases, and no case has subsequently been found to be malignant. Of these thirty-seven patients, more than half were under 40 years of age, and none of them subsequently became pregnant. The pathologic conditions were: small fibroids, some with mild pelvic inflammatory disease: metritis, or myopathic hemorrhage, sometimes associated with heart disease or syphilis; certain cases characterized by hyperplasia of the endometrium; and a few cases in which the bleeding followed operation for pelvic inflammatory disease, in which there was conservation of an ovary, and the bleeding was thought to be due to a cystic condition of the ovary. The results were, as a rule, fairly satisfactory; sometimes they were ideal. While the hemorrhage was controlled less positively and less promptly than by the usual effective doses of radium, the treatment seemed to be under better control, and, as a rule, permanent cessation of menstruation did not result unless the woman was old enough for that to be negligible. We feel from this experience that mild inflammatory disease does not act as a contraindication to roentgen-ray therapy as it does to radium, and that therefore in a small fibroid with inflammatory complications, the roentgen-ray treatment would be the treatment of choice. Another point is this, that when operating for pelvic inflammatory disease, it is a comfort to the operator to feel that in the event of menorrhagia later on, he can control it by roentgen ray, and therefore can be a little more conservative than otherwise.

Dr. Henry Schmitz, Chicago: In order to apply the correct treatment in uterine hemorrhages of benign origin, we divide them into four groups: (1) the myomas of the uterus; (2) the hemorrhagic metropathies or functional bleedings; (3) the hemorrhages due to inflammatory conditions of the uterus and adnexa and displacements of the uterus, and (4) the symptomatic bleedings which are secondary to other primary conditions, as tuberculosis, heart disease and kidney disease. The indications for treatment are based entirely on this grouping. We invariably precede the radiation treatment with a dilation of the cervical canal and a curettage, for it is an impossibility to know whether there may not be a hidden malignancy in these conditions. The cases in Group 3 are never treated with radiation, because if we remove the cause the hemorrhages should cease. Intramural myomas of the uterus, free from degeneration and complicating diseases of a size of a ten or twelve weeks' pregnancy, are treated with radium in very small doses to control the bleeding, but not to arrest menstruation. We use an intra-uterine applicator which has a diameter of 1 or 1.5 cm., so that we really use distant application of radium and not contact application. We give only from 200 to 300 mg. element hours in the majority of these cases to control the excessive bleedings, and have the satisfaction that these patients continue to menstruate. In the essential hemorrhages we distinguish between the hemorrhages occurring at the beginning of menstrual life and those at the cessation of menstrual life. These are the two periods in which they usually occur. In the former, we wish to arrest the bleeding but under no circumstances stop the processes of menstruation and gestation. Here again we use very small doses of 200 mg. element hours and wait at least three months before resorting to a second application, which is rarely necessary. The menopausal bleedings are treated the same as the myomas. In the symptomatic bleedings we apply the radium for the control of the bleedings in case the hemorrhage is so severe that it contributes to the clinical process of the primary disease, such as tuberculosis or heart disease. The roentgen rays are used in very large fibroids, when we surmise that the administration of the radium will probably not control the bleeding or the growth, since the action of radium is purely local. Here we desire the so-called homogeneous penetration of the entire tumor with the roentgen ray. On the other hand, if we should have to use the roentgen ray in the essential or symptomatic bleedings, then we can use a very simple method of calculating the dose. We know that the ovaries lie from 6 to 7 cm. beneath a line drawn through the anterior superior spinous process of the ilium. If we wish temporarily to arrest the function of the ovary, i. e., destroy the maturing follicles, we should apply from 15 to 20 per cent. of an erythema skin dose at the ovaries. After six or seven months, the remaining primary follicles will have matured and menstruation is reestablished. On the other hand, if we wish completely to destroy the function of the ovaries, then we should apply a dose of at least from 30 to 35 per cent. of an erythema dose, which will destroy the primary follicles. This effect has been termed roentgen-ray castration. The point I wish to emphasize particularly is that we should never treat uterine hemorrhages unless we have made a diagnostic curettage to exclude the presence of malignancy.

Dr. B. H. Orndoff, Chicago: The complication of a fibroid by an inflammatory condition in the pelvis is very essential in order to determine the proper character of treatment to be applied, and in this diagnosis I wish to emphasize the importance of pneumoperitoneum in pelvic diagnosis and the use of a peritoneoscope for making direct observations in the pelvis. With pneumoperitoneum or with the abdomen filled with a gaseous medium, the vacuum in the abdomen is released and the organs can be displaced from their usual positions. Those fixed in a definite position can be determined, and by fluorescent screen observations and by films made of the pelvis in the proper position, data can be secured with regard to pregnancy and for the presence of tumors and other pathologic conditions that can scarcely be secured in a positive way by any other method. With the abdomen filled with a gaseous medium, an instrument which we have termed the peritoneoscope, which is a modified Jacobæus thoracoscope, can safely be inserted in the abdominal wall, and with the patient in the proper position, with the hips elevated above the shoulders, so that the organs will fall out of the pelvis (those that are not fixed in that position) an inspection of the pelvic organs often serves a purpose in differentiating pathologic conditions at this point, which can not be secured short of a laparotomy or surgical examination. I believe that the importance of these examinations should be emphasized, and large institutions where numbers of cases are handled should have these available methods of diagnosis.

Dr. Dudley Mackey, Bloomfield, N. J.: A woman, aged about 45, was told she had a fibroid of the uterus. She was referred to a specialist for radium treatment. Because of the position and size of the fibroid, radium was contraindicated, and a report was made that the use of the roentgen ray would cause a necrosis of the intestine in this area. I desire to know whether treating a patient under such circumstances would endanger the intestinal tract when deep therapy is used. The patient was later operated on and died.

Dr. Oscar L. Norsworthy, Houston, Texas: Though tumors projecting into the uterine cavity are generally accepted as operative cases, there are some cases of uterine hemorrhage caused by the presence of nonmalignant growths, both intra-uterine and extra-uterine, that are safest treated with radium. Knowledge of intra-uterine conditions are next in importance to that of extra-uterine pelvic complications in deciding for or against radium and the technic of its application. A fairly accurate idea of the shape and size of the uterine cavity can be arrived at by careful use of a uterine sound, and the study of scrapings from the cavity will differentiate the type of growth. Long nonflexible applicators cannot be placed so as to conform to a tumor projecting into the uterine cavity, nor can they be placed so that a tumor situated on the fundus and one on the body can be irradiated at the same time.

Dr. John S. Derr, Atlanta, Ga.: I treated the first case of essential uterine hemorrhage treated by irradiation in Atlanta, Ga., in 1914, with excellent results. I used the old gas water-cooled tube with the short focal distance and only leather filtration. The woman was 40 years old at the time, and she is still young looking. Since that time I have treated more than 100 cases of uterine hemorrhage and fibroid tumors. I have had fibroids reaching up nearly to the umbilicus practically disappear under roentgen-ray treatment. It is certainly a pleasure to hear Dr. Newcomet favor the roentgen ray rather than radium in the treatment of these conditions. I have never yet failed to stop a case of hemorrhage by roentgen ray, and have had three previously treated with radium. Dr. Pfahler some years ago reported a case of fibroid tumor that he treated with roentgen ray and the woman afterward married and came to a successful pregnancy and was delivered of a normal child.

Dr. William S. Newcomet, Philadelphia: In practically all of these cases curettage was done except in those in which a cardiac or a lung condition would not permit anesthesia. Answering Dr. Mackey, in regard to the patient who died, what condition did they find at operation?

Dr. Mackey: Uterus adherent to the bladder, a large nonmalignant fibroid.

Dr. Newcomet: One cannot for one minute conceive why the case could not be treated, and safely treated, too. With mild irradiation, radium might have been employed, but it cannot be denied that the roentgen ray would have been safer. Dr. Schmitz called attention to the fact that when radium is placed in the uterus for the treatment of these tumors, it is not expected that this is going to radiate the tip of that mass. That was just the point that I brought out in the paper. With radium, it is a close-up radiation. We all know that the radiation spreads out inversely as the square. Well, naturally a comparatively short distance rapidly lowers the effect of the radium, and, when there is an application as shown in the charts of Dr. Norsworthy, the amount of radiation on the inner side of the tumor and the amount of radiation on the outer edges differ enormously. Therefore, we cannot believe that all the retrograde change of the tumor is entirely due to the radiation of the tumor mass. It is due to the effect of the radiation on the endometrium of the uterus. The retrograde changes in a pelvic mass, when the roentgen rays are used, are due to the changes produced in the pelvic organs. One is a general reaction on all the pelvic organs, while the other is a purely local reaction on the endometrium of the uterus.

DUODENAL ANTIPERISTALSIS

FURTHER OBSERVATIONS *

W. F. HENDERSON, M.D.
JACKSON, MISS.

That the peristaltic wave in the gastro-intestinal tract is normally in an analward direction is, I believe, axiomatic, with the exception of the proximal portion of the colon. Here antiperistalsis has been so commonly observed that it is certainly accepted as the usual, if not the normal, procedure.

A perusal of the literature on antiperistalsis in the duodenum offers so many disappointments that one approaches this subject with some trepidation. It is, of course, a matter of common knowledge that the peristaltic wave reverses itself in obstructive lesions at or near the duodenojejunal junction, whether the lesion is intrinsic or extrensic to the intestine. Cole and Holzknecht, independently of each other, experimentally produced this in 1910 by mechanical blocking of the lumen. Joseph and Metzler,[1] in rabbits, and Wheelon and Thomas,[2] in dogs, studied the motility of the duodenum by means of balloons anchored in the duodenum and antrum, but they observed no antiperistalsis. Thorning and Smith[3] observed antiperistalsis in a dilated duodenum due to extensive adhesions in the ileocecal region, and they deplore the paucity of literature on the subject. Alvarez,[4] in his extensive work, has observed retrograde peristalsis in all portions of the gastro-intestinal tract, including the duodenum, and

---

has found colonic contents on the back of the tongue. He describes the retrograde rushes quite clearly, while Henderson [5] of Toronto doubts the existence of such a thing, saying: "A true reverse peristalsis, I believe, has never been observed."

Arens [6] has observed retrograde peristalsis at this point more than a hundred times in a series of approximately 300 gallbladder cases, and attributes the phenomenon to an associated duodenitis. Paul Eisen [7] has observed the condition only nine times, each with a different existing pathologic condition, and remarks that "the absence of regurgitation is especially noticeable in cases of diseased gallbladder where one would expect to find it." My own observations would lead me to take the point of view just expressed.

In a recent preliminary report,[8] I presented a series of thirty-five cases of duodenal regurgitation, ascribing its causes to the presence of hookworms with the associated duodenitis. With the original report as a basis, it is now my purpose to review the already reported cases together with a large number observed since that report and to present additional findings.

PATHOLOGY

In describing the changes in hookworm disease, Darling [9] states that the pathologic changes due to hookworm are caused in part by oozing of blood from the worm bites (hemorrhage), and by the bacterial invasion of the mucosa. Hemorrhage of greater or lesser severity always accompanies *Ancylostoma duodenale,* with its formable hook-mouthed parts, and the worms are seen to have blood in the intestinal tract. At necropsy, in severe cases, the mucosa of the small intestions is dotted over with minute worm bits, some of which have blood stained margins, indicative of the source of the blood that bathes the mucous surface near by.

In mild infections, the lesions consist of minute tears in the mucous membrane and of small hematomas, or blood cysts, in which adult worms may occasionally be found. Solitary ulcers 2 cm. in diameter may arise on these blood cysts, for they communicate with the lumen of the intestine. In severe infections there is a bacterial invasion of the tunica propria of the mucosa, their entrance probably effected through the worm bite. A chronic inflammatory reaction follows the invasion, which would seem also to be the cause of the peculiar intermittent fever characteristic of severe infections.

GENERAL CONSIDERATIONS

In the first few instances in which antiperistalsis was seen, little significance was attached to it, and no explanation was offered beyond the statement that it was commonly seen in obstructive lesions at this point. Its observation in two brothers on the same day, in whom obstruction obviously did not exist, and for which no pathologic reason could be ascribed, served to stimulate my interest and gave impetus to my investigation. The laboratory reported a marked eosinophilia in the two patients and gave a positive report for hookworm ova in the stool. It occurred to me that the presence of the worms, together with the associated duodenitis and ulcer formation, might be the explanation. Blood and stool examinations were at once determined in all patients who presented this condition and with whom the proper cooperation could be secured.

Retrograde peristalsis, as I have observed it, has commonly been seen in young subjects, usually in the second and third decades. The examination is not other than that of the usual barium meal procedure employed in routine gastro-intestinal work. The patient is observed in the upright position and, since a barium filled stomach displaced backward by pressure could obstruct the lumen of the intestine, the gloved hand is never used for manipulation of the stomach, it being allowed to empty itself unaided. For obvious reasons, antiperistalsis in the prone position has been disregarded. When pylorospasm prolongs itself unduly, the patient is allowed to sit in an anteroom until its disappearance.

The roentgen-ray examination shows little or no cardiaspasms, although hyperperistalsis accompanied by considerable pylorospasm is the rule. It will be observed that the behavior of the stomach is not unlike that observed in the commonly seen duodenal ulcer of peptic origin. In addition, the spasmodic manifestations extend to the duodenum itself, the food passing slowly and apparently with some difficulty to the duodenojejunal juncture, where it pauses and passes backward to the bulb, after which it oscillates between these two points from two to eight times, or, in rare cases, even more. The stomach frequently shows some residue at the six hour examination while the head of the meal is usually at or beyond the splenic flexure.

The antiperistaltic wave in this condition is a clear cut, copious discharge backward to the bulb, appearing not unlike a fluid propelled from an ordinary piston syringe, and is not to be confused with the antiperistaltic rushes described by Alvarez, in which he observed that the duodenal contents continued their analward motion, while a fleeting wave passed in the opposite direction, much as a ripple might pass upstream on the surface of a moving column of water.

Antiperistalsis has been noted in a total of 102 patients, with positive stool reports for hookworm ova in ninety-five cases (93 per cent.). Of the seven cases reported negative for ova, two were dismissed with a single stool examination, which, in the light of subsequent investigation, I consider insufficient evidence; cancer of the head of the pancreas accounted for one; acute pancreatitis for another; enlarged tuberculous lymph nodes with external pressure for another, and cholecystitis for the remaining two.

REPORT OF CASES

CASE 1.—J. J., a man, aged 32, whose family history was of no particular interest, had been treated by his own physician "all his life for stomach trouble." The patient was poorly developed and poorly nourished. He weighed 121 pounds (55 kg.). The sclerae were yellow, and the skin had a dry, leathery appearance. The remainder of the physical examination was negative.

A barium meal was given. One and one-half hours' waiting was required before the stomach could be induced to begin emptying, at which time a normal stomach and cap were observed with hyperperistalsis and hypermotility. Antiperistalsis in the second and third portions of the duodenum were pronounced. The roentgen-ray diagnosis was: intestinal parasites. The laboratory report showed: red blood corpuscles, 4,000,000; eosinophils, 9. The Wassermann reaction was negative. The malaria test was negative. The stool contained a large number of hookworm ova.

The patient received five treatments of thymol; his digestive disturbances have disappeared; a gain of 14 pounds (6.4 kg.) was observed by his physician, and the man is now back at work apparently well. A reexamination showed no antiperistalsis or other pathologic condition.

9. Darling, S. D.: International Health Board Report.

CASE 2.—Miss C. G., aged 17, whose family history was negative and who had had the usual diseases of childhood, with no serious illness, complained of inability to sleep; loss of considerable weight; vomiting of food at irregular intervals, and a slight cough, accompanied by such a profound depression that it became necessary for her to leave school. A physical examination by her physician, aside from a moderate anemia, was negative. The stool showed no ova of any kind. A gastro-intestinal study was done by me. No pathologic change was observed, with the single exception of antiperistalsis in the second and third portions of the duodenum. In spite of the previous stool examination, parasitosis was suggested to the clinician. Magnesia magma was given; the laboratory reported a stool positive for hookworm. Two weeks after carbon tetrachlorid treatment, the patient reported a gain of 4 pounds (1.8 kg.), normal sleep and no depression. She returned to school apparently well. There was no opportunity to observe this patient roentgenologically following the treatment.

CASE 3.—Miss R. L. W., aged 21, whose family history was of no interest, had had "stomach trouble" for some years. Her family stated that "spells" of some kind were of common occurrence, and were increasing in frequency. Examination showed her to be poorly developed and poorly nourished, weighing 98 pounds (44.5 kg.). Anemia was evident on casual observation, and the patient appeared listless. The hemoglobin was 60; there was no eosinophilia; the stool was negative for parasites; the Wassermann reaction was negative; the urine was normal, and gastric analysis was not made. The appendix had been removed two years before examination.

The physician requested a roentgen-ray study. The chest was normal; cardiospasm was absent. The stomach, considerably dilated, lay in the pelvis with no waves appearing at the end of half an hour. An hour later, no food had passed through the pylorus. As the patient stepped from the fluoroscope she was seized with an epileptiform attack, which lasted for three or four minutes, immediately after which the stomach began emptying itself. Antiperistalsis of the second and third portions of the duodenum was greatly in evidence. There was some retention in six hours. No other pathologic changes were noted.

The probability of parasites was suggested to the clinician, and after two examinations the laboratory reported positive stools for *Uncinaria*. The patient received three treatments for this condition before the stool was free from ova. She gained in weight. The "stomach trouble," together with the "spells," disappeared, and her physician tells me that she is well.

CASE 4.—J. S. L., a man, aged 30, was operated on in 1919 for appendicitis, with only temporary relief. The weight loss since that time had been 12 pounds (5.5 kg.). Recently, attacks of indigestion had been marked. Sour eructations were common and he was continually swallowing and belching air as though attempting to "scatch himself." He had become despondent over his condition. A recent roentgen-ray examination in a neighboring city revealed antiperistalsis in the duodenum probably due to adhesions about the old appendix scar, and he had come in for an operation for this condition.

He was referred to the roentgen-ray department. The antiperistalsis noted by the other physician was visible at my examination. The laboratory reported the stool positive for the parasites. Appropriate treatment was instituted, and two and one-half months later the patient reported himself as well. No operation was done. Reexamination shows no antiperistalsis, and the laboratory reports show no ova in the stool.

CASE 5.—M. B., a girl, aged 10, had always been sickly; she was unusually bright in school, but subject to constant attacks of digestive disturbances and acidosis. Her physical condition did not allow her to run and play with the other children. A diagnosis of cyclic vomiting had been made by two pediatricians, and of congenital pyloric stenosis by a third. An appetite for inedible articles (hair, bits of cloth, etc.), had been noted by her parents, and lately she had developed the habit of swallowing and belching air.

I was requested to look at the stomach for a possible bezoar. A roentgen-ray examination showed no foreign body in the stomach, and obstinate pylorospasm lasting thirty minutes, during which the child vomited once. There was exaggerated antiperistalsis in the duodenum. The examination was otherwise negative. The suggested diagnosis of intestinal parasites was given. The laboratory report showed: hemoglobin, 70; red blood corpuscles, 4,500,000; eosinophils, 12. The stool examination revealed no parasites. The second stool examination after magnesia magma was given revealed hookworm ova. Examination of the stool was reported negative after four months of active treatment. The vomiting had ceased; the digestive disturbances with the abnormal appetite had disappeared. The child is well, and reexamination gives no roentgen-ray evidence of any pathologic condition.

ECONOMIC CONSIDERATIONS

Considerable interest has been shown of late in intestinal parasites throughout the United States. The constantly shifting population, together with the emigrants from the warmer climates, have made this more than a local problem, although it is naturally of more interest and the effects are more widespread along our Southern border. A zone of infection surrounds the earth from about 38 degrees north to 34 degrees south latitude.

In Brazil, Smillie and Darling[10] estimated that the working efficiency of the men on the coffee fazendas, taking fazendas as a whole, was one-fourth less than that of otherwise normal, noninfected men. This decreased production was attributed almost entirely to the hookworms they were carrying. The psychologic board of the U. S. Army officially reported that in the case of 10,000 men at Camp Travis, Texas, tests indicated the mentality of white men with hookworm disease to be about 33 per cent. inferior to the mentality of white men without it.

Williams[11] states that a conservative estimate of the hookworm disease in Harrison County, Miss., in January, 1918, was 20,000 cases in a total population of 35,000. Basing an estimate of diminished production of one-third the figure given above, this would be the equivalent of 6,000 nonproducers in this one county.

COMMENT

I have examined certain of the patients in this series, after treatment for uncinariasis, with the result that those who still showed the phenomenon were sent back for further treatment, at which time multiple stool examinations still showed the presence of ova. In those cases in which, after treatment, the phenomenon had disappeared, it is interesting to note that repeated stool examinations have shown no ova.

The criticism that the roentgen ray has become omnivorous is not a just one. As physicians first, interested in disease, and only later as interpreters of shadows in terms of pathologic changes in particular organs, it is incumbent on the roentgenologists to assist the clinician in whatever way they can. The peptic ulcer commonly seen in the duodenum, with its associated duodenitis, is responsible for the structural and spasmotic changes in the bulb which even a tyro is wont to associate with its true pathology. It is not contended that the hookworms are solely responsible for duodenal antiperistalsis, but it is not taxing our credulity too far to believe that ulcers of this etiology and in this location are able to produce phenomena by which their presence can be detected. It is not unthinkable that a disease which can and does produce clinical manifestations, varying from a mild anemia and indigestion to epilepsy, would make itself manifest when the site of the pathologic changes—the duodenum—is visualized by the barium meal method. In my opinion, hookworm infection must be excluded by careful laboratory work before duodenal antiperistalsis can be attributed with safety to other pathologic conditions.

ABSTRACT OF DISCUSSION

Dr. L. A. Fortier, New Orleans: This paper is especially valuable to the physicians of the South. The work was made possible by the high percentage of infected persons in Mississippi. The conclusions are very logical. When hookworms are present in patients with abdominal complaints, antiperistalsis is seen. When the patient is freed from parasites, the symptoms, including antiperistalsis, disappear. This happening in all cases proves to me that the parasites are the cause of the reverse peristalsis. Roentgenologists can be of help by asking for feces examinations in cases of antiperistalsis in the duodenum not accounted for by other well known pathologic conditions, as adhesions, gallbladder disease or obstruction of tumors.

Dr. L. T. LeWald, New York: The subject interests me very much, having studied hookworm as a pathologist in the tropics many years ago, and I am rather surprised to find that the control of the situation at the present time is so poor when the etiology is so well known. I had supposed that hookworm was a thing of the past, but apparently it is well to the front. I hope that in his conclusion Dr. Henderson will give us a little more definite way of recognizing the antiperistalsis. I understood him to say that it was not to be seen in the upright position.

Dr. W. F. Henderson, Jackson, Miss.: In answering Dr. LeWald, I am sure that he misinterpreted what was said. My paper stated that I consider this of importance only when the patient is standing erect, and that for obvious reasons I have disregarded antiperistalsis with the patient in the prone position. I should like to call attention to one particular phase of this. I do not suppose that the physicians in the North and East ever have any trouble with their appendix cases—they probably cure all of them—but in the South most of our patients with chronic appendicitis have just about as much trouble after operation. I cited one case in which a man had been operated on for chronic appendicitis and I would urge that we make sure that when we consider a case as chronic appendicitis we rule out other things. The hookworm is responsible for a very large number of intra-abdominal symptoms; that is, pain and what not. It is very easy to confuse these symptoms with a great many other conditions, and we should at least go very carefully into the case before attributing chronic abdominal pain to an appendix.

Social Worker's Function.—The social worker's function is chiefly therapeutic. A failure to recognize this fact has sometimes resulted in making her chief duty that of financial investigation for the purpose of excluding patients who are ineligible for dispensary care. While in the course of her work she may obtain information regarding finances that is of value to the administrator, obtaining this information should not be her main objective. Not only does this tend to lessen the value of her real purpose but it places upon her a duty that belongs elsewhere. It is likely to place her in a false position with the patient—it may lose for her the friendly relationship with him that is essential for the successful execution of her work. The investigation of the patient's financial resources after a diagnosis has been made when the physician is faced with the problem of prescribing treatment that may be beyond the patient's means is distinctly another matter. Certain adjustments in the home requiring the expenditure of money may be necessary before treatment can be completed. The social worker in making the type of financial investigation that rounds out the physician's effective treatment of the case is not only within her province but she is performing one of her distinct functions.—*Hosp. Social Service* **12**:138 (Sept.) 1925.

OCULAR PHENOMENA PRODUCED BY TEMPORAL LOBE TUMORS *

WALTER I. LILLIE, M.D.
ROCHESTER, MINN.

A detailed study of the ocular changes produced by temporal lobe tumors has been made in order to ascertain the frequency of correct localization from an ophthalmologic standpoint. Cushing's [1] report that perimetric field defects in temporal lobe lesions were of paramount diagnostic value, localizing definitely the site of thirty-three of thirty-nine tumors of the temporal lobe, was a further stimulus to this study.

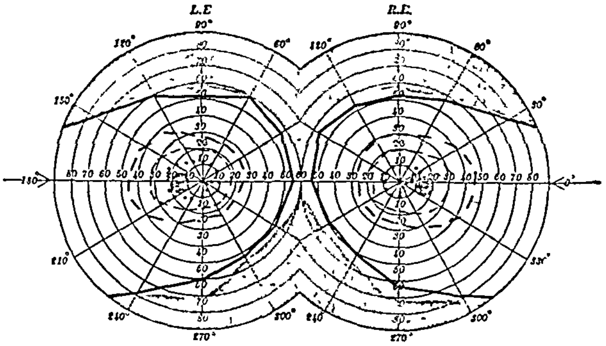

Fig. 1.—Vision right eye, 6/4; left eye, 6/4. Perimetric fields normal for form, right homonymous lower quadrant defect for green; bilateral enlargement of the blind spots.

In a series of 168 cases of certified cerebral tumors examined in the Mayo Clinic during the last five years, sixty were located in the temporal lobes. In all but three of these cases, operation was performed; and in these three, the location was diagnosed correctly, as proved by necropsy. There were fifty-three cases of infiltrating gliomas, three of dural endotheliomas, two of calcified hematomas, and two of angiomas.

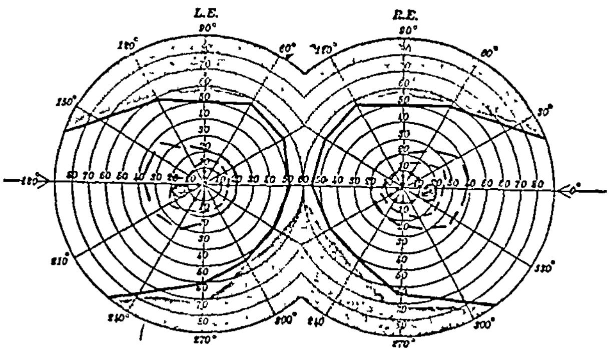

Fig. 2.—Vision right eye, 6/6; left eye, 6/6. Perimetric fields normal for form, left homonymous upper quadrant defect for red and green; bilateral enlargement of the blind spots.

OCULAR CHANGES

The ocular changes may be divided into four groups: (1) changes of visual acuity; (2) changes of the optic disks; (3) changes in the perimetric fields, and (4) oculomotor changes.

Changes in Visual Acuity.—The vision was normal in thirty-two cases, and not determined in nine. In the remaining nineteen cases there was visual disturbance in one or both eyes; in four of these cases there was a history of poor vision in one eye. The vision was moderately reduced in two cases in which the fundi were normal, and in one in which there was a mild pallor of both disks. The vision in these three cases was improved by proper glasses In the remaining twelve cases, the visual decrease was probably due to a beginning secondary optic atrophy, resulting from the bilateral choking of the disks.

---

* From the Section on Ophthalmology, the Mayo Clinic.

* Read before the Section on Ophthalmology at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

[1] Cushing, Harvey: Distortions of the Visual Fields in Cases of Brain Tumor, VI, The Field Defects Produced by Temporal Lobe Lesions, Tr. Am. Neurol. Assn., 1921, pp. 374-423.

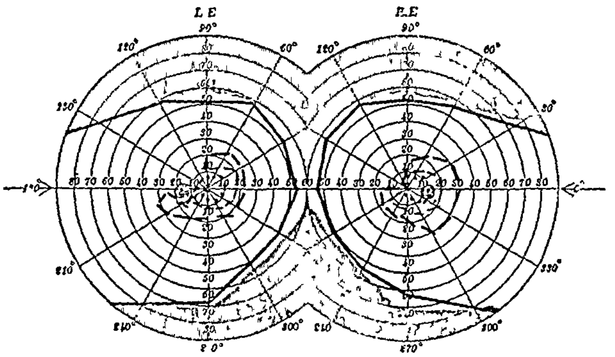

Fig. 3 —Vision right eye, 6/7; left eye, 6/5 Perimetric fields normal for form, left homonymous upper quadrant defect for blue, red and green; bilateral enlargement of the blind spots

Changes in the Optic Disks.—In forty-five cases there were bilateral choked disks ranging from one-half to 7 diopters swelling. The choking of the disk was higher on the contralateral side as often as on the homolateral side. The choking of the disk was equal in twenty-four cases. In one case there was definite bilateral secondary optic atrophy without edema, at first examination. In thirteen cases the fundi were normal, and in one there was mild pallor of both disks. In all the cases examined, except those in which the fundi were normal and one in which there was mild pallor of the disks, enlarged blind spots were noted.

Changes in the Perimetric Fields.—The field changes may be classified into (1) normal fields, (2) homonymous quadrant defects for colors, and form and colors, and (3) homonymous hemianopia for colors, and form and colors.

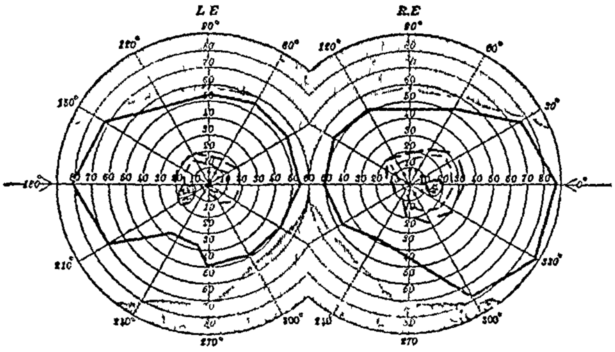

Fig 4 —Vision right eye, 6/7; left eye, 6/10 Left homonymous lower quadrant defect for form and colors, bilateral enlargement of the blind spots

1. In eight cases the perimetric fields were normal, both for colors and for form. In three of these the blind spots were enlarged, owing to the choking of the disks; the other five had normal fundi. All the eight cases were infiltrating gliomas, except one, which was a calcified hematoma.

2. There were ten cases of quadrant defect for one or more colors, the defect being in the upper quadrant in six cases, and in the lower quadrant in four. Homonymous quadrant defects for form and colors were present in fifteen cases, nine in the lower quadrant and six in the upper (Figs. 1 to 6).

3. Homonymous hemianopia for colors with form fields normal was present in three cases, while a complete homonymous hemianopia for colors and form was found in fifteen cases. In one case there was a complete macula preservation (Fig. 7 to 9).

Perimetric fields were not obtainable in nine cases because of the mental condition of the patient. In eleven cases of definite aphasia, nine homonymous quadrant defects for form and colors were accurately charted by a simple procedure. Instead of relying on the patient to tell when the object or color is seen, he should be instructed to tap the table as soon as he sees the moving object or the color just named. In this manner a very accurate defect can be elicited if present. Such defects can be verified by repeated examinations.

In this series of sixty cases, seventeen were definitely localized by the perimetric field defects only, as the neurologic findings were only general in character. In contrast, fifteen cases were definitely localized by the neurologic examination, while the ophthalmologic examination was of no localizing value. In six of these cases, the fields were normal; and in nine, the fields were not obtainable owing to the mental condition of the patient.

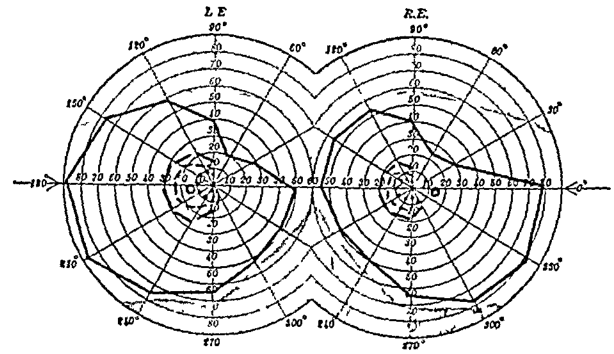

Fig 5 —Vision right eye, 6/10; left eye, 6/12. Right homonymous upper quadrant defect for form and colors; blind spots normal; fundi normal

Definite localization as to the site of the lesion was possible in forty-three of the sixty cases, from definite perimetric field defects alone, while definite localization was possible in forty of the sixty cases from the neurologic examination alone.

Oculomotor Changes.—The oculomotor changes were less common. There was paresis of the left abducens in six cases, ptosis of the left upper lid in two, partial external and internal ophthalmoplegia in two, and convergence weakness in three. All the oculomotor changes, except the convergence weakness, were located on the left side, but the tumors were equal on the two sides. The cause of this is not known, as the tumors were nearly equally divided, thirty-four in the left lobe and twenty-six in the right.

NEUROLOGIC CHANGES

The neurologic findings, in order of frequency, are: generalized convulsions, partial hemiplegia, transitory numbness of arm or leg, aphasia, jacksonian convulsions, unilateral incoordination, uncinate attacks, and hallucinations of taste and smell. None of the cases presented visual hallucinations of any type.

ROENTGENOGRAPHIC CHANGES

Nothing of localizing value was shown from the roentgenograms of the head, except in the three cases of endotheliomas and in two of calcified hematomas. There were fifteen cases of enlarged sella turcica with and without erosion of the posterior clinoid processes. The remaining cases were negative. The enlargement of the sella turcica is of no clinical importance when associated with bilateral choked disks, except that it is another sign of increased intracranial pressure. Although the enlargement is present in 25 per cent. of these cases, it is also present in about 50 to 60 per cent. of cases of lesions of the posterior fossae, especially the cerebellar. In chiasmal lesions, the sella turcica is enlarged and eroded in about 65 per cent. of the cases, but a lesion in this region is rarely associated with a bilateral choked disk.

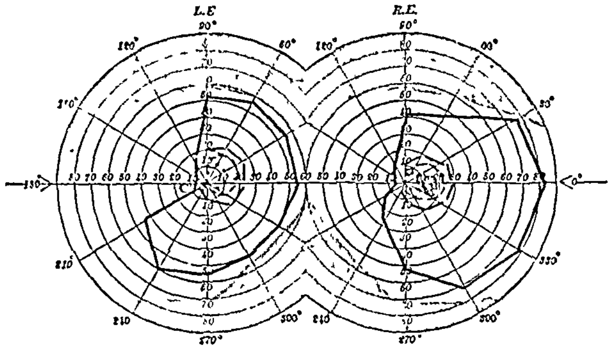

Fig. 6.—Vision right eye, 6/20; left eye, 6/10. Partial left homonymous hemianopia for form; complete homonymous hemianopia for colors; right blind spot enlarged.

SUMMARY

The ocular changes characteristic of temporal lobe tumors are found in the perimetric fields. In the early cases, the homonymous quadrant defects either for colors or for form or for both are common enough to be of great clinical significance, especially if these defects are associated with bilateral choked disks. This was true in forty-three out of fifty-one cases in the series in which the perimetric fields could be charted. No scotomatous defects were found.

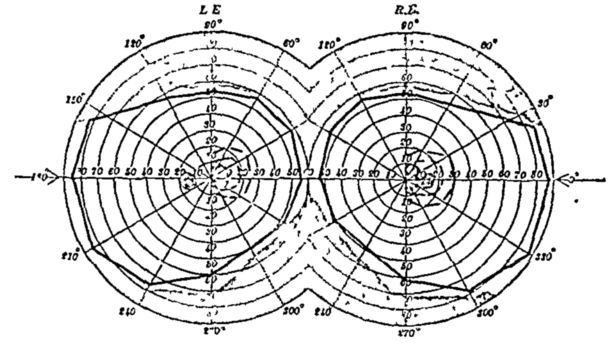

Fig. 7.—Vision right eye, 6/60; left eye, 6/30. Perimetric fields normal for form, left homonymous hemianopia for colors; bilateral enlargement of the blind spots

These findings agree closely with those published by Cushing in 1921, except for the absence of visual hallucinations in my series of cases. If the homonymous quadrant defect is added to the syndrome of Kennedy,[2] a definite syndrome can be established for temporal lobe lesions.

CONCLUSIONS

1. Temporal lobe tumors are common (sixty out of 168 verified cerebral tumors).

2. Homonymous quadrant defects, either for colors or for form, associated with bilateral choked disks, are characteristic of this location (forty-three out of fifty-one cases).

3. The choking of the disk was higher on the contralateral side as often as on the homolateral side.

4. Visual hallucinations were absent.

5. An ocular syndrome could be established for early temporal lobe tumors; namely, normal visual acuity, bilateral choked disks, and homonymous quadrant defects either for colors or form.

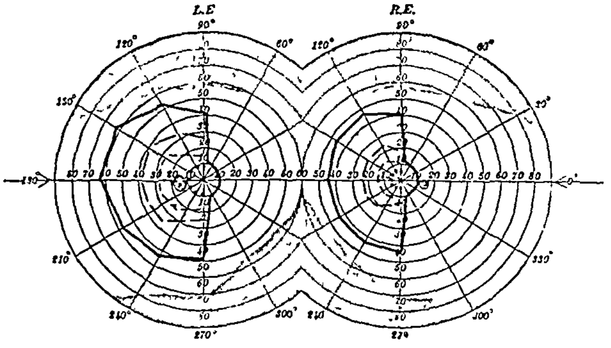

Fig. 8.—Vision right eye, 6/30; left eye, 6/15. Right homonymous hemianopia for form and colors, with preservation of both macula; left blind spot enlarged.

ABSTRACT OF DISCUSSION

Dr. Emory Hill, Richmond, Va.: Localization of tumors of the brain was facilitated by the studies of Foster Kennedy published in 1911, and again by Cushing in 1921. The former presented an accurate picture of temporal lobe tumor with one valuable piece of evidence omitted; namely, the homonymous defects in the visual fields especially prominent in lower or upper quadrants. The latter added this additional evidence, made possible by the use of very small test objects employed to outline the fields. As a result, it cannot be said that tumors of the temporosphenoidal lobe are the most difficult brain tumors to diagnose. Our attention has been drawn too strongly to the cerebellum, because of choked disks, and to the occipital lobes, because of homonymous defects. The combination of these two findings should point to a temporal lobe as the source of a space restricting lesion increasing the intracranial pressure and impinging on the geniculocalcarine visual fibers. Other symptoms of importance are the loss of the abdominal reflex on the opposite side, visual hallucinations, and uncinate attacks; but these should not be overemphasized. Dr. Lillie's contribution suggests that temporal lobe tumors may be much more frequent than we have believed; he finds sixty in a series of 168 cases of certified

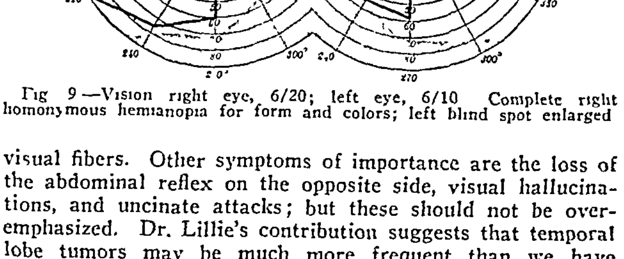

Fig. 9.—Vision right eye, 6/20; left eye, 6/10. Complete right homonymous hemianopia for form and colors; left blind spot enlarged

cerebral tumors, as compared to fifty-nine in Cushing's series of 276 cases. Visual fields were of great value in both these series, sometimes constituting the determining factor in localization. Uncinate attacks seem to have been of much less importance, while visual hallucinations were absent in Dr. Lillie's series. Cushing found them in thirteen cases. They are of quite striking character when they do occur, and can be distinguished from the vague sensations of light and colors noted in occipital lesions, being concrete images projected in the blind half of the field of vision. Several impressions have been gained from a series of these cases in the department of neurologic surgery, which I have had opportunity to study through the kindness of Dr. C. C. Coleman. The diagnosis, or even the suspicion, of brain tumors is not yet in the minds of the profession as a whole; we are seeing the cases too late. Accurate visual fields are impossible in many cases because of the mental state of the patients. When fields can be charted with any approach to accuracy, they usually show the homonymous quadrant defects which Dr. Lillie describes. Of equal importance, cases of tumor, which we have some reason to expect to find in the temporosphenoidal region, prove to be elsewhere when choked disk and field defects are absent. Unquestionably, the presence of homonymous defects and choked disks is strong evidence of tumor or its equivalent in the temporal lobe. Encroachment on the angular gyrus in left sided tumors furnishes additional valuable evidence through the speech difficulties produced. The value of ventricular puncture followed by air injection is worthy of mention. Compression of a ventricle by a tumor on the corresponding side, and obstruction preventing the passage of air from one side to the other, may assist materially in the diagnosis.

---

[2] Kennedy, Foster: The Symptomatology of Temporosphenoidal Tumors, Arch. Int. Med. 8: 317-350 (Sept.) 1911.

Dr. G. E. de Schweinitz, Philadelphia: The frequency with which distortions of the fields occur with tumor of the temporal lobe is attested by the fact that in only eight of his series of sixty cases "the perimetric fields were normal." In Cushing's notable essay, reliable perimetric charts were obtained in thirty-nine of his fifty-nine temporal lobe cases, and in only six of them "the fields were at all times normal." Naturally, before a visual field can be labeled "normal," the perimetric work must possess the quality of exactness; quantitative perimetry must be employed.

Although color perimetry, for various reasons, is often far from satisfactory, and most of the visual results can be obtained with carefully graded white test objects, it is not quite safe to disregard color fields or, more accurately, what may be discovered with color tests. Doubtless all of us will agree that one examination should be used as a check against the other, but with the greater reliance on the quantitative form and white field, on account of their greater threshold of accuracy. Cushing believes that the homonymous field defects, such as he and Dr. Lillie portray, indicate an involvement of the temporal lobe of the optic radiations, although he notes that tract involvement may be expected as a late feature of all temporal lobe tumors.

We all know that homonymous hemianopia, complete or quadrant, is not infrequently found in pituitary body tumors due to tract interference. In my own series of more than 100 cases it was evident in fully 6 per cent. of the cases, and this does not include those charts in which there was a "tendency" to a homonymous defect. In such circumstances the homonymous quadrant defects of temporal lobe tumor and of certain types of hypophysial disorder are strikingly similar. Naturally, the usual presence of choked disk in the temporal lobe cases and its rarity in pituitary body tumors would be a differential point of importance. A perimetric differential sign of value, on which Traquair dwells, is that in the pituitary body cases, a scotoma, central or paracentral, is frequent, while usually, if not always, it is absent in the temporal lobe cases. In our author's series "no scotomatous defects were found—a confirmation of the statement just made. Traquair believes the scotomas of pituitary body disease represent an acuity of pressure and depend on disturbance of the vascular supply of the papillomacular bundle. Fully admitting the importance of this explanation, it has seemed to me that the possible toxic origin of these scotomas cannot be entirely disregarded, and Dr. Schaeffer and I endeavored to determine the pathway whereby such toxins, if it be conceded that they can be elaborated, could reach the papillomacular fibers.

Dr. A. W. Adson, Rochester, Minn.: I am interested in the series of cases Dr. Lillie has reported, since I operated on the patients at the Mayo Clinic. I wish to emphasize the value of the ophthalmologic findings. Brain tumors of the cerebrum usually present symptoms of intracranial pressure before localizing symptoms develop. While ventriculography is of some value in localization, it cannot be relied on in all cases, nor is the Bárány examination without error. I have, therefore, frequently been compelled to wait for the development of reflex disturbances at the onset of a motor or sensory paralysis. Thus, the results of careful and thorough perimetric findings have been of additional value in aiding early localization.

Dr. W. I. Lillie, Rochester, Minn.: Dr. de Schweinitz raised a question as to the differential diagnosis of early chiasmal and early temporal lobe lesions. I now have in manuscript form a study of six verified chiasmal and six verified temporal lobe lesions, all showing an homonymous notching of form and color fields. The fundi were normal in all the cases. In the chiasmal lesions there was usually a decrease in the visual acuity, and a marked enlargement of the blind spots, while in the early temporal lobe lesions before the appearance of choked disks, the blind spots were normal in size, and the visual acuity was good. In a previous paper on chiasmal lesions, all the early cases in which the fields of vision were still sufficient to map out the blind spots, all were found to be enlarged, and the temporal fields defects for form or colors were continuous with the enlargement of the blind spots. This has not been found in the temporal lobe lesions, even when choked disks are present.

PHYSIOLOGY OF THE LIVER

PRESENT STATUS OF OUR KNOWLEDGE *

A. J. CARLSON, Ph.D.
CHICAGO

The following methods are employed in the investigation of liver function in man and in animals:

1. The secretory or excretory functions of the liver can be investigated by biliary fistulas in man and in animals or in acute experiments in animals by collecting the bile direct from the duct. Thus, the chemistry of the bile both in the gallbladder and as directly secreted by the liver has been investigated and is approximately known. The same method yields data with reference to secretagogues that may stimulate production of bile, the relation of foods to bile secretion, and in acute experiments it is possible to study the evacuation mechanisms of the duct and gallbladder systems aside from the production of bile by the liver cells.

2. In acute experiments it is possible to collect portal and hepatic blood both during digestion and in fasting. This method has yielded important data on the liver function. The same method has also been employed in investigating various possible detoxicating functions of the liver. The substance or substances under investigation is introduced into the portal vein and an analysis of the concentration or of the change made as they appear or fail to appear in the hepatic vein blood.

3. The Eck fistula operation in experimental animals has also yielded data of importance on the problem of

---

* From the Hull Physiology Laboratory of the University of Chicago.

* Read before the joint meeting of the Section on Pathology and Physiology and the Section on Gastro-Enterology and Proctology at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

liver function. This operation is the anastomosis of the portal vein with the inferior vena cava so that all of the portal blood is shunted into the general circulation. This method has yielded important data in two directions: (1) the rôle played by the substances absorbed from the alimentary canal in the stimulation of the liver to bile production; (2) data on the apparent detoxicating function of the liver, particularly in connection with protein absorption and protein metabolism.

4. Chemical analysis of the blood and urine in cases of spontaneous liver disease or experimental injury as by specific liver poisons have also yielded some data of importance.

5. Extirpation of the liver in animals has added further data of importance, particularly in the relation of the liver to blood sugar, urea and uric acid. It has also raised the question of why abolishing the liver function, as accomplished by extirpation of the liver, in otherwise healthy animals is followed by death within from twenty-four to thirty-six hours.

6. Direct chemical and histologic analyses of liver tissue have yielded data of importance as to the storage of glycogen and fats in the liver, the storage of iron and other substances and the formation or storage of enzymes, as well as data bearing on the phagocytic activity of the endothelial cells of the liver capillaries.

7. Finally, perfusion of the excised liver has also contributed toward our knowledge of liver function.

It is a commentary on the complexity of the liver functions and the difficulty in securing conclusive data that, despite the pursuit of these various methods by competent investigators, both in the laboratory and in the clinical branches, much remains obscure and uncertain in the matter of liver function. Nevertheless, certain facts are fairly well established, and I propose briefly to enumerate these facts. There is one great difficulty, however, in stating and discussing these apparently established facts; namely, that we cannot always infer that the physiologic disturbances noted after various diseases of the liver are direct or indirect results of the impairment to liver function. Obviously, the results of liver impairment will be the more grave in proportion as any particular function is an exclusive liver function.

I. THE RELATION OF THE LIVER TO COAGULATION OF THE BLOOD

We have fairly conclusive experimental evidence that fibrinogen is produced in the liver or under the direct influence of the liver; at least this appears to be true for regeneration of fibrinogen after hemorrhage. It is also true that decrease in the concentration of the blood fibrinogen has been reported in some cases of liver injuries; but it is striking that there may be a great deal of pathologic change in the liver without disturbance of the fibrinogen concentration or blood coagulation. This can probably be explained in the light of recent evidence that 15 or 20 per cent. of the normal quantity of liver tissue suffices to meet the ordinary bodily needs (Mann). It is further known that under the influence of proteoses the liver produces substances that both accelerate and retard coagulation. Whether the latter group of substances, "antithrombin," is identical with Howell's "heparin," a substance obtained from the liver by Howell which decreases coagulation, even in vitro, is not known. There are further indications of the relation of the liver to blood coagulation in various hemorrhagic diseases, particularly in infancy.

II. THE RELATION OF THE LIVER TO PROTEIN METABOLISM

That the liver in mammals is the chief organ producing urea from cleavage products of protein metabolism and from ammonia absorbed from the alimentary canal has long been held as probable, although not so definitely proved as to go unchallenged. Folin and his co-workers have reported experiments which they interpret as showing that in mammals uric acid, for example, is destroyed principally in the blood; but the recent work of Mann and his associates by methods of total extirpation of the liver seems to show that the liver, after all, is the main organ that forms urea and destroys uric acid. Of course, even these experiments of Mann are open to the objection that the failure to produce urea and destroy uric acid after liver extirpation may be due to indirect impairment of other tissues or, changes in the blood composition. At present the latter alternative seems to me the least probable one. Liver perfusion experiments, as well as portal and hepatic venous blood chemistry, seem to show a considerable deamidization in the liver, but this is probably not an exclusive liver function. These processes probably go on to a certain extent in every living cell in the body. While the so-called meat poisoning following high protein diet in Eck fistula dogs indicates a definite rôle of the liver in connection with taking care of some of the immediate end-products of the protein digestion or the regulation of cellular protein metabolism, neither blood nor urinary analysis in such meat intoxication has yielded the final answer as to the precise nature of these processes or even the specific substances responsible for the symptoms of intoxication. The intoxication does not appear to be due to ammonia.

III. RELATION OF THE LIVER TO CARBOHYDRATE METABOLISM

Since the fundamental discovery of Claude Bernard of glycogen storage in the liver, a great amount of work has centered on this problem, particularly in relation to hypoglycemia and hyperglycemia, diabetes mellitus, and various forms of glycosuria. The possible direct nervous control of this phase of liver function has also been investigated with, at present, indecisive results. Particularly noteworthy are the facts that in severe diabetes mellitus or experimental diabetes following total extirpation of the pancreas, the liver cells practically lose their ability to store glycogen despite the high sugar content of the blood. This type of liver failure may be present without any evidence of serious impairment of other liver functions. The fact that the liver can again store glycogen on administration of the pancreatic hormone, insulin, is an illustration of reciprocal dependence of the liver cells on hormones or substances produced in other organs of the body. There are indications in the experimental literature of similar dependence of the normal detoxicating processes of the liver on hormones from the parathyroid glands, although in this case the data are by no means as direct or as conclusive as in the case of dependence of the liver cells on the pancreas hormone for normal storage of glycogen. The glycogen storage rôle of the liver cells is, of course, shared by the muscle tissue and other tissues of the body, although the recent work of Mann on liver extirpation seems to show that after total loss of the liver the animal completely loses its ability to regulate the level of the blood sugar. This is an important fact that only the liver extirpation method could have yielded. This regulation does not seem to depend on the quantity of glycogen in the liver, although when liver glycogen is present this source of glycogen is also used to mobilize blood sugar in hypoglycemia. Evidently, the liver produces some substance other than sugar necessary for the correlation of the blood sugar and tissue sugar; or else in the absence of the liver, toxic substances developed in the blood and the tissues upset the normal mechanism serving to maintain a fairly regular level of blood sugar, even under extreme conditions of carbohydrate ingestion or sugar utilization by muscular work. The same fact is indicated by Eck fistula dogs after chronic protein intoxication in which we have a progressive liver degeneration and persistent hypoglycemia (S. A. Matthews). The liver seems to be the main, if not the only, organ capable of forming glycogen from fructose and galactose.

IV. THE RELATION OF THE LIVER TO FAT METABOLISM

This problem is at present not well worked out. Direct chemical analysis of fats found in the liver, at least under certain conditions, seems to show that the liver desaturates fats. This has been interpreted as proving that the liver in this way prepares the fat for oxidation in other tissues, but it is still an open question whether other tissues besides the liver do not also have the faculty of desaturating and thus directly oxidizing fats. A curious and interesting relation seems to obtain between glycogen storage and fat storage in the liver in that when liver glycogen is diminished fat storage is increased.

V. BILE FORMATION

The formation of bile by the liver appears to be a process both of excretion and of secretion. Apparently the bile pigment can be to a large extent formed in tissues outside the liver. It is probably also formed in the liver itself, since the liver is one of the main sites of final solution of the erythrocytes; but on the basis of recent work by Mann and his associates, we must assume for the present that as regards the bile pigment the liver acts mainly as an excretory organ, and this view is in harmony with the well known fact that jaundice may appear as a result of an excess rate of hemolysis when there is no obstruction at all in the bile passages and, therefore, a free flow of bile from the liver into the intestines. Under these conditions it is obvious that the production of bile pigment from liberated hemoglobin exceeds the excretory capacity of the liver and hence some of the symptoms of jaundice. The bile salts, or rather the bile acids, appear to be specifically synthesized in the liver; hence these are true secretory products of liver activity. The liver, like other tissues, probably has the power to form cholesterin; the cholesterin of the bile may therefore be partly an excretory and partly a secretory function, depending on the activity of the liver cells. The excretory rôle of the liver is further indicated by the great number of substances artificially introduced into the body which appears in the bile. Some of these substances are at the same time excreted by the kidneys; others, again, like tetrachlorphenolphthalein, appear to be exclusively excreted by the liver. This phase of liver action has been extensively exploited in recent years with the view of developing reliable clinical tests of the liver functions. It must be noted that such tests touch only the excretory capacity of the liver. They do not touch the other fundamental liver processes, and one must be careful in drawing conclusions as to liver function on the basis of excretory tests alone, in view of the fact that some functions of the liver may be impaired at the same time that others seem to be relatively unimpaired.

VI. FUNCTIONS OF THE GALLBLADDER

The gallbladder seems to be an anomaly, since it is absent completely in some mammals and it can be extirpated in man and the experimental animal without any demonstrable influence on liver function or bile formation. It is definitely demonstrated that the bile in the gallbladder is concentrated; that is, there is considerable water absorption. Apparently some mucin is added to the bile in the gallbladder. The gallbladder itself is feebly contractile by virtue of the small amount of muscle tissue in its wall. We must remember that the entire liver, including the gallbladder and the duct system, is a diverticulum of the intestine, and we must therefore expect some remnants in structure and function in the duct system from this original intestinal anlage.

Bile is continually produced by the normal liver even in the fasting man and animals, and it continues to flow into the intestine provided there is no obstruction to the duct system, even during prolonged fasting. I feel that the rôle of the gallbladder as the storage organ for bile has been greatly exaggerated, and many textbooks of physiology err when they state that bile does not enter the intestine except during digestion. The inference from such a statement is that bile secreted during fasting is stored in the gallbladder. The gallbladder is not of sufficient size for such storage, even though considerable absorption of water from the bile takes place in that organ.

Any one working on large numbers of laboratory animals must be struck with the relatively uniform size of this organ at necropsy. We find in general the same content of bladder bile in the same species of animal irrespective of whether the animal is at the height of digestion or in a prolonged fast. The secretory pressure of bile is relatively low. Various figures are given by different observers. It is further reported that the secretory pressure of bile is lower than the normal tonus of the so-called sphincter of Oddi, a system of smooth muscle fibers at the entrance of the bile duct into the lumen of the duodenum. The resistance to the flow of bile into the duodenum is probably determined more by the tonus of the muscle wall of the duodenum than by the tonus of the so-called sphincter of Oddi, since the bile duct runs for some distance obliquely through this muscle layer. The state of tonus or periodic contractions of the duodenum must therefore be of importance in the flow of bile into the intestines, irrespective of any contractile power of the gallbladder or secretory pressure in the liver itself. Food in the stomach and intestines leads to increased secretion of bile. Hydrochloric acid or acid gastric juice in the duodenum leads to increased flow of bile. Since there is a continuous secretion of more or less acid gastric juice into the stomach, even in fasting, we have at least one mechanism that may play a rôle in the continuous production of bile by the fasting liver, although, of course, continued destruction of erythrocytes as well as the continuous absorption of bile acid from the intestine are additional mechanisms. There is indisputable evidence that the bile salts themselves are true cholagogues. It is also true that the "secretin" of Bayliss and Starling, when injected intravenously, causes some increase in the secretion of bile; but it is at present doubtful whether this secretin in the sense that Bayliss and Starling used the term is a normal mechanism either for pancreas or for liver secretion. Aside from foods, acid gastric juice, the bile salts or whole bile, there are at present no definitely demonstrated cholagogues. This is a curious commentary on numerous kinds of "liver pills" and "liver remedies" that have grown so luxuriantly from time to time in the hothouse of therapy. It has been shown that part of the increased bile production in the response to foods is due to the absorption of substances from the alimentary canal rather than to the reflex action, since bile secretion in response to a meal is decreased in the Eck fistula dog, in which the portal blood is shunted into the general circulation and only a small fraction of the digestive products thus comes into contact with the liver through the hepatic artery.

VII. RELATION OF THE NERVOUS SYSTEM TO LIVER FUNCTION AND BILE EVACUATION

The relation of the nervous system to liver function and bile evacuation forms an interesting and challenging chapter in the literature on liver function in health and disease. Most of the problems remain at present incompletely solved. The following statements may be briefly made:

1. Section of both vagi and both pairs of splanchnic nerves induces no demonstrable change in liver function or in evacuation of bile into the intestines. This seems to show that the extrinsic nerves connecting the liver and the bile systems with the central nervous system are not necessary in normal liver process. In this respect we find a parallel in the normal function of the stomach and intestines after complete denervation. Conclusive as these experiments seem, they do not permit the corollary that the nerves connecting the liver and the bile system with the central nervous system play no rôle in normal or abnormal liver functions.

2. The famous "puncture" experiments of Claude Bernard, that is, injury to the medulla leading to hyperglycemia from rapid liberation of liver glycogen, have been abundantly confirmed but not yet completely analyzed. Macleod has reported the following facts:

(*a*) Stimulation of the peripheral end of the splanchnic nerve causes liberation of liver glycogen. The same stimulation, after previous excision of the suprarenals on the same side, does not produce excess liberation of the liver glycogen.

(*b*) Stimulation of the splanchnic nerves after section of the hepatic plexus also fails to produce liberation of liver glycogen. Hence, splanchnic nerve stimulation apparently does not produce hyperglycemia by liberation of epinephrin. However, stimulation of the splanchnic nerve peripheral to the suprarenal produces hyperglycemia when the suprarenals are intact, but not when they are extirpated. Macleod therefore concludes that the splanchnic nerves contain true glycogen fibers to the liver, but that the action of these nerve fibers on the liver cells depends on something given off to the blood by the suprarenals. This phase of the problem requires further investigation before even these conclusions can be accepted.

3. Cannon and his co-workers have reported that stimulation of the hepatic nerves liberates something in the blood which has a direct stimulative action on the denervated heart. This is particularly true, according to Cannon, when the experiment is made on the animal at the height of digesting a protein meal. In regard to most of the present experiments on the rôle of the hepatic nerves in liver function, it must be noted that it is extremely difficult to isolate the effect of vasomotor changes in the liver due to such stimulation from the possible effects of other types of nerve fibers in the same nerve trunk on the hepatic cells direct, since many of the liver functions, notably the storage of glycogen, are sensitive to the hydrogen ion concentration, which, of course, is quickly changed by liver vasoconstriction.

4. As regards the extrinsic nerve control of the contractions of the gallbladder and the musculature of the bile passages, and particularly the sphincter of Oddi, there are few fields in experimental physiology in which so much serious work has been done with so few conclusive results. In crucial experiments one may obtain a feeble contraction of the gallbladder on *the stimulation of the peripheral end of the cut vagi.* Investigators have also reported that this stimulation causes relaxation of the sphincter of Oddi, and that stimulation of the peripheral end of the cut splanchnic nerves, on the other hand, causes relaxation of the tonus of the gallbladder and contraction of the sphincter of Oddi. Equally competent observers have failed to obtain the latter results.

Now, from the fact that both vagi and the splanchnic systems send motor as well as inhibitory fibers both to the gastric and possibly to the duodenal musculature, it is highly probable that this original primitive nerve supply is also present in the gallbladder and hepatic duct system. The fact, however, that no disturbance follows section of these nerves seems to show that it is of no fundamental or primary importance in health, and that reflexes of prime importance involving the gallbladder and duct system are local, as in the case of the coordination of gastric and intestinal motility.

5. When food or acid gastric juice enters the duodenum, duodenal motility is initiated or augmented both by local and by long reflexes, and increased secretion is produced in the stomach, pancreas and liver. Some increased tonus may be induced both in the gallbladder and in the duct system, and these, aided by peristalsis of the duodenum and by increased secretory pressure of bile, probably account for the copious flow of bile into the intestine parallel with digestion.

6. The practical aspect of this question has been emphasized in the last few years by the introduction of the so-called Meltzer-Lyon method of nonsurgical drainage of the gallbladder. This method assumes that on the introduction of magnesium sulphate directly into the duodenum by means of the duodenal tube there follows relaxation of the sphincter of Oddi and contraction of the gallbladder, and hence a drainage of the bile from the gallbladder and duct system to a degree not produced by foods, water or gastric juice in the duodenum, or by magnesium sulphate given by mouth. I have seen no satisfactory data proving these assumptions, and I question them in toto on the basis of what is known concerning the physiology of the liver, the duodenum and the liver excreting systems.

I have no right to and I do not propose to question the reports of the effects on patients of this therapy, but I should like to see controls and statistics like those that we require in the therapies of other diseases. What is the natural history of the maladies in which this drainage has been used? It has been used in migraine, in nausea, in undernutrition and in many gastro-intestinal disorders of obscure etiology and uncertain duration. What is the average duration of these maladies in the absence of duodenal drainage? We cannot establish facts or reliable therapies in this or any other field by the ordinary testimonial method. Magnesium sulphate is, of course, an old and well known stimulant to intestinal peristalsis and defecation. When introduced into the duodenum, some of it will escape down into the small intestine and the large bowel, even though attempts are made to drain the duodenum after a minute or two. I cannot see that the clinical results reported can possibly be due either to the drainage of the gallbladder or to drainage of the liver and the pancreas, or even to evacuation of some of the bile by way of the duodenal tube, as I know no evidence proving that this bile is injurious when left in the intestines.

MODIFIED PHYSIOLOGIC PROCESSES FOLLOWING TOTAL REMOVAL OF THE LIVER *

FRANK C. MANN, M.D.
ROCHESTER, MINN.

The physiologic changes that occur when the liver is extirpated have been studied for several years in our laboratories. In this paper I shall present briefly a general review of the results of our experiments on the changes in physiologic processes produced by the sudden and complete removal of the liver, and discuss them in relation to the functions of the liver. Although a great many changes have been observed, data concerning the modification of carbohydrate metabolism, protein metabolism and the major constituents of the bile mainly will be presented.

Several different species of animals have been employed in the experiments, such as the goose, the duck, the frog, the turtle and the fish. While the general effects of hepatectomy have been the same in all species of animals, the variation probably depending on the difference in metabolism of the various species, I shall emphasize the results as obtained in the dog.

The method employed for removal of the liver in the dog, as well as the procedure necessary for maintaining the animal in good normal appearance and physiologic condition, has been presented. In this connection it should be noted that the success of these studies of the effect of total removal of the liver has been due to two factors: (1) the development of a method for total removal of the liver which is comparatively free from complications and does not impair the venous return from the viscera and lower extremities, and (2) the discovery that a certain level of blood sugar is necessary to maintain life, that normally the liver maintains this level, and, finally, that following removal of the liver the blood sugar level could be maintained artificially by the administration of correct amounts of glucose. By the proper utilization of these two principles, a dog could be maintained in a normal appearing condition for many hours after the loss of the liver. This furnished an opportunity to observe the changes in physiologic processes produced by the sudden loss of hepatic function over a period of several hours in an animal appearing no different from any other animal that has been subjected to etherization and operation. As a review of the pertinent literature on the subject has been given in other papers, it will not be presented here.

MODIFICATION OF CARBOHYDRATE METABOLISM FOLLOWING REMOVAL OF THE LIVER

Removal of the liver completely severs a part of the vital normal process of carbohydrate metabolism. Immediately after removal of the liver the animal appears normal for several hours, but the blood sugar level begins progressively to fall. When it reaches a certain rather definite level, a characteristic group of symptoms develops; they usually occur in an order paralleling the decrease in concentration of sugar in the blood. If glucose is injected in proper amounts when the animal is in the moribund condition associated with the low blood sugar, there is an immediate return to normal. After a period of time, which in general depends on the amount of glucose injected, the blood sugar again becomes low, the characteristic symptoms develop and injection of glucose restores to normal. This process can be repeated many times with the same result, although usually progressively increasing amounts of glucose are necessary to maintain the blood sugar above the hypoglycemic level. Finally, however, another group of symptoms develops, entirely different from those occurring when the blood sugar is low, and the animal dies, regardless of the amount of glucose administered. Thus far it has not been possible to determine the cause for the second group of symptoms and the resulting death. If glucose is administered before the blood sugar has decreased to a low level, the characteristic symptoms associated with the hypoglycemia do not develop.

Many substances were administered to the moribund hepatectomized animal to determine whether the curative effect of glucose was specific or whether other substances would replace it. No other was found except a few other sugars which are readily converted into glucose in the blood stream. Other substances that might possibly be substituted for glucose or converted into glucose, if sufficient time were given for such changes to take place, were tried by administering them in suitable and comparable amounts immediately after removal of the liver. The blood sugar and the condition of the animal were carefully observed to determine whether the decrease in blood sugar and the development of the symptoms were delayed. Among the substances thus employed were glycocoll, lactic acid, and levulose. None of these substances produced any effect when the animal was in the moribund condition. Nor did glycocoll or lactic acid produce any effect when injected at frequent intervals immediately after removal of the liver until the animal was moribund. The progressive fall in the blood sugar level, and the time after removal of the liver at which the hypoglycemic condition developed, were not in any way affected. It was possible to keep the hepatectomized animal alive, but not in a normal appearing condition, by the injection of levulose, beginning the injections immediately after operation. It was necessary to administer the levulose more frequently and in larger amounts than the glucose, and the animal did not exhibit the same general well being as when glucose was used. Furthermore, levulose maintained life for a shorter time.

It is not necessary to describe here the characteristic group of symptoms that occur in association with the

* From the Division of Experimental Surgery and Pathology, the Mayo Foundation.

* Read before the joint meeting of the Section on Pathology and Physiology and the Section on Gastro-Enterology and Proctology at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

low blood sugar following hepatectomy and the strikingly beneficial effect produced by the injection of glucose in the moribund condition of hypoglycemia, not only because such a description was given somewhat in detail in the first articles, but also because, with the recent discovery of insulin, it was soon found that an almost identical hypoglycemic condition could be produced with it as had been produced in hepatectomized dogs.

In this connection it might be well to state that our observations support the idea that these characteristic symptoms are directly dependent on the hypoglycemia. Furthermore, while no explanation of the cause of the hypoglycemia after hepatectomy can be given at present, it is certain that at least part of the lost glucose is used for the maintenance of metabolism, and in all probability the symptoms of hypoglycemia are directly due to the loss of the available foodstuff.

After it had been found that the liver was necessary to the maintenance of the normal blood sugar level, it seemed desirable to know whether it was also responsible for producing the increases in blood sugar. The hyperglycemic conditions can be divided into two types: (1) the more or less permanently sustained hyperglycemia that follows the removal of the pancreas, and (2) the transitory hyperglycemia that follows states of asphyxia, excitement or operative trauma, and the administration of certain drugs, such as epinephrin.

The effect of hepatectomy was studied at various periods after pancreatectomy. If the liver and pancreas are removed at the same time, no different result is observed than when the liver alone is removed. If the liver is removed after definite and marked hyperglycemia has occurred following pancreatectomy, the blood sugar decreases seemingly more precipitately than in the normal hepatectomized dog, and the characteristic hypoglycemic symptoms develop. Usually such symptoms occur at a much higher blood sugar level if the pancreas has been removed some hours previous to the removal of the liver than if only the liver has been removed. The beneficial effect of glucose is very transitory in the hypoglycemic, pancreatectomized animal.

The effect of hepatectomy on the transitory hyperglycemia produced by anesthesia and operation, asphyxia and epinephrin was investigated. In no instance did an increase in blood sugar occur following these procedures in a hepatectomized animal. As a matter of fact, it was not possible to produce an increase in blood sugar in a hepatectomized animal except by the administration of glucose or related sugars.

The glycogen content of the muscle of the hepatectomized animals was found to decrease while the blood sugar was decreasing. However, the muscle glycogen rarely decreased more than 50 per cent. between the time of operation and the beginning of the moribund period. Furthermore, there was always an amount of glycogen in the muscles when the animal was moribund which, if it had been converted into glucose and added to the blood stream, would have been sufficient to maintain the blood sugar considerably longer. If, after an animal has been moribund, glucose is injected in amounts sufficient to keep the blood sugar above normal, the muscle glycogen will increase after a few hours, and there may be more than before the liver was removed. Muscle glycogen may also be increased in the hepatectomized animal by the injection of lactic acid and levulose.

As hepatectomy so greatly alters the metabolism, it was desirable to determine whether the respiratory quotient and total heat production were affected by the loss of the liver. It was also hoped that these studies might furnish some clue to what happened to the glucose that disappeared after hepatectomy. Accordingly, animals prepared for removal of the liver were trained for the basal metabolism observation. After fairly constant results had been obtained with regard to the respiratory quotient and total heat production, as well as the effect of the intravenous injection of various amounts of glucose on the same factors, the liver was removed. Observations were made on the metabolism of the hepatectomized dog during the normal period after operation, when hypoglycemic and moribund, and during the recovery after the injection of glucose.

This series of experiments was very difficult, and there were many possible sources of error which could not be wholly eliminated. The data at present do not justify definite conclusions. It can be stated, however, that the respiratory quotient appears to increase after removal of the liver and that the total heat production decreases as the animal becomes hypoglycemic. Both the respiratory quotient and the total heat production increase after the intravenous injection of glucose, and the response is seemingly more marked in the hepatectomized animal than in the normal animal.

MODIFICATION OF PROTEIN METABOLISM BY REMOVAL OF THE LIVER

Estimations of the importance of the liver in relation to protein metabolism and the various nitrogenous constitutents of the blood vary. Certain observers consider that this organ is very important to protein metabolism and that it is the sole source of some of these nitrogenous constituents; others deny that the liver has anything more to do with protein metabolism and the function of these nitrogen constiuents than any other tissue of the body.

Experiments showed that protein metabolism is greatly modified by removal of the liver. They definitely proved that the liver has a great deal to do with the metabolism of this major foodstuff and the origin of some of the nitrogenous constituents of the blood. The manner by which removal of the liver affects protein metabolism can be best illustrated by a separate consideration of the effect of hepatectomy on the various nitrogenous constituents of the blood.

The urea content of the blood following removal of the liver depends entirely on the amount excreted from the body. If the kidneys are removed at the same time as the liver, or if the animal becomes anuric after hepatectomy, the urea content of the blood remains the same or falls slightly below its preoperative level. The decrease noted in such experiments can be accounted for by the amount lost in the saliva and vomitus. If the secretion of urine is maintained after hepatectomy, there is a marked decrease, not only in the urea content of the blood, but also in the amount eliminated through the urine and in the urea content of the tissues of the body, as the muscles. If the kidneys are removed from eight to twenty-four hours before the liver is removed, so that at the time of hepatectomy the blood urea level is far above normal, no further increase in blood urea takes place. The urea found in the blood and tissues and excreted after operation accounts for all the urea present at the time of operation. These results conclusively prove that the production of urea absolutely ceases after removal of the liver.

Normally, the dog does not show more than a trace of uric acid in the blood or excrete uric acid in any appreciable amount in the urine, as this nitrogenous constituent is further oxidized to allantoin. After removal of the liver, uric acid appears in the blood, and concomitantly, a great amount will be excreted in the urine. The amount of urates excreted in the urine of a hepatectomized dog is often so great that about half the volume is a heavy flocculent precipitate, and so concentrated that crystals form almost immediately after the urine is voided. Uric acid injected into the normal dog is very quickly destroyed. Uric acid injected into the hepatectomized dog may be almost entirely recovered in the urine, or, if the kidneys are removed, the injected uric acid will approximately all be found in the muscles and blood. These experiments prove conclusively that the destruction of uric acid in the normal dog depends on the presence of the liver, since the destruction ceases as soon as the liver is removed. They suggest that the liver in man may be of considerable importance in the metabolism of the purins.

Removal of the liver is followed by a progressive increase in the amino-acid content of the blood. If the kidneys are removed at the same time as the liver, the amino-acids increase more rapidly in the blood. One amino-acid, glycocoll, has been injected intravenously to determine whether it would in any measure take the place of glucose, either in preventing the development of the hypoglycemic symptoms or in restoring the animal to normal after they had developed. Glycocoll never produced any beneficial action. It would thus seem that it could not in any measure take the place of glucose in the hepatectomized animal. There was never any evidence of the formation of urea following the injection of amino-acids into the hepatectomized animal. These observations, taken as a whole, would imply that the normal mechanism for the utilization of amino-acids is probably destroyed by the removal of the liver.

The changes in the blood creatinin after removal of the liver depend entirely on the kidneys. If the kidneys are active, the blood creatinin does not change. If the kidneys are removed as well, or the animal becomes anuric, the creatinin increases in the blood at the same rate as when only the kidneys are removed. The creatin behaves in a similar manner. The liver would therefore appear to take no specific part in the creatinin-creatin metabolism.

The result of experiments on the effect of removing the liver on the formation of ammonia are not entirely satisfactory. There is a shift in the relation of urea and ammonia nitrogen in the urine, with a relative increase in ammonia nitrogen compared to the decrease in urea nitrogen. There does not appear to be an increase in the total amount of ammonia in the urine or in the tissue. The liver probably does not have any special part in the production of ammonia.

THE CONSTITUENTS OF THE BILE AFTER REMOVAL OF THE LIVER

Bile production is probably the best known and one of the most important functions of the liver. The bile is composed of several substances, of which bilirubin, the bile salts and cholesterol are considered the most important. One of the most debated questions concerning the action of the liver has been whether it is responsible for elaborating these three important constituents of the bile or whether they are formed elsewhere in the body and merely excreted by the liver. Estimating the amount of these substances in the blood before and at various times after hepatectomy offered an excellent method of studying this problem.

The results of experiments are very definite as regards bilirubin. This important constituent of the bile can be formed in tissues other than the liver. A yellow color has consistently developed in the urine, plasma and fatty tissue of all hepatectomized animals living more than six hours. The yellow in the urine is usually observed in the first specimen secreted after operation. In from three to six hours after removal of the liver, the plasma becomes tinged with yellow, which usually increases progressively until death. A yellow tinge also develops in the sclerotics of the animals that live sixteen hours or more after operation, and can be sometimes seen in the mucous membranes as well. At necropsy all the fatty tissue is a dirty yellow. This yellow pigment, wherever found, was positive for bilirubin in all the chemical tests employed, including all those that are generally accepted.

The accepted chemical tests for bilirubin are not considered absolutely specific, since a few other substances will give a positive reaction. These substances, however, are not normal constituents of the blood. It would seem, therefore, that while the possibility does exist that a substance other than bilirubin might occur in the blood which would give the bilirubin reaction, the chemical identification of the pigment is practically definite. The possibility must also be considered that there may be substances intermediate between hemoglobin and bile pigment, as found in the bile, which would give a positive chemical test for bilirubin. It is possible that these intermediary substances could be formed outside the liver, but that the elaboration of the pigment in its final form goes on only in the liver. All observations were opposed to these views and tended to prove that the pigment which accumulated in the hepatectomized dog was the same as the pigment found in the bile. As all the accepted chemical tests gave a positive reaction for bilirubin with the pigment in the blood of the hepatectomized animals, only the physical methods of identification of the pigment remained. Through the cooperation of Sheard of the Section on Physics the pigment was tested in the only other known manner; namely, by determining the curve of its light transmission. The liver was removed from one dog, and the gallbladder was removed and the common bile duct ligated in another dog. When the plasma had become markedly yellow in each animal, about eighteen hours after operation, specimens of plasma from each dog were given to Sheard to determine the curve of light transmission with the spectrophotometer. The curves obtained from the two pigments were identical. This would seem to add the final evidence that the pigment which develops in the hepatectomized animal is bilirubin.

The possible sources of the pigment were carefully investigated. As the liver was totally removed, the possibility of remaining liver tissue having caused the production of the pigment need not be considered. That the pigment was not squeezed from the liver at the time of operation is proved by its absence from the plasma immediately after operation, by its progressive increase and by the failure of careful clamping of the vena cava before hepatectomy to prevent its occurrence. That it was not just the result of the absorption of bile from the intestine which had been discharged previous to hepatectomy is proved by the failure of resection of the gastro-intestinal tract at the time of hepatectomy to prevent its occurrence, and by the disappearance of pigment from the contents of the gastro-intestinal tract within a few hours after hepatectomy, while the pigment in the plasma increased progressively. That it had not just been stored in some organ previous to hepatectomy is evident, since the amount in the urine and the amount found in the plasma and tissues at death was too large to have been stored in any one organ or tissue without giving marked evidence of its existence. As the pigment appears in animals in which both the liver and spleen are removed, the latter organ is clearly not necessary for its formation. Furthermore, it appears when no blood is present in the peritoneal or any other serous cavity, so that the cells lining these cavities are not essential to its production.

The results of our experiments, therefore, show conclusively that after removal of the liver, a pigment accumulates in the body, which in all its characteristics, chemical and physical, appears to be bilirubin and which is made by some organ or tissue without the intervention of the liver. This proves definitely that the liver is not essential to the formation of bilirubin. At least a portion of the bile pigment can be produced outside the liver, and to some extent the liver must be considered an excretory organ so far as this constituent of the bile is concerned.

The effect of extirpation of the liver on the incidence of the other two important constituents of the bile, the bile salts and cholesterol, in the blood was not so clearly demonstrated. Estimations of the cholesterol of the blood before, and at various periods after, removal of the liver did not show any significant changes. These results do not permit the drawing of conclusions in regard to the relationship of the liver to this substance. They might be interpreted as showing that cholesterol is made by the liver and that when this organ is removed no change in the blood content would occur because its utilization is so slow. On the other hand, they might mean that the liver merely excretes cholesterol after it has been made elsewhere in the body but that the rate of its production over its utilization and excretion is too slow to produce a measurable increase in the blood during the experiments.

Data on the relationship of the liver to the formation of bile salts are also inconclusive. Present chemical methods are not sufficiently delicate to determine the accumulation of bile salts in the blood following the obstruction of the common bile duct during the period the hepatectomized animal is kept alive. It would therefore seem impossible to hope to obtain results in the hepatectomized animal until a more delicate method of detection and estimation of bile salts in the blood has been elaborated. We have, however, obtained positive Pettenkofer's tests for bile acids in dialysates of plasma obtained several hours after the liver was removed in dogs whose dialyzed plasma gave no tests for bile acids before operation.

THE PHYSIOLOGIC SIGNIFICANCE OF THE MODIFIED PHYSIOLOGIC PROCESSES FOLLOWING TOTAL REMOVAL OF THE LIVER

Conclusions must be drawn cautiously with regard to the function of an organ, when they are based on a study of the effect of its removal. It is always quite possible that many of the results following removal may be secondary and not directly related to the activity of the organ in question. However, many of the results of the effect of hepatectomy have been so definite and their significance so clear that conclusions are justified.

Many other changes observed after hepatectomy require confirmatory data before conclusions can be drawn.

Certain functions of the liver would appear to be clearly defined. The liver is functioning at all times to maintain the normal blood sugar level. Furthermore, the production of the permanent and transitory condition of hyperglycemia, not due to the administration of carbohydrate, depends on the liver. The liver is not only the storehouse for carbohydrates and the seat of the mechanism whereby a fairly constant blood sugar level is maintained, but it probably also has the ability to make glucose from other available sources. This predominant and responsible position of the liver with regard to maintaining the blood sugar level under varying conditions and employing, when necessary, a variety of materials, suggests also a necessary and more or less specific relation to protein metabolism. Thus urea formation ceases and the amino-acids increase after removal of the liver. The organ also has an important share in the metabolism of the purins.

The glycogen mechanism of the muscle is probably of little importance with regard to the general blood sugar content. It would appear that the glycogen in the liver acts as a reservoir from which the liver can maintain a fairly constant level of blood sugar under varying conditions of absorption of carbohydrate and utilization of glucose, while the glycogen in the muscles is mainly for the purpose of muscular metabolism. The liver to some extent is but an excretory organ as regards bile pigment.

SUMMARY

The blood sugar decreases from the instant the liver is removed. Muscle glycogen decreases concomitantly. When the blood sugar falls to a certain level the characteristic symptoms associated with low blood sugar appear, and if glucose is not administered, the animal will die in a condition of hypoglycemia. The proper administration of glucose prevents the hypoglycemia and the development of the characteristic symptoms, and prolongs the life of the animal many hours until a different condition develops and the animal dies. The cause of death in the latter condition has not been determined. The action of glucose in the hypoglycemic condition is specific. The decrease in blood sugar following hepatectomy also occurs in the condition of hyperglycemia that follows extirpation of the pancreas. The transitory hyperglycemia that follows the administration of epinephrin, production of asphyxia and similar procedures does not occur after hepatectomy. An animal will die following the development of hypoglycemia with a considerable amount of glycogen still present in the muscles. If the blood sugar level is maintained above normal in the hepatectomized animal, muscle glycogen will increase. Urea formation ceases immediately after removal of the liver. The amino-acids, which normally would have entered into the process of urea formation, accumulate in the blood and, if the kidneys are active, are excreted in the urine. Uric acid is not destroyed, and it actually accumulates in the blood and tissues or is excreted in the urine if renal activity is maintained. A yellow pigment accumulates in the hepatectomized animal which gives a positive reaction to the accepted chemical tests for bilirubin as well as produces the same curve of light transmission, with the spectrophotometer, as bilirubin.

THE CLINICAL USE OF TESTS FOR HEPATIC FUNCTION [*]

CARL H. GREENE, M.D.
ROCHESTER, MINN.

The recent advances in physiology and biochemistry are responsible for a renewed emphasis on the functional changes accompanying disease of the different organs. The development of rapid and simple methods of blood analysis, in particular, has contributed largely toward this end.

The most widespread and striking applications of functional tests to clinical medicine have been made in the study of renal diseases. The kidney is preponderantly an excretory organ and, consequently, peculiarly suitable for functional study. Both the initial material, the blood, and the excretory product, the urine, are readily available for analysis. In consequence, tests of renal function are widely used and their value, especially that of the determination of the blood urea and the excretion of phenolsulphonephthalein, is firmly established.

The clinical study of the activities of the liver is much more difficult, for it is an organ with manifold functions, and detailed knowledge of some of its normal physiologic activities is extremely inadequate. The liver is chiefly concerned with the blood borne to it by the portal vein; this blood comes from the abdominal viscera and may contain many substances not present in the general circulation. The bile cannot be directly collected for study, and the material obtained by duodenal drainage may be mixed with an unknown amount of intestinal content. Therefore, the approach to the functional study of the liver must be indirect and correspondingly difficult.

Many tests for the various individual activities of the liver have been devised. Some are of doubtful value; others have interesting possibilities and promise to be useful to the clinician.

During the last two years, I have been making a comparative study of the more promising of these tests in an effort to determine their place in clinical medicine. Through the cooperation of the Mayo Clinic staff it has been possible to study patients with hepatic disease from the medical, surgical, pathologic and physiologic aspects, as well as from the laboratory point of view. A series of more than 700 cases has been thoroughly studied in this way.[1] At this time, it will be possible to indicate the more important conclusions.

GENERAL METABOLIC ACTIVITIES OF THE LIVER

Carbohydrate Metabolism.—Since the time of Claude Bernard, the importance of the liver in relation to the storing of glycogen and the regulation of the blood sugar has been manifest. Many attempts have been made to demonstrate changes in the glycogenic activity of the liver. Fructose has been the sugar most commonly used for this purpose. A diminished ability on the part of the organism to utilize this sugar, as evidenced by its appearance in the urine or by an undue increase in the amount in the blood following the administration of fructose, has been thought to indicate functional inefficiency of the liver.

It can be shown experimentally that a diminished fructose tolerance follows toxic injury to the liver by phosphorus, chloroform or hydrazin. A similar reduction in fructose tolerance following experimental ligation of the common bile duct has been observed by investigators.

The clinical application of such experimental findings is difficult. Numerous factors, such as pancreatic, pituitary or other endocrine disorders, influence the ability of the organism to metabolize carbohydrates. The clinical use of the original test devised by Strauss has generally been abandoned. We have used the more recent modification recommended by MacLean and de Wesselow, and studied the change in the blood sugar following fructose administration. We have not been able to show specific changes that could be definitely ascribed to hepatic damage alone. In general, we believe that while tests of fructose tolerance may be valuable from an experimental standpoint, they are of questionable importance in the diagnosis and treatment of the individual patient.

Protein Metabolism.—The liver is known to be the seat of much of the intermediary nitrogen metabolism in the body. Frerichs was one of the first to recognize the importance of crystals of the amino-acids, leucin and tyrosin in the urine of patients with acute yellow atrophy. During the last two decades, much has been written concerning the urinary nitrogen partition in hepatic disease. Rowntree, Marshall and Chesney emphasized the difficulty of interpretation in such studies, and called attention to the accompanying changes in the blood; they found that the proportion of blood urea was slightly decreased in hepatic disease. More recently, Bollman, Mann and Magath have reported evidence pointing to a cessation of urea formation in dogs after complete extirpation of the liver. In our experimental animals with obstructive jaundice, there was usually a sharp and definite decrease in both the relative and absolute values of the blood urea. These low values persisted until shortly before the death of the animal, when a terminal rise of blood urea occurred. This probably was evidence of terminal renal insufficiency.

Clinical experience has not demonstrated a significant departure from the normal in the blood urea. In patients with jaundice, the average value for the blood urea apparently is slightly lower than in those without jaundice, but the change is not sufficiently marked to be of diagnostic importance. In the dog, urea formation ceases after the complete removal of the liver. In man, a comparable degree of hepatic insufficiency is not observed, even with the grossest hepatic changes.

Following operation for the relief of obstruction of the biliary tract, patients not infrequently become extremely toxic. This condition is accompanied by increasing jaundice and a rise in the blood urea, even though the output of urine is maintained. Impairment of one function of the liver, such as that of bile excretion, is not necessarily paralleled by changes in the other physiologic activities. This fact indicates the necessity in the functional study of the liver of employing a diversity of tests that will include the multiple activities of that organ. Mention should be made of the strikingly beneficial action of the intravenous administration of glucose in combating this toxemia.

---

[1] Greene, C. H.; Snell, A. M., and Walters, Waltman: Clinical and Experimental Studies in Diseases of the Liver, I, A Survey of Tests for Hepatic Function, Arch. Int. Med. **36**: *248-272* (Aug.) 1925. Snell, A. M.; Greene, C. H., and Rowntree, L. G.: II, A Comparative Study of Certain Tests for Hepatic Function in Experimental Obstructive Jaundice, ibid. **36**: *273-291* (Aug.) 1925. Greene, C. H.; McVicar, C. S.; Rowntree, L. G., and Walters, Waltman: III, A Comparative Study of Certain Tests for Hepatic Function in Patients with Obstructive Jaundice, ibid. **36**: *418-436* (Sept.) 1925.

In the dog, the liver is directly concerned with the metabolism of uric acid which accumulates in the blood following hepatectomy; in man, no noteworthy change in the amount of uric acid or other nonprotein nitrogenous constituents of the blood has been observed in hepatic disease.

FORMATION AND EXCRETION OF BILE

Bile Pigments.—Since the most striking hepatic disorders are those accompanied by the retention of bile and consequent jaundice, much attention has been paid to the presence and source of bile pigments in the blood, urine and feces. Mann's experiments have finally and conclusively proved the contention of Whipple and Hooper that bile pigment may be formed outside the liver and excreted by that organ. Obstructive, hemolytic and hepatogenous types of jaundice must each be recognized as possible from a physiologic point of view.

A century ago, Tiedeman and Gmelin reported the presence of bile pigment in the blood of a patient with obstructive jaundice. Gmelin's test is classic and, until the last few years, was the standard method for the recognition and study of the bile pigments. Recently, van den Bergh has devised a quantitative and more sensitive test for bile pigments. This method has made it possible to study the bile pigment or bilirubin content of the blood serum in patients with jaundice. The test is important from both the physiologic standpoint and that of clinical usefulness; it is quite as important to study the serum bilirubin in hepatic disease as it is to measure the blood urea in renal disease. Bilirubin cannot be shown by the van den Bergh test to be normally present in the serum of the dog. Following ligation of the common bile duct, it appears in increasing amounts, although large quantities are not found until forty-eight hours or more after operation. If the gallbladder is removed at the time the common duct is ligated, bilirubin appears in the serum much more rapidly, and large amounts are found within from twelve to twenty-four hours. After the preliminary rise, the bilirubin content of the serum is quite constant during the period of obstruction. In all cases, the appearance of clinical signs of icterus follows the increase in the pigment content of the blood.

The study of the serum bilirubin is of equal clinical usefulness: (1) in estimating the degree of retention of bile in patients with obstructive jaundice; (2) in furnishing a quantitative index for the degree of jaundice observed in the various toxic or infectious types; (3) in following the course of jaundice due to any cause, and (4) in demonstrating the presence of latent icterus.

In connection with latent icterus, a number of concrete diagnostic applications may be mentioned. In pneumonia, exophthalmic goiter, the toxemias of pregnancy, or following the administration of chloroform or arsphenamin, high bilirubin values predict the onset of toxic icterus with its important prognostic import. In heart disease, emphysema or arterial hypertension, rising levels of serum bilirubin foreshadow passive congestion of the liver as the result of myocardial failure. In secondary anemias, except those of hemolytic origin, normal bilirubin values are the rule. For example, in differentiating occult carcinoma and pernicious anemia, a high figure would argue for the latter diagnosis provided metastasis to the liver could be excluded. However, in the presence of carcinoma, elevation of the bilirubin value indicates involvement of the liver or biliary passages.

Determinations of the serum bilirubin are most valuable in the differential diagnosis of cases of abdominal colic. As pointed out by Blalock, less than a third of all biliary colic is followed by manifest icterus. In the remainder, not associated with jaundice, diagnosis may be extremely difficult. Following biliary colic, the serum bilirubin is elevated, although not always to a degree or for a length of time sufficient to color the skin or sclerotics. In such cases, the demonstration of latent icterus is diagnostic. We have also seen a few acute cases of severe but unlocalized abdominal pain, in which the finding of serum bilirubin in amounts considerably above the normal has served to establish the diagnosis.

Bile Salts.—Hemolytic jaundice is probably associated with bilirubinemia, or the presence of bile pigments in the blood. In obstructive jaundice, on the other hand, we are dealing with a condition in which bile is absorbed and both bile pigments and bile salts are present in the blood. The possibility of a dissociated jaundice, in which there is an accumulation solely of bile salts in the blood, has long been discussed, particularly by French clinicians. This problem can be solved only by quantitative studies, and so far, there has been no adequate clinical method for the study of metabolism of bile salts. A method for the quantitative study of the bile salts in the blood has been greatly needed. Such a method has recently been developed in our laboratory. It promises to be very useful, and it is hoped that it may aid in establishing the relation of bile salts to hepatic disease.

An increase in the ultramicroscopic fat particles or hemoconia in the serum after a fat meal has been used by Brulé as an index to the presence of bile salts in the intestine. This normal increase does not occur with biliary obstruction. It is obvious that this test gives results roughly comparable to an examination of the stools for bile, and the French clinicians have emphasized its value in determining the presence or absence of obstruction of the common duct. The clinical and experimental studies in the Mayo Clinic have, in general, been confirmatory.

DETOXICATION IN THE BODY

The body possesses a truly remarkable ability to detoxify many poisonous compounds. The conjugation of benzoic acid with glycocoll to form hippuric acid, or the excretion of camphor as camphor glycuronate, are examples of this detoxifying activity that has been ascribed to the liver. As yet, however, there has been no thoroughly satisfactory means for measuring the detoxifying power of the body. More recent experiments indicate that it is not entirely confined to the liver.

Widal has suggested that the liver removes and destroys toxic products of cleavage of the protein which are present in the portal blood, the so-called proteopexic activity. In the presence of hepatic disease, these products enter the general circulation, and a temporary leukopenia or hemoclastic crisis is produced. Widal has utilized the hemoclastic crisis as a test for hepatic function. This test has been employed both clinically and experimentally in the Mayo Clinic, but its diagnostic value has not yet been established.

The delay in the coagulation time of the blood in cases of obstructive jaundice is too well known to require special comment. The value of calcium chlorid intravenously, as a preoperative measure to prevent later hemorrhage, has been amply demonstrated.

EXCRETION OF DYES

Many dyes when injected intravenously are excreted wholly or in part through the bile. Phenoltetrachlorphthalein, rose bengal, methylene blue and mercurochrome-200 soluble are examples. Tetrabromphenolphthalein and tetra-iodophenolphthalein have been used to permit the roentgenographic delineation of the gallbladder. Others have been used as tests of hepatic function. I shall consider only phenoltetrachlorphthalein, as it was the first to be introduced and has been the most thoroughly studied. The value of the different substitutes is yet to be finally established.

When the phenoltetrachlorphthalein test was originally introduced into clinical medicine by Rowntree, Hurwitz and Bloomfield, the attempt was made to measure its excretion in the stools. This work established the specificity of the dye excretion by the liver, and demonstrated the possibilities of employing the method as a functional test. Whipple, Peightal and Clark established its value in experimental injuries of the liver. Later, the method of collecting bile by a duodenal tube was substituted. Neither was wholly satisfactory for routine clinical use. Rosenthal introduced the study of the rate at which the dye left the blood stream. In hepatic disorders, the rate of dye removal is greatly reduced. It is the clinical use of this modified test, the Rowntree-Rosenthal test, that I shall discuss.

The technic of the test is simple. The solution of the dye may be obtained in ampules. One cubic centimeter of this solution is injected intravenously for each 10 kg. of body weight. Fifteen minutes, one hour, and two hours later, blood samples are taken, 5 c.c. at each time being ample. The clear serum is separated, a drop of alkali is added to bring out the color of the dye, and comparison is then made with standard tubes. Normally, the dye is rapidly removed from the blood stream. At the end of fifteen minutes, only from 5 to 7 per cent. remains, while at the end of an hour, only traces of dye are present. In patients with obstructive jaundice, as much as 30 per cent. of the dye may still be present in the blood stream two hours after the injection.

To secure an experimental background for the interpretation of clinical findings, we have studied the changes observed in the elimination of phenoltetrachlorphthalein after the ligation of the common bile duct in dogs. Bile is retained in such animals, the time at which jaundice appears depending on the presence or absence of the gallbladder. These dogs have a progressively increasing degree of dye retention which is found to be parallel to the increase in the serum bilirubin.

The changes observed in man are quite similar. A series of cases of obstructive jaundice due to stone or postoperative stricture of the common bile duct have been studied. Cases of cholecystitis without jaundice showed only the slightest degree of dye retention. With the development of jaundice, the changes in elimination of phenoltetrachlorphthalein became definite and characteristic. In all cases, there was marked retention of dye in the blood stream. As in dogs with experimental obstruction of the common bile duct, the degree of dye retention roughly corresponded to the degree of retention of bile pigment.

Following the operative relief of the obstruction in these patients, there was a rapid decrease in the amount of serum bilirubin and in the degree of dye retention. The serum bilirubin speedily returned to normal. Following the first decrease, however, the phenoltetrachlorphthalein test often showed a moderate but persistent retention of dye. Possibly this is related to the residual hepatitis observed in nearly all patients who have suffered from biliary obstruction for any extended period.

The changes observed in the other clinical varieties of icterus were quite similar to those seen in obstructive jaundice. In acute infectious or catarrhal icterus, in toxic jaundice, whether associated with syphilis and treatment by arsenicals or chloroform anesthesia, in pneumonia, exophthalmic goiter and in acute yellow atrophy of the liver, marked retention of dye is present. Again the degree of dye retention closely parallels the increase in the serum bilirubin. In such cases, icterus is the outstanding manifestation, and it dominates both the clinical picture and the laboratory findings.

The dye test, however, is of greatest clinical value in those cases of hepatic disease in which jaundice is not present. The obstetricians have applied the test in the differentiation of the toxemia of pregnancy from neurotic vomiting and eclampsia of nephritic origin. In the toxemia, the dye test will apparently indicate hepatic changes before the increase in serum bilirubin is established. In carcinoma of the gastro-intestinal tract, normal readings are obtained before extension of the growth begins. Moderate retention was found in a series of cases of carcinoma of the stomach or colon without jaundice, and the surgeon found obvious metastasis to the liver in most of them. The degree of retention of the dye depends, in part, on the extent of the malignant process in the liver, so that a normal test will not positively exclude the presence of small metastatic nodules there.

Definite changes can be shown in cirrhosis by means of the dye test, although the correlation of laboratory findings with the clinical picture must be made with care. The retention of dye has definite diagnostic value in biliary, syphilitic or portal cirrhosis.

The various functional tests contribute but little, from the standpoint of the differential diagnosis of hepatic diseases. This, perhaps, is to be expected, for experience with tests of renal function has likewise demonstrated that functional changes are not necessarily characteristic of the particular etiologic agent.

The liver is an organ with a large factor of safety, for a large proportion of it can be removed experimentally and the remnant will still suffice for normal function. Again, disturbance in one type of physiologic activity does not necessarily indicate commensurate disturbance in other functions of the liver. The presence of a normal amount of bilirubin in the serum and the absence of dye retention will not exclude hepatic disease. Positive tests, on the other hand, are of great value in indicating the probable presence of definite and widespread hepatic damage. Although the present hepatic functional tests are not ideal, their introduction is another milestone on the road to the better understanding of diseases of the liver.

[Editorial Note.—This paper, together with the papers by Drs. Carlson and Mann, which precede it, and three papers, by Dr. Opie, by Drs. McClure and Mendenhall and Mildred Huntsinger and by Drs. Lyon and Swalm, respectively, to appear next week, are part of a symposium on "Liver Function." The discussion will follow the papers to be published in our next issue.]

THE CORRELATION OF FEDERAL HEALTH AGENCIES *

LINSLY R. WILLIAMS, M.D.
NEW YORK

Of the hundred or more major administrative units of the national government, at least thirty are concerned directly or indirectly with some phase of the public health. These bureaus or other divisions are scattered through the ten executive departments and the score or so of independent establishments of the United States. Generally speaking, they carry on their activities more or less independently. Of the thirty, only eight have a major and primary interest in public health, the others having a less significant relationship to the subject, for their health or medical activities are usually carried on as secondary to the general scope of the various bureaus.

The public health operations of the federal government were not established all at once, but have grown up by a process of political and administrative evolution extending over a long period of time. A brief historical statement showing the gradual development of these bureaus will be of interest and of value by indicating the manner in which the different departments have availed themselves of favorable opportunities to add health duties to their other functions.

The first important congressional enactment to deal with health was a law of 1798 that authorized collectors of customs to collect 20 cents a month from each American seaman on merchant ships arriving from foreign ports, in order that medical relief might be given to those needing it. Out of this activity grew the Marine Hospital Service, though it was not definitely organized as such until 1870. Many other duties, such as the administration of national quarantine laws, medical inspection of immigrants, and investigations of diseases were added to its responsibilities from time to time, and in 1902 the name of this service was changed to the Public Health and Marine Hospital Service. In the following years, Congress imposed on the service still other duties, more and more of a public health nature, so that in 1912 the name was again changed, this time to the Public Health Service. The many splendid achievements of the bureau, which is today the principal health agency of the federal government, are so well known to all members of the medical profession that there is no need to take the time to dwell on them. It will be noted that the Public Health Service is in the Treasury Department for historical reasons only. The collectors of customs of the same department now collect quarantine charges, inspect vessels for sanitary conditions, and regulate the importation of certain articles, such as meat and drugs, which must conform to certain standards of purity. The domestic regulation of narcotics is administered by the Bureau of Internal Revenue of the Treasury Department.

Except for the creation of a medical establishment in the army, which was authorized as early as 1798, the next medical agency of the government was the hospital for the insane, which was created in 1855 and is now under the Interior Department. In 1873 a medical and education division was set up by the Office of Indian Affairs, though it was in existence for only four years and was not revived as a unit until 1909. Investigations of animal diseases were authorized by Congress in 1878, and this work was gradually extended until 1884, when a Bureau of Animal Industry was established in the Department of Agriculture. Today, much of the operation of this important bureau touches on human health. Ten years later (1894), the Secretary of Agriculture was given an appropriation of $10,000 to conduct investigations in nutrition. At present there is a Bureau of Home Economics, which receives an appropriation of more than $100,000 annually in order to conduct these studies and other work relating to the home.

The collection of national vital statistics was authorized by an act of 1902 and placed under the supervision of the Bureau of the Census of the Department of Commerce. The Food and Drugs Act of 1906 imposed the carrying out of the necessary analytic work on the Bureau of Chemistry of the Department of Agriculture, and another law passed at the same time required the Bureau of Animal Industry to inspect all meat intended for shipment in interstate commerce. The control and licensing of biologic products, however, had been assigned to the Secretary of the Treasury by an act of 1902, and delegated by him to the Public Health Service.

From 1910 on, many other new bureaus with health interests have been created. In that year the Bureau of Mines was established in the Interior Department, and one of its main objectives was to conduct research to benefit the health and safety of miners. The Public Health Service was authorized to detail a medical officer to this bureau in 1917. Also in 1910, a division of school hygiene appeared in the Bureau of Education of the Interior Department. The Bureau of Education likewise has administered medical relief to the natives of Alaska since 1909. A Children's Bureau was created in the Department of Commerce and Labor in 1912, transferred to the Department of Labor in 1913, and its scope was much broadened in 1921, when the federal Maternity and Infancy Act was passed.

Among other bureaus that may be mentioned are the United States Employees Compensation Commission, organized in 1916 to give compensation and medical aid to injured federal employees; the Women's Bureau, established in the Department of Labor in 1920; the United States Veterans' Bureau, which came into being in 1921 to give medical care and vocational rehabilitation, among other things, to ex-service men; the federal Narcotics Control Board, formed in 1922 to administer the act prohibiting the importation of opium except for medicinal purposes; and, finally, the Bureau of Dairying, which was made a separate bureau in the Department of Agriculture in 1923, after having been a division of the Bureau of Animal Industry for many years. A detailed study of all these federal health activities is now being conducted under the auspices of the Institute for Government Research of Washington, D. C., by Mr. James A. Tobey, whose long experience as Washington representative and later secretary of the National Health Council has made him thoroughly conversant with these matters. No attempt has been made to enumerate each and every bureau having a health interest, and more detailed information may be secured by those interested directly from Mr. Tobey.

Proposals that these federal health activities should be effectively coordinated are not new. From 1910 to 1912, an intensive agitation was conducted throughout the country for a national bureau of health with a

---

* Read before the Section on Preventive and Industrial Medicine and Public Health at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

secretary in the Cabinet. President Taft recommended such a bureau in two of his messages to Congress, and the American Medical Association passed a resolution indorsing the proposition, which was sponsored by the Committee of One Hundred of the American Association for the Advancement of Science. There was some precedent for such a bureau, for at one time the United States did have a national board of health. It was established by Congress in 1879 for a four year period. In 1882 its functions were restricted to the investigation of smallpox, cholera and yellow fever, but no appropriations were made to the board after 1885, and the act creating it was definitely repealed in 1893.

During the World War, President Wilson issued an executive order to the effect that all federal health work, except that conducted by the army and navy, and the industrial hygiene activities of the Bureau of Labor Statistics, should be exercised under the supervision and control of the Secretary of the Treasury, which meant, of course, the Public Health Service. After the war, it was proposed completely to reorganize all the executive departments. The plan that was finally recommended by a joint congressional committee, headed by a representative of President Harding, included a scheme for a new Department of Welfare. In the session of Congress that adjourned last March, this had become a Department of Education and Relief, the only health agency included in the proposed department, however, being the Public Health Service. For many reasons, this plan was thoroughly unsound, though the general reorganization idea contained some excellent provisions. Congress took no action on the matter. The Sixty-Ninth Congress will meet according to law on the first Monday of next December. It is to be hoped that a definite, practical plan, decided on by the medical and sanitary professions, and by experts in political science, agreeable to the bureau chiefs concerned, and with the support of the administration, may be presented to Congress for its approval.

The bureaus that may now be said to have a major interest in national health are: Public Health Service (Treasury); Children's Bureau (Labor); Division of Vital Statistics, Bureau of Census (Commerce); Bureau of Chemistry (Agriculture); Bureau of Home Economics (Agriculture); Bureau of Animal Industry (Agriculture); Division of School Hygiene, Bureau of Education (Interior); Medical Division, Office of Indian Affairs (Interior).

Any plan for the correlation of federal health work must take into consideration these bureaus, though whether all of them or parts of them should be combined in a new department is a matter to be determined only after a most careful study and the consideration of all the factors, administrative, legal and political which enter into the problem. Whatever seems to be the best plan, whether all these bureaus and divisions are brought together or not, there must be worked out some form of efficacious cooperation between them. This might be effected by having a medical liaison officer in any new arrangement that is decided on or by provisions for the assignment of medical and sanitary officers from a central bureau of health to other branches of the government carrying on health activities. At the present time, many of these bureaus are not entirely familiar with the work being done by the others. Though duplication may be more apparent than real, because the field is so vast and diversified, there is, nevertheless, some overlapping and there are also some unfilled gaps.

The promotion of national vitality is as important to the welfare of this country as is commerce, agriculture, industry, finance, foreign affairs, public works, or any other legitimate function of government. Most of these matters have been accorded the recognition due them by having a secretary in the President's Cabinet. The ideal condition would be likewise to have a secretary of public health. It is a question, however, whether it would be expedient at this time to advocate such an arrangement. There should be, however, some high official in charge of all major public health activities of the national government. He might be an assistant secretary for public health in some existing department or in a new one to be established in accordance with the general reorganization scheme, or he might be a commissioner of public health without a seat in the Cabinet, but in charge of an independent establishment. It is almost needless to remark that this officer should be a well qualified sanitarian.

SUMMARY

In this paper, an attempt has been made in a limited time to call attention to the present lack of correlation of federal health agencies, many of which, of course, are accomplishing very valuable and significant results. While making certain general suggestions for coordination, no recommendation for any definite plan is made, for such a suggestion would be premature. The subject will, however, be before the medical and sanitary professions for definite conclusions in the near future and a positive stand should then be taken. For the present, there is no doubt that in the interests of efficiency there must be practical coordination and that this should be brought about as soon as possible. The history of all worth-while social legislation indicates, however, that, no matter what its merits, it requires presentation to several congresses before such measures are finally adopted.

While the care of the public health in this country is, under our form of government, primarily vested in the individual states, the federal government does have certain proper duties, such as those involving foreign and domestic quarantine, interstate commerce, research, revenue matters, and the care of the health of the wards of the government. These duties can undoubtedly be more effective and can contribute more completely to the enhancement of national health and happiness, if they are conducted in a more unified way, thus supplementing the many notable achievements which these federal bureaus already have to their credit.

370 Seventh Avenue.

ABSTRACT OF DISCUSSION

Dr. W. S. Leathers, Nashville, Tenn.: It is evident that during recent years there has been a definite tendency to reorganize the departments of the federal government with the object of preventing overlapping of functions, and also with a view of economizing public expenditures. In the consideration of federal health agencies there is not so much necessity for the rearrangement and transfer of governmental functions and agencies as the clear understanding of public health needs, the responsibility of the federal government in relation thereto, and additional funds to meet these needs. The equity in our form of government predicates as full autonomy as possible for state and local governments. The authority and duties of the respective state governments should be recognized in any readjustment or reorganization of federal health agencies. For a great many years there has been much discussion with reference to having a national department of health, with a secretary in the cabinet. I think that many of us who formerly were somewhat enthusiastic in this development have come to realize that at least for the present such a step is not advisable. The United States Public Health Service has been and should be the most important governmental agency in the prevention and control of disease and the promotion of the public health. The Public Health Service has, up to the present time, undergone steady and efficient development in the Treasury Department. It seems that this was the most practicable relationship for the health service because of the power and prestige of this department and relative independence enjoyed by the Public Health Service, and also because of its being unhampered by undesirable political considerations. Scientific research is the fundamental function of the federal government in relation to health conservation. It has been indicated that other problems of public health must of necessity devolve largely on state and local authorities, but investigation and research in the etiology and mode of transmission and methods employed in the control of disease and in the elevation of health standards is definitely a function of the federal health service. This does not mean that the Public Health Service and other federal agencies engaged in health work should not cooperate with and assist in every practicable way in the development of state and local health organizations; but there can be no question that the advancement of knowledge relating to health and disease is more distinctively a function of the federal government than the general promotion of public health. This, however, can be accomplished only provided proper facilities and highly trained scientists are available through a more adequate financial support. It seems to me that the outstanding need of the federal government is the bringing together under one roof of all facilities of the Public Health Service in the District of Columbia and their enlargement to meet the constantly increasing demands made on it.

Dr. A. T. McCormack, Louisville, Ky.: Those of us who are familiar with the splendid work being done by the Surgeon General of the United States Public Health Service appreciate particularly the efforts he has successfully made to have lists of officers, with all different activities in Washington compiled, but we realize, as he cannot, that to furnish lists of all the officers of federal bureaus and state health departments, some work has had to be done by other bureaus having relations with public health activities. I agree with Dr. Leathers that much has been accomplished under Dr. Cumming's supervision with so small a staff. We are able to be successful only when we have the charming personality of such a man as our Surgeon General. For many reasons our Public Health Service is outstanding and is recognized by foreign governments at present, but it seems to me of utmost importance that we have a system coordinated; that our scattered bureaus under health and education be permanently organized so that the Public Health Service furnishes not only the arterial system and brain, but in some way the vertebral column of public health, so that impulses that start at the head may go through the entire system in some reasonable degree of time.

Dr. Haven Emerson, New York: The members of this section do not need to be reminded that the American Medical Association through its former Council on Health and Public Instruction and through action of the Board of Trustees has in previous years supported efforts to have federal health activities coordinated, and it seems to me particularly timely that when the President of the United States has given his personal approval to studies designed to accomplish or prepare for adjustment and central direction of these government functions we should take advantage of that point of view, and assist so far as possible in this movement. I therefore offer the following resolution for consideration of this section:

Resolved, That the Section on Preventive Medicine and Public Health request the Board of Trustees of the American Medical Association to appoint a committee to cooperate with other groups, lay or professional, which may have as their objective the central direction of and responsibility for all the health activities of the federal government.

We must proceed conservatively and maintain the view that Dr. Williams has presented. I hope that the section will feel that it is not going beyond our province to express the attitude of the section in this way.

Dr. George M. Kober, Washington, D. C.: I second the resolution, because I believe that some action should be taken and the time is ripe, in view of the fact that Secretary Hoover has broken the ice in the way of consolidation and, in his own department, cooperation; he is a business man and does not believe in duplication and waste, and this will go a great way in helping the movement in which we are deeply interested. I was one of the Committee of One Hundred some fifteen years ago and it fell to my lot to present the first statement before the Senate and House congressional committees, and to educate our legislators in matters relating to preventive medicine. This education was not without results; the Public Health Service has assumed functions it has never attained before, and it seems to me that the time has arrived for a further expansion of national public health work.

Dr. S. W. Welch, Montgomery, Ala.: The remarks of Dr. Leathers were admirable. He expressed appropriately, clearly and positively the feelings of those of us who are actively engaged in public health work. It is a question which we should approach very carefully. I was in Washington last winter when the new welfare bill was under consideration. I do not think that any of us engaged in public health work approved of it. The educational people did not approve of it, and yet it was slated to pass. If it had not been caught in the jam of the Muscle Shoals bill, I think it would have been a law today. I do not think that we should ask Congress to give us a secretary in the cabinet at this time. If we could coordinate all the federal public health activities under one head, as suggested by Dr. Leathers, our difficulties might be solved. At one time I was very much in favor of a secretary of public health in the cabinet, but developments in the last few years have caused me to doubt the wisdom of it.

Dr. Linsly R. Williams, Albany, N. Y.: I have been very much interested to hear the suggestions made in regard to whether or not we should have a secretary at the head of a department of health. I recall very vividly discussing that matter with the secretary of the treasury during Mr. Taft's administration. Mr. McVeagh said to me at that time, "It would be perfectly feasible and proper to have a secretary for the promotion of health now, if it were not for the fact that we would have to have a department of labor as well, and it is not the policy of the government to increase the number of cabinet officers." I remarked to him that it was quite likely that they would have a department of labor any way, and so why not have a department of health also? As you know, the department of labor was not created then, but the Department of Commerce and Labor was, and subsequently it was divided into two departments. At the present time there is a determined movement to create a department of education, the name having been concealed in some way as a department of welfare or the like. Whether there will be a department of education and health, or whether a department of education alone seems to me immaterial; but there is one thing that does seem perfectly definite to those interested in this matter, who were in a measure responsible for Mr. Tobey starting on this study. That is that there must be a definite statement drawn up of functions of every individual bureau, that all these activities and all their preparations be put together into one definite report. Such a report must be printed and widely circulated. When that is done it will then be possible to think out not only what type of organization is really best, but what type of organization is feasible. Whether we have a commission or bureau or what not, it seems to me quite immaterial so long as we have what Dr. Leathers and Dr. McCormack and Dr. Welch have indicated, so long as we have a program of definite activities all under one roof. When that is accomplished I think we shall have gone a long way, whether we have a cabinet officer or not.

Summaries of Original Articles.—The *Archiv für Schiffs- und Tropen-Hygiene, etc.,* has joined the constantly increasing list of those journals which demand that every original article shall be accompanied with a brief summary. Many of them now give summaries in two other languages, but only the Scandinavian *Acta* journals and some of the Japanese ban their own language completely throughout, and use only the three main congress languages.

MECHANISM OF THE ANTIEDEMIC ACTION OF EPINEPHRIN *

J. D. PILCHER, M.D.
CLEVELAND

Epinephrin is widely used against the phenomena of urticaria; the mechanism of this action seems not to have been solved. This question was therefore investigated in a study of the phenomena of wheal production from the intradermal injection of codein solution; such an injection of codein (0.15 c.c. of a 1: 1,000 solution in saline solution) forms a wheal averaging about 1.3 cm. in diameter surrounded by a flushed area about 4 cm. in diameter, the reaction being practically indistinguishable from an urticarial lesion of similar size which often follows the injection of therapeutic serums. The reaction attains the maximum within from ten to fifteen minutes and has usually faded entirely in an hour or thereabouts. The edema of the wheal site is due to increased permeability of the minute skin vessels.[1] The experiments were made on a number of infants and children and the results are as follows:

An intramuscular injection of epinephrin (from 0.15 to 0.3 mg.) distinctly lessened the wheal formation of codein and hastened the absorption of the edema fluid, whether the epinephrin injection preceded the codein injection by two or three minutes, the two were given simultaneously, or the epinephrin was given two or three minutes after the codein injection.

SIMULTANEOUS INJECTIONS OF EPINEPHRIN AND CODEIN SOLUTIONS

When the reagents are injected in the same solution, a concentration of epinephrin of 1: 10,000 had little if any primary effect on the codein (1: 1,000) wheal formation but did somewhat hasten the disappearance time of the wheal. Even with epinephrin 1: 1,000, the wheal reaction was not greatly modified. However, from ten to fifteen minutes after the mixed fluids were injected, a narrow border of blanching appeared about the wheal border and gradually the entire wheal area was blanched; this persisted the usual time for these dilutions of epinephrin (from two to four hours). Although epinephrin 1: 100,000 blanches skin for an hour or longer, when given mixed with codein 1: 1,000, no blanching at all appeared. Histamin 1: 5,000 in epinephrin 1: 10,000 solution gave results identical with codein.

CODEIN INTO EPINEPHRIN BLANCHED SKIN

When a codein injection was made into the center of an area of blanched skin 5 by 8 cm., a wheal 1 cm. in diameter was formed, considerably smaller than the normal and surrounded by a narrow flushed border; the disappearance time was shortened. With a blanched area 3 by 3 cm., the codein action broke through the partial epinephrin "block" at one border of the wheal, and the flush extended beyond the blanched area. When the codein phenomenon faded, the blanching of epinephrin returned and persisted for several hours. With more dilute epinephrin solutions, the effect was much less marked.

In view of the fact that the systemic action of epinephrin (from intramuscular injections) lessened codein wheal formation, although the concentration of epinephrin at the wheal site must have been very low, while the local action of epinephrin in high concentrations was slight, the effect of local injections of epinephrin in concentrations that caused no visible paling of the skin was investigated. It was considered possible that the local applications of such low concentrations of epinephrin might influence the codein action; such was not the case, however, for intradermal injections of epinephrin, one part in a billion (one part in one hundred million causes blanching), in no way modified the action of codein subsequently injected into the same site.

MECHANISM OF THE EPINEPHRIN ANTAGONISM

These observations show that epinephrin locally has very little or no effect on the wheal production unless it is injected in concentrations that actually arrest the local circulation; while the intramuscular injection decreases the wheal production very markedly, although the concentration of epinephrin is very much lower. This suggests that the antiedemic action of epinephrin is not a direct local effect, but that it is a secondary result of some unexplained systemic action. The existence of a systemic reaction with these doses of epinephrin was manifested in some cases by distinct pallor of the skin as a whole and by vomiting. Analogous antiedemic effects of epinephrin have been described for mustard-oil conjunctivitis,[2] for paraphenylendiamin [3] and clinically for various urticarias. Petersen, Levinson and Hughes [4] have discussed the effects of epinephrin on cell permeability, but their results do not appear to have been uniform.

CONCLUSION

The antiedemic action of epinephrin is due to a systemic and not a local action. The nature of the systemic action is not explained.

SYNERGISM OF MAGNESIUM SULPHATE AND MORPHIN AND MAGNESIUM SULPHATE AND ETHER *

JAMES T. GWATHMEY, M.D.
NEW YORK

When anything new in medicine or surgery is proposed, it is natural and obvious that it will be criticized. Such criticism, to be of value, should be unbiased and accurate; otherwise, false and misleading statements occur.

In 1898, the late Samuel J. Meltzer of the Rockefeller Institute made the surprising discovery that 2 drops of a 5 per cent. solution of magnesium sulphate injected intracerebrally in a rabbit produced complete anesthesia and relaxation lasting several hours. In their first publication in 1905, Meltzer and Auer [1] made the general statement that the salts of magnesium are capable of inhibiting the entire nervous system, and assumed in particular that these salts are also capable of producing *anesthesia and other inhibitory effects on* the central nervous system. This first publication led to an extensive literature on the subject. Some of the writers insisted that magnesium exerts only a curare-like action; others criticized from other angles. Finally,

Meltzer and his co-workers established definitely the anesthetic properties of magnesium sulphate in both animal and man.

Table 1.—*Case Illustrating Difference Between Magnesium Sulphate and Plain Water When Used with Morphin*

Badly lacerated wound of leg, gas infection, opened wide December 1; gastrocnemius severed.

December		Duration, Hours
2.	1: 15 a. m. Morphin, 1/5; $MgSO_4$, 2 c.c., 25 per cent.; quiet until 5	5¾
	6: 15 a. m. Morphin, 1/12; $MgSO_4$, 2 c.c., 25 per cent.; no pain all day	18
	The magnesium was now discontinued. Morphin alone used.	
3.	1: 30 p. m. Morphin, 1/6; pain in two hours	2
	3: 25 p. m. Morphin, 1/6; pain at 6: 40 p. m.	3¼
	The magnesium was again added to the morphin.	
	6: 55 p. m. Morphin, 1/6; $MgSO_4$, 25 per cent., 2 c.c.; no pain till next day	23
4.	5: 00 p. m. Morphin, 1/10; $MgSO_4$, 2 c.c., 25 per cent.; no pain till next a. m.	17
5.	10: 15 a. m. Morphin, 1/10; $MgSO_4$, 3 c.c., 25 per cent.; quiet all day	10
	8: 15 p. m. $MgSO_4$, 3 c.c.; very good night	19
6.	3: 50 p. m. $MgSO_4$, 3 c.c., 25 per cent.; severe pain after three hours	3
	6: 15 p. m. Morphin, 1/8; $MgSO_4$, 2 c.c., 25 per cent.; jerking of leg in two hours	2
	9: 15 p. m. Morphin, 1/8; $MgSO_4$, 2 c.c., 25 per cent.; quiet night	19
	The patient required one hypodermic of morphin, 1/10 to 1/6, and $MgSO_4$, 2 c.c., 25 per cent., each day after this until December 13. Codein and morphin alone did not give relief.

The synergism between magnesium sulphate and morphin was first observed in the laboratory by E. J. Pellini[2] of the University and Bellevue Hospital Medical College and immediately applied in the clinic, where its value was proved beyond question by trained observers.

The case presented in Table 1, from A. V. S. Lambert's[3] service of the Presbyterian Hospital, New York, illustrates the difference between magnesium sulphate and plain water when used with morphin.

From this protocol it may be concluded that when the magnesium sulphate (from 2 to 4 c.c. of a 25 per cent. chemically pure solution) is used with morphin, the value of the morphin is increased from 50 to 100 per cent. By either increasing or repeating the dose of morphin with sterile water, its action is intensified but not prolonged, as when used with magnesium sulphate.

Table 2, prepared from a number of cases selected at random from more than 200 similar cases at the Presbyterian Hospital, still further illustrates the synergism of morphin and magnesium sulphate as "occurring in man."

	Average lapse of time	4+

Table 3 gives a clean-cut picture of the comparative results obtained by Smythe[4] in 1922 and 1923, employing three hypodermic injections of one-eighth grain (8 mg.) of morphin dissolved in 2 c.c. of a 25 per cent. solution of magnesium sulphate, with 1/150 grain (0.4 mg.) of atropin added to the second dose, given at twenty minute intervals as a preliminary to nitrous oxid-oxygen and procain anesthesia for general operations. One third of the patients thus prepared did not require an analgesic after operation. The table shows that the patients go on an average four times as long after an operation before an analgesic is required than patients who were given morphin dissolved in sterile water alone. Smythe states that the patient is neither frightened nor apprehensive concerning the operation or its outcome. The stage of induction is greatly shortened and there is rarely a period of excitement. The patient remains pink throughout the operation; the pulse rate rarely exceeds 90, generally varying from 80 to 84. The appetite returns earlier in patients operated on when magnesium sulphate had been employed because of the absence of pain and restlessness incident to the trauma inflicted at operation.

Harmon,[5] also has published accurate comparative data showing the synergism between magnesium sulphate and morphin occurring in man. He states that when the patient is given morphin in divided doses in magnesium sulphate solution prior to operation, there is a greater postoperative comfort, less nausea and vomiting; and a decreased amount of morphin is required.

Gwathmey,[6] in 1921, defined precisely the difference between the synergism of magnesium sulphate and morphin and the synergism between magnesium sulphate and ether: "It seems to act mechanically with morphin, holding it in contact with the tissues longer than the morphin can maintain such contact alone; but with ether the magnesium sulphate acts by deepening or increasing the effect rather than by prolonging it."

The synergism between magnesium sulphate and ether was demonstrated conclusively by Meltzer and Auer,[7] in 1913, when they observed that, after the intramuscular injection of one half or less of the anesthetic dose of magnesium sulphate, rabbits and dogs are readily and deeply anesthetized by inhalations of small doses of ether which are insufficient to anesthetize normal animals. In the experiments which they reported, rabbits were given 0.6 gm. (or less) and dogs 0.8 gm. (or less) of magnesium sulphate per kilogram. With these small doses the animals were only slightly affected; if ether was insufflated eight or ten minutes after such an injection, the animals became deeply anesthetized. The dose of ether that was sufficient to cause deep anesthesia was hardly a tenth of the dose that was otherwise required for a similar deep anesthesia without the help of magnesium sulphate. *By the administration of smaller doses of magnesium sulphate and ether, the first stage anesthesia was reached and maintained; that is, complete lack of sensation and the necessary general relaxation for all surgical procedures with the maintenance of special reflexes and without any peripheral paralysis.* Meltzer and Auer, in 1913, in collaboration with Peck and Elsberg, employed the combination clinically in seven cases. The patients were given from 0.4 to 0.6 gm. of magnesium sulphate per kilogram intramuscularly, which was less than half of the effective dose. The ether was administered by endotrachael insufflation. In no case did the patients retain a spark of consciousness even when the concentration of ether in the insufflation was about one sixth of the concentration usually employed. In all the cases there was complete relaxation of the muscles, and in no case was there even the slightest indication of pain while operations were being done in deep, sensitive places, as for example in radical breast amputations or radical removal of extensive, deeply located gland swellings in the neck and laparotomies with manipulation of the parietal peritoneum or gallbladder. With small doses of magnesium sulphate and very lightly maintained ether insufflation, there was often present a certain degree of lid reflex, even at times a spontaneous movement of the lids, without the slightest reaction to the operation on the part of the patient. In such cases the patient awoke shortly after the interruption of the administration of ether and the removal of the insufflation tube, but he could in no way remember the proceedings during the operation.

Gwathmey and Hooper,[8] in quantitative experiments, have found that the intravenous administration of less than one half the anesthetic dose of magnesium sulphate combined with approximately one ninth the anesthetic dose of ether produces surgical anesthesia without increasing the toxicity of the combination. A brief abstract of the experiments follows:

When 6 per cent. ether in physiologic sodium chlorid solution was injected into the internal saphenous vein of the albino rat, the average anesthetic dose was 744 mg. per kilogram, but the minimum lethal dose was over 2½ times 744, or 1,892 mg. per kilogram, indicating a wide margin of safety. When a 6 per cent. solution of magnesium sulphate was given, the same technic being used, the average anesthetic dose was 185 mg. per kilogram, and the average minimum lethal dose was 190 mg. per kilogram, showing a margin so narrow that it would be unsafe to use magnesium sulphate alone as a general anesthetic. If, however, a 6 per cent. ether and 6 per cent. magnesium sulphate solution in physiologic sodium chlorid solution is given, the average anesthetic dose is 170.8 mg. per kilogram, and the average minimum lethal dose is 344.4 mg. per kilogram; i. e., the lethal dose is more than twice the amount of the anesthetic dose, giving a wide margin of safety.

If this combined anesthetic dose, 170.8 mg. per kilogram (ether, 6 per cent.; magnesium sulphate, 6 per cent.) is analyzed, we get the result given in Table 4.

TABLE 4.—*Analysis of Combined Anesthetic Dose*

170.8 mg.	85.4 mg. ether equals 11.48 per cent. anesthetic dose ether alone (744 mg.).
	85.4 mg. $MgSO_4$ equals 46.16 per cent. anesthetic dose $MgSO_4$ alone (185 mg.).

Total, 57.64 per cent. of combined calculated anesthetic dose (296.32 mg.).

Therapeutically, 11.48 + 46.16 equals 100 instead of 57.64 (definite synergism).

The toxicity of ether and magnesium sulphate in combination is a simple summation of the toxicities of the two compounds, as shown in Table 5.

TABLE 5.—*Toxicity of Ether and Magnesium Sulphate in Combination*

344.4 mg.	172.2 mg. ether equals 9.1 per cent. M. L. D. ether alone (1,892 mg.).
	172.2 mg. $MgSO_4$ equals 90.6 per cent. M. L. D. $MgSO_4$ alone (190 mg.).

Total, 99.7 per cent. of combined calculated M. L. D. (345.4 mg.).

From these results we may conclude that ether and magnesium sulphate act synergistically in producing anesthesia without producing any increase in toxicity.

[7] Meltzer, S. J., and Auer, J.: Ueber die anästhetische und lahmende Wirkung von Magnesium unterstützt durch Aether, Zentralbl. f. Physiol. **27**: 632, 1913.

[8] Gwathmey, J. T., and Hooper, C. W.: Synergistic Analgesia and Anesthesia with Special Reference to Magnesium Sulphate, Ether, Morphine and Novocaine, J. Lab. & Clin. Med. **10**: 641 (May) 1925.

Subcutaneous experiments with the albino rat demonstrated that the addition of 2.5 per cent. procain to the magnesium sulphate solution (50 per cent.) or to the magnesium sulphate solution with morphin increases the efficiency, definitely prolongs the effect, and allays irritation, without increasing toxicity. The synergism between magnesium sulphate and procain is definite because procain in itself produces no general analgesic action when injected subcutaneously in the albino rat. The addition of 2.5 per cent. procain increased the efficiency of the magnesium sulphate approximately 50 per cent. The combination of magnesium sulphate (50 per cent.) with procain (2.5 per cent.) may be a good substitute for morphin in general practice. A simple and convincing experiment for any physician is to compare the results produced on the same patient by an injection of one-eighth grain of morphin dissolved in sterile water with those produced with one-eighth grain of morphin dissolved in 2 c.c. of sterile magnesium sulphate solution (50 per cent.) with procain (2.5 per cent.).

If the addition of magnesium sulphate did no more than prolong the morphin effect it would be of great value to the anesthetist. The clinical effects, however, are of even greater importance.

1. The respirations of a patient receiving two or three injections of morphin (one-eighth grain) dissolved in 2 c.c. magnesium sulphate solution (50 per cent.) usually average twenty (normal).
2. The addition of the magnesium sulphate shortens the time of induction, gives a smoother anesthesia and decreases the amount of the anesthetic.
3. Postoperative nausea and vomiting is reduced and in many cases is completely abolished.
4. Wound and gas pains are more often absent and as a result convalescence is shorter and more agreeable.
5. The amount of postoperative morphin is reduced to a minimum.
6. When ether is employed as the anesthetic, the synergists save life. The following experiment is taken from a paper by Gwathmey and Hooper yet to be published: Four healthy albino rats were employed for each experiment. Two of the animals were given intramuscularly 0.8 c.c. per kilogram magnesium sulphate solution (50 per cent.) with procain (2.5 per cent.) and morphin (one-eighth grain in 2 c.c.). The other two animals served as controls and were not given anything. Ten minutes after the preliminary injections, all four animals were placed in the same gas chamber and given exactly the same ether vapor. The controls jumped around and struggled against the anesthetic and finally died within from eight to ten minutes. The synergized animals were anesthetized quickly and quietly and did not die within eight or ten minutes but survived the anesthetic for from twenty to twenty-five minutes. This experiment was repeated several times and always with the same results.

CONCLUSIONS

1. Satisfactory evidence is submitted to show that synergism between magnesium sulphate and morphin *does* occur in man. This evidence was in existence before the present discussion.
2. This synergism, with laboratory animals, is life saving when ether vapor is used as the anesthetic.
3. The synergism between magnesium sulphate and ether has been established for the albino rat, rabbit, dog and man. When properly applied the dose of ether sufficient to produce and maintain satisfactory anesthesia is reduced by one-half or more.

40 East Forty-First Street.

POSTENCEPHALITIC TIC OF THE DIAPHRAGM

PULMONARY OVERVENTILATION, AND RELIEF BY BLOCKADE OF PHRENIC NERVES *

C. J. GAMBLE, M.D.
O. H. PERRY PEPPER, M.D.
AND
G. P. MULLER, M.D.
PHILADELPHIA

This case deserves to be recorded not only because of its own clinical interest, but also because it exemplifies so well the modern method of coordinated team work in the study and treatment of an obscure case. The hospital records of the case include contributions from a variety of sources, each of help in arriving at the final diagnosis or in the treatment. Some might perhaps have been dispensed with and short cuts taken, but only at the expense of thoroughness and certainty.

REPORT OF CASE

A man, aged 38, of Polish birth, was primarily referred in March, 1925, by Dr. C. E. Ervin of the Geisinger Memorial Hospital of Danville, Pa., to Dr. C. H. Frazier in the surgical clinic of the University Hospital. The patient, in November, 1924, had had an illness which was probably acute epidemic encephalitis. The definite symptoms at that time had been pains in the head, back and extremities, with some weakness of the left hand and perhaps of the right side of the face. The hands had shown a tremor. The patient believed that he had been delirious for some little time but did not know how long. From this illness he slowly improved, until, Jan. 13, 1925, he first noticed some disturbances of respiration. He seemed to be breathing fast and hard, he said, and for comfort had to be propped up against several pillows. It was this disturbance of respiration which took him to the Geisinger Memorial Hospital and which led to their referring him to the University Hospital.

In March, under Dr. Frazier's care in the neurosurgical clinic, the patient was very carefully studied, and the following positive findings were discovered:

1. Vague hemianesthesia of the right side of the body.
2. Slight impairment of the seventh and eighth nerves.
3. Horizontal nystagmus. Left pupil negative to light, right pupil sluggish to light.
4. Spinal fluid pressure, 15 mm.
5. Negative Wassermann reaction.
6. Marked tachypnea, with no explanation for this in the examination of the heart or lungs. With each movement of the chest there was at times a slight partial closing of the left fist.

A careful laryngeal examination was performed by Dr. Gabriel Tucker, and no cause for the dyspnea was discovered. A thorough vestibular examination by Dr. Fischer revealed no symptoms of intracranial trouble. Roentgenologic examinations were made of the head for the pituitary fossa and for the sinuses and mastoid region, also of the chest. All of these were negative except for some clouding of the left mastoid. The surgical staff then referred the patient to the medical clinic for further study.

On examination in the medical clinic, it was noted that the patient was "dyspneic" and that the respiratory rate was 84 to the minute. However, he lay flat in bed and was not cyanotic. He complained of pain in the left arm from the shoulder to the elbow and of soreness of the right arm. He also was made very miserable by the distress which the disturbed breathing gave him.

The routine physical examination revealed little else than the findings already recorded, which were thought to be sequelae of the attack of encephalitis. A tremor of the outstretched hands was present, especially on the left, and some ataxia and weakness of the left hand. The routine laboratory tests were all normal.

---

* From the Hospital of the University of Pennsylvania.

A careful study of the disturbance of breathing was made by one of us (C. J. G.), with pneumographic tracings taken of the chest and abdomen simultaneously. Apparently the following conclusions were justified:

1. The rapid chest movements which had been counted as respirations were slight excursions of the thorax which tended to follow the frequently repeated tic or spasm of the diaphragm. This tic occurred as a rule between 60 and 90 times a minute. It was not synchronous with the heart rate. The chest appeared to drop a beat occasionally, so that its frequency of expansion was slightly below that of the diaphragm.
2. Under conditions requiring increased ventilation such as immediately following a prolonged holding of the breath, the thoracic excursion fell into an exact 2 to 1 rhythm, an inspiration following immediately after every second tic. This condition was also observed on numerous occasions while the patient slept. It was also present throughout one day while the patient was awake. No cause could be discovered for the change in this rhythm or for the return to the more usual one on the succeeding day. The slower respiration was accompanied by greater subjective comfort and a more normal blood analysis, as shown in the accompanying table.
3. Holding the breath abolished the movements of the chest, but the tic continued without change. Neither morphin sulphate, one-third grain (0.02 gm.), nor scopolamin or atropin had any effect on the tic.
4. When, under the fluoroscope, the patient was instructed to take a deep breath, the diaphragm could be seen moving in inspiration and expiration, with the more frequent minor contractions of the tic superadded to the larger excursion. When the breathing was not voluntarily controlled, the only motion of the diaphragm was the tic.

It was suggested that the diaphragmatic tic might be producing sufficient pulmonary ventilation to render normal respiratory movements unnecessary. Studies were therefore requested of the department of research medicine to reveal whether this hypothesis was tenable, and were carried out by Dr. J. Harold Austin, the head of that department:

Two specimens of blood were analyzed, one taken when the chest movements were at the rate of 70 per minute, the second when the rate of the coarser movements was 36 per minute, although the tic was at its usual rate.

Results of Blood Analysis

	March 20 Respiratory Rate 70	March 27 Respiratory Rate 36	Normal
Carbon dioxid of venous serum (corrected for oxygen unsaturation)	57 per cent. by volume	62 per cent. by volume	40-60 per cent. by volume
p_H of arterial blood........	7.55	7.43	7.3-7.5
Carbon dioxid tension of arterial blood	18 mm.	40 mm.	35-45 mm.

These figures reveal a shift of the reaction of the blood toward the alkaline side, in this instance in all probability due to the pulmonary overventilation with the excessive blowing off of carbon dioxid, which is evident from the conspicuous lowering of the carbon dioxid tension, and the fact that if the blood of the first date had been saturated at 40 mm. carbon dioxid tension, its serum would have had approximately the p_H and carbon dioxid content of the second specimen. Such a change in the reaction of the blood might be expected to result in the elimination of alkali in the urine as a compensatory or balancing mechanism. The urine of this patient was therefore examined and found to be alkaline to litmus and to have a p_H of 7.3, which is a shift well toward the alkaline side (the normal range of urinary p_H being from 5.0 to 7.5).

These studies confirmed the view that there was overventilation going on as a result of the tic with the synchronous and rapid respiratory movements. The respiratory center was not receiving normal stimuli to respiration and was not sending out strong rhythmic impulses. It seemed possible that there was no actual damage of the respiratory center itself, as might be feared after encephalitis (postencephalitic respiratory syndrome), but that the respiratory disturbance was wholly secondary to the overventilation induced by the diaphragmatic tic. If this were so, an abolishment of the tic should restore the breathing to normal.

In postencephalitic singultus (epidemic hiccup), relief has been obtained by blockage of the phrenic nerves by injection of procain or alcohol, or by freezing the nerves or even by their section. This apparently radical procedure does not disable the diaphragm as much as might be anticipated at first, perhaps because of the innervation of the peripheral part of the diaphragm by the intercostal nerves. The similarity of the present case to one of epidemic hiccup and the patient's distress seemed to justify the suggestion that blockage of the phrenic nerves be attempted.

Consultations were therefore requested with Dr. William G. Spiller, professor of neurology, and with Dr. G. P. Muller of the surgical service. Dr. Spiller agreed with the diagnosis of encephalitis as the basis for the trouble, but was not enthusiastic over the nerve blockage, probably believing that this was but one of several results of the encephalitis and that the tendency of such lesions was to be progressive. Dr. Muller gave the opinion that the blocking of the phrenic nerves could be easily performed, and with little danger. The patient was therefore transferred back to the surgical service for operation.

April 4, Dr. G. P. Muller performed the following operation: Through a small incision on each side of the neck, the phrenic nerve was exposed and frozen with ethyl chlorid spray. The incisions were closed without drainage. During the operation it was noted that the respiratory rate fell from 96 per minute to 20 per minute. A fuller report of this case from its surgical aspects will be made later by Dr. Muller in connection with other observations on the diaphragm.

At once on recovering from the ether anesthesia, the patient expressed his delight at his relief from respiratory distress, and this relief has persisted to date (October 27), a period of almost seven months.

Tracings taken by Dr. Gamble now showed normal respiratory movements, and in the fluoroscope the diaphragmatic movements could not be distinguished from those of a normal person with a small excursion. No tic could be observed. The breathing was apparently normal in every way. The respiratory rate was never rapid. When the breath was held the chest was entirely quiet and none of the jerky movements, which the tic had formerly caused, could be seen. There was no dyspnea or discomfort after climbing three flights of stairs in thirty seconds. No chemical studies were made after the operation.

The patient expressed himself as so much relieved and so comfortable that he insisted on leaving the hospital with the avowed intention of going back to work. He was allowed to leave after being warned that the relief might prove transitory, for it is known that freezing abolishes nerve function for only six to ten months, after which period the tic may return

COMMENT

It is apparent that the relief given this patient was merely symptomatic and perhaps only temporary, and that it will have little or no effect on the course of the disease. On the other hand, the patient did obtain great comfort, and a complete relief from the symptom which was his chief complaint, and a return to economic usefulness. This was well worth while.

The correct analysis of this case depended primarily on the recognition that the so-called rapid breathing was not due to frequent normal respiratory movements but to definitely abnormal spasmodic contractions of the diaphragm. Once this observation was confirmed by fluoroscopic examination and by pneumographic tracings, it was possible to test the correctness of our hypothesis by chemical analysis of the blood and urine. With this added evidence we were justified in taking a step, which at first glance might seem very radical, but the safety of which had been proved and for which there was good anatomic and physiologic basis.

Skill and technic were required to perform the delicate surgical operation and the special examinations reported above. It is only by such cooperative investigation that the best results, in many cases, can be obtained; and the present report, as was said at the outset, is submitted not only because the case is rare and interesting, but because it illustrates a successful application of intensive cooperative investigation.

Clinical Notes, Suggestions, and New Instruments

FISH LINE SUTURES

GEORGE F. CHANDLER, M.D., KINGSTON, N. Y.

For the last two years, I have been using ordinary "Starling" braided silk black fish line for all skin sutures and for all conditions, such as retention sutures in the perineum, which have been commonly made with silk or silkworm gut. Every surgeon to whom I have suggested it and who has used it is enthusiastic.

Silk swells continuously under moisture of the tissues and therefore is hard to remove, usually causing pain. Silk-worm gut cuts the tissue. Linen shrinks and allows the skin coccus to enter alongside the suture, frequently causing stitch abscess.

It occurred to me that the makers of fish line must have developed a structure that would act well in moisture. Experience has taught that boiling makes no difference with the line, and that it can be boiled and boiled again without harm or change. The large size of this suture makes it possible to support the skin incision, if it is used as a chain suture, with very few perforations of the needle. Six or eight locked sutures in an abdominal incision are enough, and they can be removed with absolute ease on the tenth day, leaving a very beautiful scar. Also, time can be saved in closure.

The moderate cost of this line, or suture, is another advantage. At the Kingston City Hospital, we buy it in boxes containing 100 yards each, at a cost of between 2 and 3 cents a yard. We use the Swastika brand, Size 5 F, but this is not necessarily the only one that may be suitable.

11 East Chestnut Street.

DRAINAGE OF THE GALLBLADDER

CHARLES W. MOOTS, M.D., TOLEDO, OHIO

As the technic presented here has never come to the notice of myself or my local friends, it may be of interest to the profession generally. I have used it in cases demanding drainage of the gallbladder when the much preferred operation of cholecystectomy was frankly contraindicated.

A man, aged 44, with a typical history of attacks of gallstone colic, was operated on, Aug. 20, 1925, at Mercy Hospital. When the abdomen was opened, the gallbladder looked and felt healthy, except that it contained five stones. The appendix was found to be in a state of subacute inflammation. What was more serious was the finding of the entire pancreas fully 50 per cent. increased in size, the surface being smooth, however.

The latter finding decided against removal of the gallbladder, and after the stones were removed, it was drained with three-fourths inch rubber tube, well held in by two rows of chromic catgut in such a manner as to turn the serosa against the tube. The appendix was then removed, and the wound closed. The patient was in a good condition; the systolic blood pressure was 120; diastolic, 80.

The patient did well for forty hours, at which time emesis began and recurred from every ten to fifteen minutes for the following twenty-four hours, when his condition became alarming, and the usual treatments failed to give relief. The emesis always had some bile, and finally had a fecal odor. There was great abdominal distention. I tested out the patency of the rubber drainage tube, gallbladder, cystic duct and common duct by slowly and carefully injecting, by means of a glass syringe, a warm boric acid solution through these structures. The patient was able to tell me when the solution reached the duodenum.

I then placed in the glass syringe a 2 ounce (60 c.c.) saturated solution of magnesium sulphate and slowly injected all of it into the duodenum through the drainage tube, gallbladder, cystic duct and common duct. Within forty-five minutes, the patient had a copious, watery stool, with evacuation of much gas, and was at once relieved of all bad symptoms, being able to take fluids freely. He slept all night, with no other medication. The following morning his condition was good, but the same treatment was repeated in order to watch the results. Another free movement of the bowels occurred, followed by a feeling of well being, which continued until his departure for home sixteen days later.

The following precautions are advisable:

(*a*) One should make sure that there can be no leaking about the tubing where it is stitched into the gallbladder.

(*b*) It should be ascertained whether there is any formidable obstruction in the cystic or the common duct.

2485 Collingwood Avenue.

New and Nonofficial Remedies

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION. W. A. PUCKNER, SECRETARY.

ARSPHENAMINE-D. R. L. (See New and Nonofficial Remedies, 1925, p. 47).

The following dosage forms have been accepted:

Arsphenamine-D. R. L., 0.3 Gm. Ampules.
Arsphenamine-D. R. L., 0.5 Gm. Ampules.

NEOARSPHENAMINE-D. R. L. (See New and Nonofficial Remedies, 1925, p. 49).

The following dosage form has been accepted:

Neoarsphenamine-D. R. L., 0.15 Gm. Ampules.

SCARLET FEVER STREPTOCOCCUS ANTITOXIN (See THE JOURNAL, May 2, 1925, p. 1338).

Lederle Antitoxin Laboratories, New York.

Scarlet Fever Streptococcus Antitoxin-Lederle (Refined and Concentrated).—It is prepared by immunizing horses by the subcutaneous injection of the toxic filtrate obtained by growing the scarlet fever streptococcus in broth; also by injecting cultures of the scarlet fever streptococcus. The serum is concentrated by a method similar to the Gibson-Banzhaf method. Each cubic centimeter neutralizes at least 50,000 skin test doses of scarlet fever toxin.

Marketed in packages of one syringe containing 1 Cc. (prophylactic dose); and in packages of one syringe containing 10 Cc. (therapeutic dose).

SAUBERMANN RADIUM EMANATION ACTIVATOR (See New and Nonofficial Remedies, 1925, p. 315).

The following apparatus has been accepted:

Saubermann Radium Emanation Activator, 100,000 Mache Units: An apparatus which imparts about 36 microcuries (100,000 Mache units) *to about 500 Cc. of water daily.*

Health Program for County.—The county and state health authorities should agree on a health program to be undertaken, the general guides being (*a*) the relative importance and the relative preventability of the disease or group of diseases; (*b*) the conjectural value of those health activities not directed specifically against particular diseases, and (*c*) the psychologic response of the people to the service.—Parran, Thomas, Jr.: *Pub. Health Rep.* **40**:987 (May 15) 1925.

SATURDAY, NOVEMBER 7, 1925

A NEW CONCEPTION OF GLYCOGEN FORMATION

Nearly three quarters of a century has elapsed since Claude Bernard's discovery of glycogen as a component of the liver. This interesting finding was soon followed by the demonstration that the glucose-yielding carbohydrate is ordinarily present in a large variety of tissues. Glycogen occurs not only in the higher animals but also in the lowly forms, so that it was soon acclaimed as one of the fundamental components of cells. The principal feature of glycogen in the body is its ready conversion to glucose, the characteristic sugar of the blood. This was recognized at the outset of the study of the subject. Knowledge of the genesis of glycogen has been attained more gradually, until today there is general agreement that it can be formed not only from carbohydrates but also from proteins—and perhaps from fats. Bernard himself looked on glycogen as a product formed in a way analogous to the secretions. Succeeding physiologists, however, have promoted the idea that this carbohydrate is a storage product; hence it was often designated as "animal starch," in contrast with starch that is a deposited source of food in plants.

Markowitz [1] of the physiologic laboratory at the University of Toronto has offered the criticism that if glycogen were merely a storage material, it should be possible to exhaust it by starvation. As a rule this is not so; in fact, it may accumulate during starvation. If conditions are developed whereby the organism, notably the liver, actually becomes glycogen-free, it is seemingly impossible to maintain the indispensable content of sugar in the blood, and thereupon disaster ensues. Markowitz has pointed out that, in the light of the common conception of glycogen as a storage material in the body, the actual accumulation of the substance in the liver during starvation, sometimes to the extent of several per cent., is a paradox. The observation, he remarks, suggests that liver glycogen is an essential step in the transformation of fat or protein to carbohydrate. When this transformation cannot take place, as after phosphorus poisoning or liver extirpation, the blood sugar falls and the organism dies unless glucose is supplied to it. Glycogen thus cannot be compared directly with the fat depots of the well fed organism; for it seems to be an obligatory, and not an optional, step in the formation of blood sugar from the noncarbohydrate stores of the organism. In other words, glycogen may serve as an essential intermediate step in the metabolism of carbohydrate, so that the absolute quantity of glycogen in the organism is a balance between glyconeogenesis and glycogenolysis.

If these views are well established, glycogen should no longer be regarded as a "static" substance in the body but rather as a dynamic material which the organism is always consuming, and almost as quickly replacing. This newer conception of the important function of glycogen as an indispensable intermediate in sugar metabolism affords a rationale for the seemingly contradictory facts that insulin, on the one hand, facilitates the utilization or consumption of sugar, yet is a potent factor in the storage of glycogen. As glycogen is stored in the liver of depancreatized animals, following the administration of both carbohydrate and insulin, and since the respiratory quotient under the same conditions rises markedly (thereby indicating sugar combustion in the body) it is evident, to quote the words of Joslin,[2] that the beginning and end of carbohydrate metabolism is dependent on insulin.

FRESH FRUITS AND VEGETABLES: VITAMINS AND BACTERIA

The importance of fruits and vegetables in the dietary of man is attested by the instinctive food choices of many generations as well as by the teachings of the science of nutrition. It has long been easy to furnish a satisfactory explanation of the individual nutritive virtues of many of the more familiar components of the human regimen in terms of proteins, fats, carbohydrates or, perhaps, inorganic salts that they happen to furnish in special abundance. The fruits and green vegetables have not fitted so easily into the groups of "energy-yielding" or "tissue-building" nutrients. Consequently, only recently could more cogent reasons be offered for their use. It would be quite possible for a person to omit fruits and vegetables from his diet without running the risk of not getting enough starch, sugar and protein. On the other hand, fruits and vegetables have rather been regarded as essential to health because they may supply certain desirable substances not usually found in other food materials. There was a time when flavor and texture were their reputed advantages. More recently their content of inorganic substances and above all their supply of the various indispensable vitamins has given them unique importance.

[2] Joslin, E. P.: The Treatment of Diabetes Mellitus, Philadelphia, Lea & Febiger, 1923, p. 24.

Reviewing our knowledge of the subject, McCollum[1] points out that fruits appear from the results of chemical analysis to be closely comparable in their composition to the familiar vegetables such as the tubers and roots. They all contain much water and varying amounts of sugars, and are relatively insignificant as sources of protein or fat. They are much more attractive to the palate than are most of the vegetables. They enjoy the popular reputation of possessing mild laxative properties, and tend to increase elimination by virtue of their mild diuretic qualities, part of which are due to the extra water consumption and part to the action of certain salts of organic acids they contain. Fruit juices or the edible parts of fruits differ from the cereal grains, and resemble in an important respect the vegetables, which are morphologically tubers or roots. There is an excess of basic radicals, which renders their ash alkaline, whereas most seeds give an acid ash. Meats are also of acid character. The meat and bread portion of our diet, when oxidized in metabolism, leads to the formation of an excess of acid over base forming substances. It is now a well established fact that a certain alkali reserve in the blood is essential to maintain its capacity to carry carbon dioxid to the lungs for elimination, and that a common pathologic condition, acidosis, exists in which this reserve falls below normal. This forms sound reason, McCollum continues, why the addition of fruits and vegetables to the diet tends to the establishment of a proper acid-base equilibrium in the various fluids of the body. The fruits differ from the leafy vegetables in containing little calcium. They resemble the tubers and roots, as they do not tend to supplement the deficiencies of seed or meat products in this respect. Nearly a decade has elapsed since our entry into the World War. There is already a peculiar historical interest merely in reading the following "official" war-time advice of the United States Food Administration: Vegetables and fruits represent a different and happier phase of the food situation than that of most of the staples. They represent a great potential reserve of foods for home consumption. Not only does their presence in the diet add to health, but it releases other foods for shipment abroad.[2]

The food consumer of the present day is confronted with an apparent conflict of advice in his desire to partake freely of the fruits and vegetables. On the one hand, there are recurring admonitions of the unsuspected dangers that may lurk in fresh foods which are commonly eaten uncooked. Putrefactive bacteria and botulism, typhoid and paratyphoid germs are some of the more or less indefinite terrors to be recalled in this connection. In the East, the prevalence of infectious diseases has raised the presumption that the organisms causing them are often conveyed by the eating of fresh fruits and vegetables—a possibility emphasized by the widespread use of human excreta as fertilizer. It has even been asserted that this practice is likely to increase among market gardeners near the large cities in this country where the immigrant farmers tend to continue the agricultural customs of their native country. On the other hand, although safety might be secured by adequate sterilization of such foods through cookery, we have been warned that heat is destructive to the indispensable vitamins. The well known genesis of scurvy on a regimen of heated milk is commonly cited in justification of such claims.

In the midst of this quandary as to the wise procedure in diet, certain newly established facts are alike helpful and reassuring. The reports of the destructive effects of heat on vitamins as a class have been "grossly exaggerated." The lability seems to apply more particularly to vitamins A and C and to depend largely on the conditions of heating employed. When the possibility of oxidation is precluded, as in commercial canning rather than open-air heating, the loss of vitamins is greatly reduced, if not actually negligible. Vitamin B is notably resistant to heat at boiling temperature. Furthermore, the extensive investigations of Mills, Bartlett and Kessel[3] at the Peking Union Medical College, in China, have brought new evidence that normal uninjured fruits and vegetables do not contain living bacteria within their tissues. We fail to realize that nature has provided these foods in sterile packages for our use. Bacteria do not penetrate the unbroken skin of fruits and vegetables kept under market conditions. Finely divided particulate matter, corresponding in size to bacteria, protozoan cysts and helminth ova, does not penetrate the stem end of fresh vegetables to any appreciable extent. Bacteria pathogenic to man may gain entrance to fruits and vegetables through injured and decayed portions, where they may remain viable and spread to a limited extent. It is therefore advisable to remove such portions before attempting the sterilization of food in any way. However, harmful micro-organisms may persist on the surfaces of fruits and vegetables for many days, according to the Peking bacteriologists. Their investigation of methods of chemical disinfection of vegetable matter in the East, through chlorination, permanganate, alcohol or comparable means has been disappointing. Hence they admonish us that dipping fruits and vegetables foten seconds into boiling water is the only method thus far discovered that will uniformly kill all pathogenic bacteria, protozoan cysts and helminth eggs that might be found contaminating such food products and render them safe for human consumption in an uncooked condition. The traveler in the Orient, as well as the resident at home in the Occident, may now be comforted by the assurance that with proper sterilization or cookery his quota of fruits and vegetables may be made microbiotically safe—and that without undue deprivation of the vitamins.

THE LIVER AND THE PANCREAS IN DIABETES

Mann and Magath[1] of the Mayo Foundation have *demonstrated cogently that the maintenance of the* normal level of sugar in the blood is absolutely dependent on the liver. The latter organ and its functioning are equally essential in the maintenance of a hyperglycemic blood sugar level, such as is observed in failure of the pancreatic activities on which the combustion of sugar in the blood seems to depend. It has been noted that the increase in blood sugar following pancreatectomy is dependent on the presence of the liver. Without an adequate amount of functioning liver tissue, the increase in blood sugar following removal of the pancreas does not occur. Thus it has been proved in another way that, whatever may be the process of carbohydrate metabolism, the liver has a vital part in that process. Distinction between the normal and the diabetic organism disappears when both liver and pancreas are removed from the body.

In commenting on these features of the metabolism of carbohydrates, Murlin[2] of the University of Rochester, N. Y., remarks that, if the liver must be present to produce the diabetic state on removal of the pancreas, we have at least a partnership instead of an individual agency to keep us normal. May it not well be, he asks, that both Minkowski and von Noorden were right, in a measure? The former set up the "failure of combustion" theory, the latter the "overproduction of sugar" theory. Banting gave us the hormone necessary to combustion, thus supporting Minkowski; but, Murlin adds, it is destroyed by too much sugar.

The last thesis cannot yet be regarded as completely demonstrated, though it is strongly supported by Murlin's studies. It has been established that insulin may be inactivated by reducing agents,[3] and perhaps reactivated by exposure to oxidizing agents. This suggested the possibility that the pancreatic hormone might be inactivated by reducing sugars, thus explaining their antidoting effects and conceivably throwing some light on the genesis of diabetes. Murlin's observations leave little doubt that in vitro, at least, an excess of glucose can render insulin impotent; it is quite likely that a similar reaction occurs in the organism itself; hence the antidotal effect of sugar against overdosage with the pancreatic hormone. Normal carbohydrate metabolism demands a proper balance between insulin and sugar. In securing this, more than one organ may be involved; and in failure to maintain the balance, the liver as well as the pancreas may at times be responsible. Speculation on the genesis of diabetes from this point of view may presently prove to be worth while.

AIR CURRENTS IN VENTILATION

The oppressiveness of an unventilated room is something that is recognized by our sensations. The effects may vary from slight discomfort to actual malaise, all of which proper ventilation aims to avert. There was a time when hygienists were greatly concerned about the chemical composition of the air in relation to health and comfort, when the "badness" of air in ordinary buildings was sought in the form of excessive amounts of carbon dioxid or more poisonous organic respiratory products. One even heard about the fatigue-producing toxins of expired air. Scientific investigation has failed to support such explanations. In considering ventilation, it attaches importance not to the chemical composition of the air but rather to physical properties, temperature, humidity and movements of the surrounding atmosphere. Successful ventilation, a well known British report states,[1] depends on the prevention of stagnation of body heat, on the one hand, and of uncomfortable chilling of the body, on the other.

The fresh and comfortable sensation produced in well ventilated rooms, in contrast with an oppressive environment, is now believed to be due in no small degree to air movement. Success in effecting a feeling of well being through ventilation consists apparently in preventing the discomfort of distinct drafts without permitting actual stagnation of the air. Baetjer[2] has recently pointed out that the movements which give comfort under ordinary room conditions seem to lie somewhere near the threshold of perceptibility. The play of a current of air on the skin may set up a number of changes, any one of which or a combination of all of which may react on our feelings of comfort. Baetjer suggests further that the current of air may stimulate directly the cutaneous sensory fibers (pressure, temperature), and the sensations thus aroused may contribute immediately to our feelings of comfort or discomfort, or they may act in an indirect way, for example, by a reflex effect on metabolism or on the vasomotor apparatus. The skin surface may undergo a vasoconstriction or a vasodilatation, locally or generally, with a resulting change in the cutaneous temperature sensations. Or the current of air may affect us by its physical effect on the skin. Heat dissipation may be influenced by changes in convection and evaporation, according to the condition of the air in regard to temperature and moisture.

[2] *Baetjer, Anna M.: Threshold Air Currents in Ventilation*, Am. J. Hyg. **4**: 650 (Nov.) 1924.

The actual experiments of Baetjer in the laboratory of physiologic hygiene at Johns Hopkins University indicate that currents of air in the neighborhood of the threshold of perceptibility contribute to our comfort, in all probability, by acting on the sensory nerves of the skin, directly or indirectly, and arousing cutaneous sensations of an agreeable kind. Currents as slight as 0.15 meter a second give a perceptible stimulus to the sensory nerves of the cheek. The value of the threshold velocity varies with the temperature, but is independent of the humidity of the current air. When current air temperature equals normal room air temperature, the threshold velocity varies from 0.2 to 0.3 meter a second. The fact that the threshold value for velocity, as determined by experiment, depends on the temperature of the current of air would lead to the belief that the temperature nerves are mainly concerned. The higher the temperature, the greater must be the velocity of the current to be perceived. Therefore, according to Baetjer, in ventilating a room, the amount of air movement should be controlled by the temperature of the moving air. As shown by her practical experiments, a room at ordinary room temperatures in which the currents are below the threshold limit produces an uncomfortable feeling of closeness, while one with currents much above the threshold values becomes unpleasant on account of the drafts. Baetjer also suggests that since an air current of threshold value is perceptible when it first strikes the skin, but ceases to be perceptible when continued for a few minutes, it is possible that air currents, rising above and falling below the threshold velocity and varying in temperature, produce a series of mild cutaneous stimulations of agreeable character. Possibly this factor may serve to explain in part the preference often expressed for window ventilation under favorable conditions over mechanical systems. In any event, the lesson from the latest experiments is that, in the case of crowded or overheated rooms, a system of ventilation which delivers the circulating air at a somewhat lower temperature than that of the room and at or slightly above threshold velocities should give the best result. Speaking practically, the air movement in a well ventilated room should not fall below the threshold value for the skin of the cheek.

Current Comment

THE DAILY INTAKE OF IODIN

The interrelation between iodin and the thyroid glands has become so familiar to both the physician and the intelligent layman that its significance no longer calls for explanation or emphasis. So far as the genesis of those thyroid conditions that are remediable by administration of iodin is concerned, fundamental facts have largely been wanting. There has been a well founded conjecture that somehow in those regions where endemic goiter is most common the availability of iodin in the air, the potable waters or the food supply must be restricted in comparison with what is true in the areas of comparative immunity from goiter among both man and animals. The quantities of the element that are involved in these differences are extremely small—amounts less than "parts per million" of the food and drink. Such minute proportions call for great refinement of analytic methods. It is the merit of McClendon of the University of Minnesota to have furnished striking illustrations of the parallelism between the incidence of endemic goiter and the iodin content of foods derived from the regions especially concerned. A similar service has since been performed by von Fellenberg[1] of Bern, in Switzerland. In places where thyroid disturbances are notably prominent, the distribution of iodin in air, water and animal foods in particular was found far less abundant than in other places known to be essentially free from endemic goiter. The differences were further accentuated by the contrasting iodin content of the excreta of persons in the localities compared. Relative richness in iodin always accompanied the more normal conditions. What this means in a quantitative way is differences of the order of magnitude of 0.05 mg. of potassium iodid or 0.038 mg. of iodin daily in the intake. Contemplation of such minute amounts—a few hundredths of a milligram—brings us to better realization of the large importance of "little things" in nutrition.

THE SIGNIFICANCE OF UROBILINURIA

The occurrence of urobilin or its immediate precursor in the urine of certain patients has long been recognized. The rational clinical interpretation of the significance of urobilinuria has awaited the more precise determination of the factors that are responsible for its genesis, transport and excretion. The long existing uncertainty as to where urobilin is formed in the body seems at length to be dispelled. The story of its behavior has been developed in a satisfactory way through the researches, among others, of McMaster and his co-workers[2] at the Rockefeller Institute of Medical Research. Thus, under normal conditions, in the dog at least, urobilin is formed only within the intestinal tract. Drainage of the entire bile quantity under sterile conditions, or retention of it by common duct occlusion, results in the prompt disappearance of the pigment from the excreta and bile. The animal becomes in fact urobilin-free. But whenever bilirubin enters the intestine urobilin is rapidly formed, part escaping with the feces while another part is absorbed from the bowel, either as such or in the form of related pigments. This secondary resorption and resecretion play an important part in the normal fate of urobilin. The latest investigations of Elman and McMaster[3] demonstrate that animals rendered urobilin-free by collection of all the bile without contact with the intestine remain urobilin-free even after severe hepatic injury. This negatives the assumption that pathologically altered liver cells can manufacture urobilin. The latter is unquestionably a product of bacterial action in the intestine or biliary passages. It is not the product of a damaged hepatic tissue, as urobilinuria is never found after liver injury except when bile pigment has been present in the intestine. When, however, the alimentary formation of urobilin becomes possible, urobilinuria is a prominent symptom of liver injury; thus it is the expression of the inability of the liver cells to remove from the circulation the urobilin brought by the portal stream, with the result that the pigment passess on to the kidneys and the urine. Indeed, urobilinuria occurs with a far less degree of liver injury than does bilirubinuria. The diagnostic possibilities revealed by such facts are important.

THE DALLAS SESSION

Papers for Section on Orthopedic Surgery

Any Fellow of the American Medical Association who wishes to present a paper before the Section on Orthopedic Surgery at the annual meeting is requested to communicate with the secretary of the section as soon as possible.

All requests for place on the program must be accompanied by an abstract of the paper. Requests for place on the program are acted on by the Executive Committee.

ARCHER O'REILLY,
3534 Washington Boulevard, St. Louis.
Secretary, Section on Orthopedic Surgery.

Conference on Negro Health Work.—A conference was held at the office of the Surgeon General, U. S. Public Health Service, October 21, to further health work among negroes. Among the delegates to the conference were Dr. Helen A. Moore, American Child Health Association; Franklin O. Nichols, National Health Council and the American Social Hygiene Association; William B. Matthews, National Tuberculosis Association, and R. Maurice Moss of the National Urban League. "More National Negro Health Work" was adopted as a new slogan. Plans to revise the literature used in this work were considered and a program outlined for National Negro Health Week during 1926. The National Tuberculosis Association, American Red Cross and the American Child Health Association have agreed to furnish special literature. The conference adjourned to meet at Tuskegee Institute, Jan. 30, 1926, when this literature will be ready for distribution. Emphasis was made on the necessity for better understanding on the part of the public of the negro health problem.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ALABAMA

Bust of General Gorgas.—The bronze bust of the late Surg. Gen. William C. Gorgas, to be presented to the state by the Medical Association of the State of Alabama, has been received at the state health department from New York.

CALIFORNIA

Officer's Commission Stolen.—The secretary of the California State Board of Medical Examiners writes that the commission of Dr. Harlen A. Todd, Visalia, given him as a medical officer in the U. S. Army during the World War, was stolen during a recent burglary.

Optometrists and the Title "Dr."—According to press reports, Attorney General U. S. Webb has advised the state board of optometry that California optometrists cannot legally call themselves "Doctors" or "Drs." in prefixes, and can only add the affixes of "Opt. D." or "O.D." when they are graduates of an accredited school of optometry; also that no California optometrist may hold out to his prospective patients that he possesses "special knowledge" of optometry as defined in the act, which defines optometry as a mechanical and not a medical science.

Society News.—The seventy-third semiannual meeting of the Southern California Medical Association will be held, November 6-7, at the Ebell Club, Los Angeles, under the presidency of Dr. Rexwald Brown, Santa Barbara. Among the speakers will be Dr. Robert E. Ramsay, Pasadena, "Myelocytomatosis Following Subcutaneous Administration of Whole Blood in a Child with Severe Leukopenia"; Dr. T. Homer Coffen, Portland, Ore., "The Failing Heart"; Dr. Samuel H. Watson, Tucson, Ariz., "Heliotherapy in Pulmonary Tuberculosis," and at 8:15 p. m., Saturday, Sir John Adams, emeritus professor of education, University of London, will speak on "Sherlock Holmes—A Study in Observation."

CONNECTICUT

Thyroid Survey.—The U. S. Public Health Service is making a thyroid survey in Connecticut at the request of the state department of health. It will cover several cities or towns in each county in the state and represent in each the examination of groups of from 500 to 1,000 school children. The primary purpose is to ascertain the percentage of thyroid enlargement and incidentally to study its relation, if any, to focal infection.

Psychiatry at Yale.—Dr. Milton C. Winternitz, dean, Yale University School of Medicine, New Haven, announced, October 31, plans for the development of work in psychiatry and mental hygiene in that school. He said, according to the New York *Times*, that the faculty of the school of medicine had placed the creation of a department of psychiatry in the foreground of its problem of development, and that Yale hopes to train physicians who "are familiar with the problem of human personality" rather than specialists. With the appointment of Dr. Arthur H. Ruggles as lecturer in psychiatry and consultant in mental hygiene to the university department of health, Yale initiates a program for the study and prevention of abnormal mental reactions in individuals. "A sane approach to the problem among the students," he said, "promises to meet with as much success as it has in general community life." The General Education Board and a Yale graduate have each provided $15,000 a year to initiate this program.

DISTRICT OF COLUMBIA

Society News.—Dr. Everett M. Ellison was elected president of the Wapiya at the annual meeting, October 27; Dr. Stewart B. Muncaster, vice president, and Dr. Fred Y. Williamson, secretary-treasurer. Wapiya is an organization of more than 100 physicians who are members by virtue of their membership in the University Club. Meetings are held weekly, and twice a month they are devoted to some subject other than medical. The official organ of the Wapiya is the

Tom Tom; the editors are Drs. John A. Foote and Ralph S. Pendexter.

Report of Public Health Committee.—A report made by the Public Health Committee of the District Board of Trade shows that during 1924 there were reported to the health department 6,553 deaths (4,140 white and 2,413 colored) making a death rate of 13.46 per thousand. The deaths from typhoid fever were eighteen white and one colored, a rate of 3 per hundred thousand; from scarlet fever, seven white and one colored, a rate of 1.6 per hundred thousand; from whooping cough, four white and nine colored, a rate of 2.6 per hundred thousand; from diphtheria, thirty, twenty-six being white and four colored, a rate of 6.2 per hundred thousand; from influenza, twenty white and thirteen colored, a rate of 6.8 per hundred thousand; from pulmonary tuberculosis, 204 white and 270 colored, giving a death rate of 97.3 per hundred thousand; 533 from cancer, 403 white and 130 colored, a rate of 109 per hundred thousand. The number of suicides were seventy-seven white and seven colored, a rate of 17.3 per hundred thousand. The number of homicides was nineteen white and thirty-five colored, a rate of 11.1 per hundred thousand. The Public Health Committee again urgently recommended an increase in the number of physicians, dentists, dental clinics and nurses for the public schools. It recommended, among other things, that twelve additional nurses be provided, four additional dental clinics be established and eight additional dentists and twelve dental nurses or assistants be provided.

FLORIDA

Personal.—Dr. James R. Bean has returned to the laboratories of the state board of health as senior bacteriologist after an absence of nearly nine years.

Society News.—Twenty-five members of the Orange County Medical Society, comprising Orange, Osceola and Seminole counties, each recently gave twenty-four hours to the instruction of Boy Scouts at the encampment of the Central Florida Council at Plymouth.

HAWAII

Pan-Pacific Medical Conference.—At the recent annual conference of the Medical Association of Hawaii, a resolution was passed endorsing the first Pan-Pacific Medical Conference, which will convene in Honolulu in 1928 just prior to the Pan-Pacific Women's Conference. The following committee was named: Dr. Nils P. Larsen, chairman; Dr. Goichi Asami, Dr. Harry H. Blodgett, Dr. Wah K. Chang, Dr. Clarence E. Fronk, Dr. Roger J. Mermod, Dr. Iga Mori, Dr. Vasco E. M. Osorio, Dr. Carl F. Reppun, Dr. Archibald N. Sinclair, Dr. C. B. Wood and Dr. Yon C. Yang.

IDAHO

Increase in Death Rate.—The death rate for Idaho for 1924, according to the Department of Commerce, was 787 per hundred thousand of population, as compared with 708 in 1923. The increase was due largely to increases in the death rates from diseases of the heart, cancer, tuberculosis, measles, syphilis, intestinal diseases and accidental causes.

ILLINOIS

Personal.—Dr. John P. Denby, Carlinville, has been elected president of the Illinois Tuberculosis Association.——Dr. Ira W. Johnson, Bridgeport, has been appointed county physician of Lawrence County.——Dr. Edward G. Ahrens, formerly with the Minnesota State Tuberculosis Sanatorium at Ah-gwah-ching, has been appointed medical director of the Macon County Tuberculosis Sanatorium, Decatur.

Chicago

Children's Home.—The Illinois Children's Home and Aid Society, 308 North Michigan Avenue, maintains receiving institutions at Duquoin and Evanston for a laboratory study of children prior to placement, and a training school at Potomac for vocational training. These institutions have a capacity of twenty-five, forty-five and thirty, respectively. The society cares for more than 1,650 children, over 1,000 of whom are in private families which receive no compensation, and over 300 of which are with private families where board is paid by the society, parents or friends; the other children are cared for temporarily by cooperative Chicago agencies.

Personal.—A dinner will be given in honor of Dr. Robert H. Babcock by his medical friends at the Drake Hotel, November 10.——Edward E. Slosson, Ph.D., editor of *Science Service,* will lecture, November 9, in Orchestra Hall under the auspices of the University of Chicago on "Chemistry and Human Welfare."——Dr. Agnes Beulah Cushman has been elected secretary of the Chicago Council of Medical Women. Dr. Mary M. S. Johnstone, of the Tuberculosis Division of the Veterans' Bureau, has been transferred temporarily to St. Louis.——Dr. Patrick J. H. Farrell was elected surgeon general of the Military Order of the World War, at the annual meeting in New York, September 26.

New Plans for Medical Arts Club.—At a meeting of the board of directors of the Medical Arts Club, held October 30, it was unanimously voted to change the name of the club to the Medical and Dental Arts Club of Chicago. C. N. Johnson, D.D.S., retiring president of the American Dental Association, was elected a member of the board of directors. Mr. John A. King was elected as business manager in place of Mr. David MacLean. The report of the Chicago Trust Company, trustee, showed that there were in the hands of the trustee $214,173.08 as a nucleus for a building fund. Plans for a building include an assembly hall seating from 700 to 800 for the regular meetings of the Chicago Medical and Chicago Dental societies and for other professional meetings and conventions, rooms for the various local special societies, headquarters for the Chicago Medical and Chicago Dental societies, the Illinois State Medical and Dental societies, the American Dental Association and others; club rooms for the convenience of the members; bedrooms for resident and out of town members and guests; the remainder of the building, including 75 per cent. of the total available space, to be rented as stores, offices and salesrooms to firms doing business with physicians and dentists.

Society News.—Dr. Anton J. Carlson addressed the South Chicago Branch of the Chicago Medical Society, October 27, on "Recent Advances in the Physiology of the Alimentary Canal."——States Attorney Robert E. Crowe addressed the Englewood Branch of the Chicago Medical Society, November 3, on "The Doctor and the Law."——There was a reception at the Chicago Athletic Club, November 4, in honor of Sir William Arbuthnot Lane and Mr. Philip Franklin, London, England, and a dinner given by the officers of the Chicago Medical Society previous to the general meeting in the Marshall Field Annex. The subject of the address of Sir W. Arbuthnot Lane was "Present Treatment of Fractures," and that of Mr. Philip Franklin, "Newer Developments in Laryngology."——Dr. William Allen Pusey will open the discussion from the dermatologic standpoint, and Dr. Maurice Lewison from the tuberculosis standpoint, following the joint paper on "The Noticeable Parallelism and Similarity Between Leprosy and Tuberculosis" to be presented before the Chicago Medical Society by Dr. Oswald E. Denney, U. S. Public Health Service, and Dr. John Ritter, Chicago, November 18.——Dr. Lewis E. Daniels, Detroit, will address the Chicago Roentgen Ray Society, November 10, at the Virginia Hotel, on "Roentgen Ray in Pathologic Pregnancies and Labor." Dr. Joseph B. DeLee will open the discussion.——The next meeting of the Chicago Laryngological and Otological Society will be November 19 at the Hotel Sherman.——Sir W. Arbuthnot Lane, London, addressed the Chicago Surgical Society at its regular meeting, November 6, at the University Club, on "Chronic Intestinal Stasis," and Dr. Donald C. Balfour, Rochester, Minn., on "Disabilities Following Gastro-Enterostomy." The regular clinical meeting of the society began at 9 o'clock at Michael Reese Hospital.

INDIANA

Society News.—Dr. William Allen Pusey, Chicago, past president of the American Medical Association, will conduct a clinic for the Tippecanoe County Medical Society, St. Elizabeth's Hospital, LaFayette, November 12, and, following a banquet at the LaFayette Club at 6 p. m., will give an address on syphilis. Members are invited to bring cases of skin disease of any kind whatever to the clinic.——Dr. Kellogg Speed, Chicago, addressed the St. Joe County Medical Society, South Bend, October 25, on "Fractures."

IOWA

Society News.—Dr. Merrill M. Myers, Des Moines, conducted a clinic on heart disease before the Jackson County Medical Society, Maquoketa, and addressed the society at the evening session on heart disease. The clinic was held under the auspices of the Iowa Tuberculosis Association.

Superintendent Appointed.—It is reported that Dr. Jesse L. McElroy, director of St. Mark's Hospital, New York, has been appointed head of the State University of Iowa Hospital, Iowa City, to succeed Dr. Bert W. Caldwell, resigned. Dr. McElroy was also formerly superintendent of the Ancker Hospital, St. Paul, Minn.

KENTUCKY

Infantile Paralysis Epidemic.—Following a conference of the city health officer of Louisville with physicians, an order was issued closing the public schools, October 22, on account of an outbreak of infantile paralysis in that city. There had then been, it is reported, nineteen cases and four deaths. There were six cases of infantile paralysis in Owensboro also, October 22, with two deaths.

Superintendent Appointed.—Dr. Paul A. Turner, Seattle, formerly state health officer of Washington, has been appointed superintendent of the Kentucky State Tuberculosis Sanatorium at Louisville, to succeed the late Dr. Samuel W. Bates. Dr. Turner, who has already taken up his new position, was also formerly city health officer of Seattle and superintendent of the Seattle Tuberculosis Sanatorium.

LOUISIANA

Castellani Accepts Professorship at Tulane.—Dr. Aldo Castellani, now professor in the London School of Tropical Medicine, has accepted an appointment as head of the department of tropical medicine at Tulane University of Louisiana School of Medicine, New Orleans, and will arrive in that city in December. The reorganized department of tropical medicine will have three assistant professors and a staff of technicians and will provide training for undergraduate and graduate students; it will conduct research on the dietary problems of tropical climes, on disturbances arising from fungi, on the parasitic diseases, and on the results of exposure to tropical sunlight. Professor Castellani was born in Florence, Italy, in 1875. He graduated from the University of Florence, did postgraduate work at the University of Bonn, and was a member of the Royal Society's commission in Uganda, 1902-1905, and director of clinique for Tropical Diseases and physician to Colombo General Hospital, 1903-1915; he discovered the cause of African sleeping sickness (trypanosomiasis) in 1902 and the cause of yaws (frambesia) in 1905. He is the co-author of a standard textbook on tropical diseases and the author of many contributions to scientific journals (The Journal, May 2, p. 1363).

MARYLAND

Personal.—Maynard M. Metcalfe, Ph.D., Johns Hopkins University School of Hygiene and Public Health, Baltimore, sailed for Rio de Janeiro, September 26, as a representative of the Smithsonian Institute, Washington, D. C., to study certain species of the one-cell parasite *Opalina*, at Montevideo.

Cancer Meeting.—The Frederick County Medical Society and the Maryland Association for the Prevention of Cancer held a joint meeting to discuss cancer at Hood College, Frederick, October 2. Dr. George H. Riggs, president, Frederick County Medical Society, presided, and Drs. Joseph C. Bloodgood, Lewellys F. Barker and Thomas S. Cullen, all of the Johns Hopkins Hospital, Baltimore, were the speakers.

The Grenfell Mission.—Drs. Ralph F. Bowers and Alvin F. Coburn have returned to Baltimore from Labrador, where they were associated with the Grenfell mission during the summer. They cruised along the coast of Labrador on the hospital ship caring for patients and assisting in operations, visited three of the hospitals and nursing stations and instructed fishermen in first aid. They were delighted with the medical facilities in that country as provided by the Grenfell Mission.

Wilmer Institute Opens.—The Wilmer Institute of Johns Hopkins Hospital, Baltimore (for the study and treatment of diseases of the eye), was officially opened, October 29, under the directorship of Dr. William Holland Wilmer, formerly of Washington, D. C. The first unit of the new institute (forty beds) has been established in a wing of the hospital formerly part of the Nurses' Home, which has been renovated and especially fitted up. The next unit will be equipped with research laboratories.

Medal Awarded to Dr. Welch.—The first W. W. Gerhard gold medal offered by the Pathological Society of Philadelphia has been awarded to Dr. William H. Welch, director, School of Hygiene and Public Health, Johns Hopkins University, Baltimore, and will be presented, November 12, when Dr. Welch will lecture before the society. The award was instituted by the Pathological Society of Philadelphia in collaboration with Dr. Arthur H. Gerhard in memory of William Wood Gerhard (1809-1872), who first differentiated typhoid fever from typhus.

MASSACHUSETTS

Personal.—Dr. Richard P. Strong, professor of tropical medicine of the Medical School of Harvard University, Boston, addressed the Medical Society of the State of Pennsylvania at Harrisburg, October 7, on "Spirochetal Infections of Man."——Dr. Guy C. Randall has been appointed state psychiatrist for Essex County to succeed the late Dr. Nelson G. Trueman.

Dr. Bigelow Appointed Commissioner of Health.—Governor Fuller appointed Dr. George H. Bigelow as state commissioner of public health, October 21, to succeed the late Dr. Eugene R. Kelley. Dr. Bigelow graduated from Harvard Medical School, was an intern at Massachusetts General Hospital, Boston, was an officer in the medical corps during the World War, was formerly director of the Cornell University Medical College clinic, New York, and since 1924 has been deputy commissioner of health of Massachusetts and director of the division of communicable diseases.

Appointments at Harvard School of Public Health.—According to the *Boston Medical and Surgical Journal*, Drs. William E. Deeks, Carlos P. Chagas and Alexander H. Rice have been appointed lecturers in tropical medicine at the Harvard School of Public Health; Dr. Albert A. Hornor, assistant in tropical medicine; R. A. Atwater, instructor in epidemiology; L. R. Cleveland, assistant professor of protozoology; Drs. Noel G. Monroe, Halstead G. Murray and Dwight L. Sisco, assistants in industrial medicine; Dr. Francis B. Grinnell, instructor in bacteriology; Dr. Fred W. Morse, Jr., assistant in bacteriology and immunology and John L. Lewis, assistant in vital statistics.

MICHIGAN

Society News.—Dr. Budd C. Corbus, Chicago, addressed the Kent County Medical Society, Grand Rapids, October 14, on "Medical and Surgical Diathermy, with Special Reference to the Treatment of Cancer."——Dr. Henry A. Christian, Hersey professor of theory and practice of physic, Harvard University Medical School, Boston, addressed the Wayne County Medical Society, Detroit, November 2, on "Achlorhydria Family Tree of Diseases."

Sterilization Law Upheld with Exception.—The supreme court of Michigan has decided that the law authorizing the sterilization of mentally defective persons was a valid exercise of police power within the limits of the constitution except as to the second division of Section 7, which the court held unconstitutional as class legislation. This part of the law referred to only those of the feebleminded class who were unable to support any children they might have and whose children probably would become public charges.

Conference of Health Officers.—At the fifth annual conference of health officers and public health nurses, Lansing, November 18-20, Dr. George F. Dick, Chicago, will speak on "Scarlet Fever," and Dr. Frederick Sears, Syracuse, N. Y., on diphtheria prevention. Among the other speakers will be Dr. Albert J. Chesley, commissioner of health of Minnesota; Dr. George T. Palmer, New York; Dr. Guy L. Kiefer, Detroit; Dr. Chalmers J. Lyons, D.D.Sc., Ann Arbor; Henry Vaughan, D.P.H., commissioner of health of Detroit, and Reuben L. Kahn, D.Sc., Lansing. Clarence C. Little, president of the University of Michigan, will address the public evening session on Wednesday.

MINNESOTA

Hospital News.—St. Andrew's Hospital, Minneapolis, is conducting a drive for $200,000 for a 100-bed extension.——The Cancer Institute and the Todd Memorial Hospital of the University of Minnesota were opened early in October, bringing the total capacity of the university hospitals to 300 beds. The Todd Memorial Hospital is for eye, ear, nose and throat patients.

Personal.—Dr. William V. Lindsay, city health officer of Winona, has been elected president of the Winona County Public Health Association.——John E. Anderson, Ph.D., assistant professor of psychology, formerly of Yale University, has taken up his work as director of the Institute of

Child Welfare of the University of Minnesota, Minneapolis, which was recently established under a grant of $250,000 from the Laura Spelman Rockefeller Memorial.——Dr. Henry Longstreet Taylor, St. Paul, president of the Minnesota Public Health Association, has been appointed president of the newly organized Minnesota Trudeau Society.

MISSISSIPPI

Hospital News.—The nurses' home at the South Mississippi Charity Hospital, Laurel, valued at about $75,000, was destroyed by fire, October 11; the occupants escaped injury.

MISSOURI

Hospital News.—Oak Manor, a new member in the group of Bethesda hospitals in St. Louis, was formally opened last month; the institution was made possible by the bequest of the late Mrs. Elizabeth Dilworth, who directed in her will that Oak Manor, her residence, and surrounding grounds be turned over to the Bethesda Corporation. Mrs. Dilworth left also a $350,000 estate which, after the death of her relatives, will revert to the Bethesda hospitals.

Joint Gynecologic Meeting.—The Chicago Gynecological Society was the guest of the St. Louis Gynecological Society, October 10. The members in attendance were entertained at breakfast at the University Club, and at clinics at the Washington University Medical School and at St. Mary's Hospital by the gynecologic and obstetrical department of St. Louis University. Following a dinner at the University Club papers were presented by Drs. Carey Culbertson, H. F. Lewis and George W. Reis, Chicago.

NEW MEXICO

Illegal Practitioner Fined.—George Calle, Albuquerque, was recently sentenced to thirty days in jail and to pay a $30 fine in police court for practicing medicine without a license, it is reported. The witness testified that she paid Calle $10 for a prescription.

State Board Election.—At a meeting of the state board of medical examiners, Santa Fe, October 13, Dr. Harry T. Watson, Gallup, was elected president for the next two years; Dr. William R. Lovelace, Albuquerque, vice president, and Dr. William T. Joyner, Roswell, secretary-treasurer.

NEW YORK CITY

Bequest to Fifth Avenue Hospital.—The will of the late Thomas F. Manville, head of Johns-Manville, Inc., which was probated, October 28, provides for a bequest of $1,000,000 to the Fifth Avenue Hospital of the City of New York, to be used to pay off any mortgage, encumbrance or lien on the hospital property, and the balance to be invested in such securties as the board of trustees of the hospital may decide. The fund is to be known as the Thomas F. Manville Endowment.

Anniversary Discourse.—George E. Vincent, Ph.D., president, Rockefeller Foundation, will deliver the seventy-ninth Anniversary Discourse at the New York Academy of Medicine, November 19, 8:30 p. m., on "The Doctor and the Changing Order." The Anniversary Discourse has been an annual occasion in November at the academy since its foundation in 1847. Among the former orators were Dr. Edward E. Janeway, Dr. William H. Welch, Dr. Hermann M. Biggs, Henry S. Pritchett, Chauncey M. Depew, George W. Wickersham, Mr. John H. Finley and Hon. George McAneny.

Personal.—Dr. Valeria H. Parker was elected president of the National Council of Women, October 31. The council represents forty national women's clubs and societies.——Dr. Samuel A. Brown, president of the New York Academy of Medicine, laid the cornerstone of the new Academy Building, October 30, and Dr. George D. Stewart, professor of surgery, University and Bellevue Hospital Medical College, was the principal speaker at the ceremonies.——George A. Soper, Ph.D., managing director for the American Society for the Control of Cancer, has returned to this city after a three months' investigation of cancer control in Europe.——Dr. Thomas M. Brennan recently was nominated a member of the board by the trustees of the Brooklyn Juvenile Protective Association.——Dr. Pierre Janet, professor of psychopathology, College de France, Paris, recently lectured at Columbia University and at Princeton, N. J.

Tuberculosis Conference.—The New York Tuberculosis and Health Conference, to be held November 19-20 at the Hotel Biltmore and the Academy of Medicine, is considered by the Committee on Tuberculosis and Public Health of the State Charities Aid Association the most important of its kind since the Albany conference of 1910, when President Taft, Governor Hughes and the Hon. Joseph H. Choate were among the speakers. At the coming conference, some of the speakers will be Dr. William H. Welch, director, School of Hygiene and Public Health, Johns Hopkins University, Baltimore; Dr. Theobald Smith, president of the National Tuberculosis Association; Dr. Livingston Farrand, president of Cornell University; Dr. Allen K. Krause, Johns Hopkins University Medical Department; Dr. Charles J. Hatfield of the Henry Phipps Institute, Philadelphia; Dr. Lawrason Brown of the Trudeau Sanatorium, Saranac Lake; Dr. Edward W. Archibald, McGill University Faculty of Medicine, Montreal; Dr. Frankwood E. Williams of the National Committee for Mental Hygiene; Dr. Sanger Brown of the New York State Commission for Mental Defectives; Dr. Frank J. Monaghan, New York City Commissioner of Health; Dr. Matthias Nicoll, Jr., New York State Commissioner of Health, and Surg. Gen. Hugh S. Cumming, U. S. Public Health Service (The Journal, October 10, p. 1144).

Society News.—The New York County Medical Society conducted a symposium on industrial surgery, October 26, at the New York Academy of Medicine. Dr. Oliver J. Fay, Des Moines, Iowa, discussed "The Evolution of Functional Nervous Disorders in Industrial Surgery"; Dr. Arial W. George, Boston, "Industrial Spine," and Dr. Harry E. Stewart, New Haven, "Physiotherapy in Industrial Injuries."——Dr. Samuel J. Kopetzky, president of the Medical Society of the County of New York, addressed the New York Pharmaceutical conference at the Hotel Pennsylvania, October 26, on "What the Physicians Require of the Pharmacist."——Dr. William H. Park will deliver the first Hermann M. Biggs Memorial lecture, given under the joint auspices of the Medical Society of the County of New York and the New York Tuberculosis and Health Association, at the New York Academy of Medicine, November 19, on "Hygienic and Preventive Measures Against Tuberculosis."——At a meeting of the New York Academy of Medicine, November 5, arranged in cooperation with the section on otology, Dr. Max A. Goldstein, St. Louis, gave a practical demonstration of modern pedagogic methods in the training of the deaf child by teachers and pupils of the Central Institute for the Deaf of St. Louis.

NORTH CAROLINA

Reduced Fares for Cripples.—The railways have arranged to give crippled patients attending the state orthopedic clinics, to be held from time to time in various counties throughout the state by leading orthopedic surgeons, the benefit of reduced railway fares.

Herbalist Sued.—J. H. Nanzetta, self-styled Indian herb doctor, who has been located in Charlotte, is reported to have been sued for $30,000 by one of his victims. It seems that one J. B. Groome of Charlotte, who claims to have been suffering from "weeping eczema," read one of Nanzetta's advertisements and went to the "herb doctor" for diagnosis and treatment. He claims that his condition was greatly aggravated, and that his eyes and other parts of his body "suffered great injury" as a result of Nanzetta's treatment.

Society News.—The annual meeting of the Ninth District Medical Society was held in Lexington under the presidency of Dr. Chalmers M. Van Poole, Salisbury, October 29. Among the speakers were Dr. William deB. MacNider, Chapel Hill, president of the state medical society, whose subject was "Nephritis"; Dr. Frank H. Richardson, Brooklyn, "Malnutrition in Children"; Dr. Verling K. Hart, Statesville, "Mastoiditis," and Dr. D. L. Smith, Spartansburg, S. C., "Physical Examination of the Child." A dinner was served, with Dr. James E. Hobgood, president, Davidson County Medical Society, acting as toastmaster.

Duke University Building Fund.—Our correspondent writes that the probating of the will of the late James B. Duke shows an addition to the endowment of Duke University, Durham, which brings the total of Mr. Duke's contributions to the institution to $40,000,000, and that of the additional sum given, $10,000,000 is for the construction and endowment of the medical school and hospital of Duke University. The will directs the immediate expenditure of $4,000,000 in constructing the medical college and hospital, while the remainder, $6,000,000, is to be for endowment. The university building fund given by Mr. Duke in 1924 ($6,000,000) was increased at the university commencement last year by $2,000,000, and more recently by $7,000,000, making a complete building fund available for immediate construction for the university proper of $15,000,000. The $4,000,000 for the buildings of the medical school and hospital gives all the departments of Duke University $19,000,000 for immediate construction work. North Carolina has not heretofore had the facilities to complete the medical course leading to the degree of M.D.

OHIO

Personal.—Dr. Archibald I. Carson has been elected president of the Cincinnati Board of Health to succeed the late Dr. Edward W. Walker; Dr. Mifflin B. Brady has been elected vice president to succeed Dr. Carson.——Dr. William S. Reed, Stockton, has been reappointed county physician.——Dr. Gaius E. Harmon of the department of hygiene and bacteriology, Western Reserve University School of Medicine, Cleveland, is spending the year 1925-1926 in study with Prof. Karl Pearson at the Biometric Laboratory, University College, London.

Babies and Children's Hospital Dedicated.—Abraham Flexner, secretary of the General Education Board of the Rockefeller Foundation, New York, gave the address at the dedication of the Babies' and Children's Hospital and Maternity Hospital of Cleveland, October 28. Each of these hospitals has a new seven story building on the campus alongside the School of Medicine and the School of Nursing of Western Reserve University, erected with funds collected in a drive in 1923. The Babies' Dispensary, founded in 1906, was the beginning of the present Babies' and Children's Hospital, while the Maternity Hospital was established more than twenty years ago. The buildings are connected by underground passageways. Much of their walls are of glass with sun porches, fresh air wards and glass rooms. A group has been working for more than seventy-five years in behalf of these hospitals. Places on the boards of trustees of this group have gone from father to son, mother to daughter, and from aunt to niece, the nucleus of the group being the early settlers of the Western Reserve Land Company. "University Hospital," which has just applied for a charter, will bring together the Babies' and Children's Hospital, the Maternity Hospital, the Lakeside Hospital and the Rainbow Hospital for Crippled Children with the School of Medicine and the School of Nursing of Western Reserve for teaching purposes.

OKLAHOMA

Personal.—Dr. Rebecca H. Mason, Chickasha, has been appointed resident physician and professor of public health at the Oklahoma College for Women.——Dr. Galvin L. Johnson, Pauls Valley, has been appointed superintendent of health for Garvin County.——Dr. Carl Puckett, state health commissioner, has been elected vice president of the Oklahoma Public Health Association; Dr. Horace T. Price, Tulsa, was elected president.

OREGON

Increase in Death Rate.—The death rate for Oregon in 1924, according to the Department of Commerce, was 1,139 per hundred thousand of population, as against 1,094 in 1923. The increase was due largely to increases in diseases of the heart and in nephritis, cancer, measles, diabetes and diphtheria.

PENNSYLVANIA

Lectures for Nurses.—The Commission for Prevention and Relief of Heart Disease has arranged a program of lectures for graduate nurses under the auspices of the Public Health Association. The first three were given, October 15, 22 and 29, at the Pittsburgh Free Dispensary, and the next three at various hospitals in the city, November 5, 12 and 19, and the subjects were: "Signs of Incipient Heart Disease"; "Care of the Cardiopathic Child"; "Choice of Occupation for Cardiopaths"; "Types of Heart Disease"; "Technic of Nursing in Heart Disease," and "Demonstration of Modern Methods for the Study of Heart Disease."

Society News.—Dr. Frederick M. Allen, New York, gave the first postgraduate lecture before the Allegheny County Medical Society, November 5, at the Carnegie Lecture Hall, on "Pernicious Anemia."——The Philadelphia County Medical Society, Philadelphia, held a cancer control meeting, November 5, which was addressed by Dr. Joseph C. Bloodgood, Baltimore, on "How Can the Medical Profession Teach the Public and Influence Them to Act in Time So That in Many Instances Cancer Can Be Prevented and Properly Treated in Its Earliest and Most Favorable Stage," and by Frederick L. Hoffman, Newark, N. J., on "Some Cancer Problems of Today."——Dr. F. R. Nager, Zurich, Switzerland, addressed the Philadelphia Laryngological Society, November 3, on "Some More Recent Otological Problems" (lantern slide demonstration).——Dr. George W. Crile, Cleveland, adressed the College of Physicians of Philadelphia, November 4, on "A New Point of View Regarding the Control of the Mortality and Morbidity of Operations Within the Hepatic Tract: A Cytoplasmic Rôle of the Liver." The discussion was opened by Drs. John B. Deaver and John H. Gibbon. Dr. George P. Muller addressed the society on "Certain Experiences with Gallbladder Surgery," and Drs. Alfred Stengel and Joshua Edwin Sweet opened the discussion.——Among others, Dr. Pascal Brooke Bland will address a joint meeting of the Obstetrical Society of Philadelphia and the Philadelphia Pediatric Society, November 10, at the College of Physicians, on "Injuries to the Infant During Delivery."

Philadelphia

University Honors Physicians.—The honorary degree of doctor of science was conferred by the University of Pennsylvania recently on Lord Bertram Dawson of Penn, physician to the King of England and the Prince of Wales; Dr. Charles H. Mayo, Rochester, Minn., and Dr. Rudolph Matas, New Orleans. The university held a special ceremony in Houston Hall, where Provost Josiah H. Penniman conferred the degrees.

The Alvarenga Prize.—The Alvarenga Prize for 1925 has been awarded to Dr. Raphael Isaacs, Boston, for his essay entitled "The Nature of the Action of Roentgen Rays on Living Tissue." The College of Physicians of Philadelphia announces that the next award of the prize, amounting to about $300, will be made, July 14, 1926, provided an essay deemed worthy of the prize shall have been offered. The essays may be on any subject in medicine but cannot have been published. They must be typewritten in English and forwarded without signature but marked with a motto and accompanied by a sealed envelop having on its outside the motto and within the name and address of the author. Essays must be received on or before May 1, 1926. Dr. John H. Girvin, 19 South Twenty-Second Street, Philadelphia, is the secretary of the committee of award.

SOUTH DAKOTA

Asylum for Insane Indians.—The superintendent of the Asylum for Insane Indians at Canton noted, in his annual report to the Commissioner of Indian Affairs, Washington, D. C., that there were 100 patients under treatment during the year ending June 30, 1925, and that the applications for admission of nineteen other patients were declined because of the overcrowded condition of the asylum. There were no cases of smallpox during the year, as employees and patients were protected by vaccination. Grain and other food products are produced on the asylum's own land. The superintendent recommended that 160 additional acres be purchased in order to raise farm products to more nearly supply the needs of the institution; he also recommended the erection of a building for epileptics, a chapel and an amusement hall.

SOUTH CAROLINA

Increase in Death Rate.—The Department of Commerce announces that the death rate for South Carolina for 1924 was 1,300 as compared with 1,185 for 1923, and that it was due largely to increases in the death rates from nephritis, heart disease, measles, whooping cough, pneumonia, typhoid fever, cancer, automobile accidents and enteritis.

TENNESSEE

Hospital News.—The new nurses' home and training school of the Memphis General Hospital, Memphis, will be named the "Dr. Marcus Haase Nurses' Home and Training School," in honor of the late Dr. Marcus Haase.

Society News.—Dr. Carl T. Speck, Cleveland, was elected president of the East Tennessee Medical Association, October 22; Drs. P. L. Brock, Morristown, and Walter S. Moore, Etowah, vice presidents, and Dr. G. Victor Williams, Chattanooga, secretary-treasurer, reelected. The next spring meeting will be in Morristown, and the fall meeting in 1926 in Maryville.

Personal.—The governor has appointed, among other members of the Tennessee Tuberculosis Hospital Commission, Dr. Charles A. Abernathy, Pulaski; Dr. Herbert Acuff, Knoxville, and Dr. James J. Durrett, Memphis. The act creating this commission provides for the establishment and maintenance of hospitals in several grand divisions of the state with the help of the various counties.

TEXAS

Society News.—At the fifty-eighth semiannual meeting of the South Texas District Medical Society, Houston, October 9, Dr. Walter T. Brown, Wallis, was elected president; Dr. William Lapat, Houston, vice president, and Dr. Jewell C. Alexander, Houston, secretary.

Personal.—W. T. Dawson, M.A., for the last two years acting professor of physiology and director of laboratory of pharmacology, Woman's Medical College of Pennsylvania, Philadelphia, has been appointed associate professor of physiology in the Medical Department of the University of Texas, Galveston.

Hatcheries for Top-Minnows.—The board of health of Texas announces plans to establish hatcheries for the propagation of top-minnows *(Gambusia affinis)* with the cooperation of the game, fish and oyster commission, which will furnish the minnows for breeding purposes. The state health officer has advised all communities desiring breeding stock to notify the commission promptly so that there may be sufficient time to propagate enough minnows for stocking all local streams, ponds, tanks or other standing water as an aid in mosquito control.

VIRGINIA

Campaign for Funds.—The Medical College of Virginia, Richmond, will launch a campaign for funds in the near future, it is reported, for a new building for biochemistry, bacteriology and pathology, and will request the next general assembly to increase the appropriation for maintenance of the medical college.

Hospital News.—A committee has been appointed at Farmville to take charge of the erection of a hospital in that community, for which funds will be provided for the cost of the building by the Commonwealth Fund of New York. Drs. William E. Smith, R. Lester Hudgins and Thomas G. Hardy, among others, are on the committee.

GENERAL

Report of Joint Committee on Sight of School Children.—A report has been made by a joint committee of the American Medical Association and the National Education Association, in cooperation with the National Committee for the Prevention of Blindness, on "Conserving the Sight of School Children." The committee studied the practices followed in public schools in caring for the eyesight needs of school children, covering 375 cities, also rural districts in every state, and was assisted by 100 ophthalmologists and by health officials and school authorities. It was found that 3,000,000 school children in this country are handicapped by defective sight and that only half of the total school population of 24,000,000 have their eyes examined and vision tested while attending school. The rural districts generally report a larger percentage of defective vision than the cities. It seems likely, the report adds, that this is due to such differing factors as conditions under which the test results were obtained, bad illumination in rural homes and schools and the small number of corrections provided for rural children. The report summarizes the extent of defective vision in schools and the practices used in conserving the eyesight and gives information for the teacher, school nurse and the school physician in the conservation of vision. The committee was at work more than a year under the chairmanship of Dr. Thomas D. Wood, professor of physical education, Columbia University, New York; it recommends that a uniform law for the examination of the eyes of school children be adopted by all states and cities.

Epidemiologic Report.—The report of the Health Section of the League of Nations, September 15, shows an improvement in the plague situation in India, all of the principal ports with the exception of Rangoon and Bombay having been free from that disease in the four weeks ending September 5. During the period covered by the report, plague was at its annual minimum in most places where it is endemic. There was a fresh outbreak reported from Senegal, Africa, of 119 cases in July, as against seventeen in June. The report shows, however, that cases of plague had occurred in widely scattered places in Africa, Asia and at Pirée in Greece and at Constantinople in Europe. There has been less cholera in India than in 1924, particularly in the valley of the Ganges, and an increase in Burma and in the Madras presidency. A severe epidemic of cholera in Kashmir reached its maximum early in May, and up to July 25 had caused 9,931 deaths, a case mortality rate of 54 per cent. Cholera is endemic in Kashmir, and in 1919 there was an epidemic with 11,516 deaths reported. Yellow fever was reported this year from places in Nigeria, the Gold Coast and Ivory Coast of Africa; one case was reported in Liberia. The report says that the disease appears to be endemic in several areas on the Guinea coast, although the number of cases reported is small. Smallpox has been more prevalent than during previous years in several African countries. There were 966 cases in Algeria this year, as against seventy-two in the corresponding period of last year; 1,546 cases in Nigeria as against 358 last year, and 1,280 as against 118 in the Gold Coast colony. The incidence of smallpox in India was higher this year than in the four preceding years, the maximum having been reached in March-April; 9,931 cases and 2,543 deaths were reported in the four weeks ending July 25, and in the preceding four weeks 12,402 cases and 3,072 deaths. A serious outbreak of smallpox occurred in Korea during the first six months this year, with 2,300 cases and 539 deaths.

Society News.—The next annual Mississippi Valley Conference on Tuberculosis will be held in Chicago under the auspices of the Chicago Tuberculosis Institute in June, 1926. ——At the annual meeting of the American Hospital Association, Louisville, Dr. Arthur C. Bachmeyer, superintendent, Cincinnati General Hospital, Cincinnati, was installed as president; Dr. Richard G. Broderick, director of hospitals, Alameda County Hospital, San Leandro, Calif., was made president-elect; Dr. Walter H. Conley, medical superintendent, Metropolitan Hospital, Welfare Island, N. Y., Miss Blanche M. Fuller, superintendent, Nebraska Methodist Episcopal Hospital, Omaha, and Mr. Wallace W. Kenney, superintendent, Victoria General Hospital, Halifax, N. S., vice presidents; Dr. William H. Walsh, Chicago, executive secretary, and Mr. Asa S. Bacon, superintendent, Presbyterian Hospital, Chicago, treasurer.——At the annual meeting of the Medical Association of the Southwest, El Paso, Texas, November 5-7, Dr. John H. Musser, New Orleans, professor of medicine, Tulane University of Louisiana School of Medicine, discussed "The Diagnosis of Cancer"; Dr. Edward Jackson, Denver, "Recent Views of Cancer by Experience with Ocular Tumors"; Dr. Mallory B. Culpepper, Carlsbad, N. M., "Tularemia"; Dr. Benjamin H. Orndoff, Chicago, professor and director of the division of roentgenology, Loyola University School of Medicine, "Radiotherapy of Malignancy with Special Reference to Breast Carcinoma"; Dr. John C. Wilson, Los Angeles, professor of clinical orthopedic surgery, College of Medical Evangelists, "Evaluation of Surgical Splinting in Spinal Caries," and Dr. Henry A. Rasmussen, U. S. Public Health Service, Fort Stanton, N. M., "Report of a Case of Pulmonary Tuberculosis Treated with 'Sanocrysin'." Colonel Shockey, M. C., U. S. Army, invited the society to the William Beaumont Hospital on the Military Reservation for its annual clinic.——The officers of the Association of American Medical Colleges were reelected at the recent annual meeting in Charleston, S. C. Dr. Hugh Cabot, Ann Arbor, Mich., is president; Dr. David L. Edsall, Boston, vice president, and Dr. Fred C. Zapffe, 3431 Lexington Street, Chicago, secretary. The next annual meeting will be in Cleveland, Oct. 25-27, 1926.

Report of Children's Bureau.—According to a report of the director of the Children's Bureau, U. S. Department of Labor, there were 290,590 children examined under the Maternity and Infancy Act in the fiscal year 1925. There were 10,806 child health conferences, 3,581 prenatal conferences attended by 35,997 women and 8,047 midwives who completed midwives' courses, 622 child health centers and fifty-seven permanent prenatal centers established. All states except Illinois, Kansas, Maine, Massachusetts and Connecticut are now cooperating under the provisions of the Maternity and Infancy Act, under the terms of which each state accepting receives $5,000 outright and an additional $5,000 when matched by the state, and the balance of the appropriation of Congress is distributed among the states on the basis of population. The total amount accepted by the states from the 1924 appropriation was $918,280.49, the largest amount accepted by any one state being about $80,000 by New York. In addition to the work already noted there have been established in twenty-four states a total of about 3,000 "little mothers" classes to teach girls of the seventh and eighth grades or older the proper care of infants, since they are so often their mothers' helpers. Although the "centers and consultations" are for well babies, defects are frequently found which require correction. The most frequent defects are refractive errors, orthopedic defects, nasopharyngeal growths, dental caries, malnutrition and enlarged glands, and these children are always referred to the family physician for correction, if there is a physician. However, poverty and lack of physicians necessitate special arrangements, and a few states have clinics at which defects may be corrected by a staff physician or by a specialist engaged for the purpose. The report says that in most places this work is done by local physicians after nurses have explained the need of it to parents and made special arrangements for it for the indigent. Some states have estimated the percentages of defects that have been thus corrected; Indiana, for example, made a series of surveys to find out what corrections had been made; South Dakota reported 490 corrections among 2,725 cases examined; Pennsylvania reported 8,678 corrections, a great majority of which involved the teeth and tonsils and adenoids.

Bequests and Donations.—The following bequests and donations have been announced recently:

The Lake County Memorial Hospital, Painesville, Ohio, $10,000 by the will of Stella L. Cummings.

The Brooklyn Home for Blind and Crippled Children, the Brooklyn Catholic Orphan Asylum, and the Home for the Aged of the Little Sisters of the Poor, each $5,000, by the will of the late Mary L. Fraser.

The Home for Incurables, New York, about $15,000, by the will of the late Laura Varian.

Jennie Stuart Memorial Hospital, Hopkinsville, Ky., $10,000, by the will of John Hubbard.

The New York Association for the Blind, $5,000, and the Herman Knapp Memorial Eye Hospital, New York, $5,000, by the will of William E. Stiger, New York.

The University, Children's and Chestnut Hill hospitals, Philadelphia, and the Bethesda Children's House, will share equally in the estate of J. E. Smith, valued at more than $50,000, on the death of the last beneficiary of the trust fund.

Roosevelt, Methodist, Rush, and Children's Homeopathic hospitals, all of Philadelphia, each $1,000, by the will of the late Charles Lockhart.

The Women's Homeopathic Hospital, Philadelphia, $3,000, by the will of Madeline K. Vandergrift, Philadelphia.

St. Joseph's Home for the Blind, Jersey City, N. J., the Home for Incurables, St. Vincent's Home, and St. Edmund's Home for Crippled Children, $1,000 each, and $500 to the Misericordia Hospital, by the will of the late Nellie Lynn, Philadelphia.

The Episcopal Hospital and the Women's Hospital, Philadelphia, each $1,000, by the will of Lina B. H. Sedridge, Philadelphia.

The Fifth Avenue Hospital, New York, $50,000, by the will of the late John E. Meek.

Prospect Heights Hospital and Brooklyn Maternity, Brooklyn, N. Y., $3,000, by the will of the late Mrs. Mary A. Carmen.

The Mary J. Drexel Children's Hospital, Philadelphia, an endowment of $5,000 for three beds.

The Jewish Hospital Association of Philadelphia, the residue of the estate of Julia Mayer, whose will stipulates that at least $100,000 shall be expended for an addition for the aged and infirm at the Jewish Hospital as a memorial to her parents, and should this not be considered practical, that sum may be used toward the construction of a maternity building.

James M. Jackson Memorial Hospital, Miami, Fla., $500,000, by the will of James M. Deering, to be used for maintenance.

St. Peter's Hospital, Brooklyn, $500, by the will of the late Mary A. McCafferty.

St. Peter's Hospital, Brooklyn, $500, by the will of the late Andrew Wachter.

The New York Orthopedic Dispensary and Hospital, New York, the residuary estate of the late Mrs. Caroline James, Northport, Long Island, said to be more than $300,000.

Mount Sinai, Presbyterian, Ruptured and Crippled, Skin and Cancer hospitals, New York, $81,657 each, by the will of the late Simon R. Weil.

LATIN AMERICA

Personal.—Dr. Luis da Silva Santos retires from the chair of anatomy at Rio after many years' service.——Dr. J. P. Fontenelle, Rio, director of the *Folha Medica* fortnightly journal, has left for the United States on the invitation of the Rockefeller Foundation to study public health administration and allied subjects.——The *Brazil-Medico* states that the imprisonment of Prof. Bruno Lobo, of the chair of bacteriology, Rio de Janeiro, still continues, and that the students, in protest, are still on strike.——Dr. Rocha Vaz presided at the recent meeting at Rio which decided the foundation of the Instituto Brazileiro de Sciencias. It aims to assemble all those who have contributed to the progress of science in Brazil "by discovery of some law or fact not previously inscribed on the records of pure or applied science."

FOREIGN

Personal.—Dr. Brongersma, professor of urology at Amsterdam, as the spokesman of the corresponding members of the French Association d'urologie, presented 44,000 francs to the association at its annual meeting at Paris in October. The income is to be awarded for the best work on disease of the urinary apparatus.——A communication in the *Presse médicale* states that Prof. I. P. Ivanov, Moscow, is soon to leave for French Guinea for research on anthropoids. He has been offered a place in the Pasteur Institute at Kindia, in French West Africa, where there is a simian colony for research. Ivanov has been conducting research on artificial fecundation for twenty-five years, and is especially interested in cross fertilization by this means.——The *Hospitalstidende* relates that Dr. G. Roussy, professor of pathologic anatomy, Paris, has been invited by the Danish Neurologic Society and the Cancer Research Committee to deliver three lectures at Copenhagen on neurologic topics and radiotherapy of cancer.——Dr. Charles Nicolle, director of the Tunis Pasteur Institute, has been invited by the Argentine public health service to inspect the northern provinces and suggest means to improve health conditions. The *Prensa Médica* hails him as the most important contributor to science that has ever visited Argentina, citing his discovery of the louse as the vector of typhus, his priority in the transmission of syphilis to monkeys and his discoveries in other fields of tropical medicine.

Deaths in Other Countries

Major General Sir **Hayward R. Whitehead**, director of medical services in Malta during the World War, at Lyndhurst, September 28; aged 70.——Dr. **B. Etchepare**, professor of psychiatry at Montevideo, president of the local medical society and of the Uruguay Psychiatry Association, and an officer in the public health service.

CORRECTION

Trip Postponed.—Surg. Gen. Hugh S. Cumming, U. S. Public Health Service, writes that by reason of urgent official duties, he was prevented from making the trip to Plymouth, Cherbourg and Bremen which was noted in THE JOURNAL, October 24.

Government Services

Ambulance Aeroplane

According to the *Army and Navy Journal*, the latest type of army aeroplane is the Cox-Klemin XA-1 type machine, which will carry two patients, an attendant and the pilot at 120 miles per hour; it is equipped with a self-starter and facilities for attending the sick with some comfort. A machine of this type was recently exhibited at Albrook Field, Balboa. This was the first time that an ambulance has been assigned to the air force of the Canal Zone.

Army Resignations

Major Edgar A. Bocock, M. C., resigned, October 31, and has been appointed superintendent of the Colorado General Hospital, Denver. One of Major Bocock's last assignments in the army was as superintendent of the Santa Tomas Hospital in the Panama Canal Zone.——Lieut. James A. Smart, M. C., resigned, effective, November 1.

Veterans' Bureau Resignations

The following physicians recently resigned from the Veterans' Bureau: Dr. Chester C. Box, August 3, at Lake City, Fla.; Dr. George D. Bragaw, June 30, at Palo Alto, Calif.; Dr. Bennette A. Burks, August 31, at Memphis, Tenn.; Dr. Paul G. Haire, August 15, at Rutland, Mass.; Dr. Roy T. Haskell, August 15, at Washington, D. C., and Dr. Edwin F. Sullivan, August 4, at Tupper Lake, N. Y.

Change in Army Transport Medical Service

The Quartermaster Corps of the U. S. Army has inaugurated a policy which relieves from transport duty those medical officers who heretofore have been assigned regularly as transport surgeons. In the future, medical attendance on army transports will be furnished by medical officers who are making the trip as a passenger. The new policy has already gone into effect.

Examination for Army Medical Corps

The Adjutant General announces that examinations of candidates for commission in the Medical Corps of the Regular Army will be held, Jan. 11-15, 1926, at various army posts. Candidates must be not less than 22½ nor more than 31½ years of age, and must have been graduated in medicine at a reputable medical college, and have had one year's hospital experience subsequent to graduation. They must pass the written examination and undergo a physical examination.

Physicians who have licenses from the National Board of Medical Examiners may be exempt from the written examination if they desire on submitting proper evidence. The examination is for the purpose of filling sixty vacancies which exist in the Medical Corps. Successful candidates will be commissioned with the rank of First Lieutenant. Requests for permission to take the examination should be addressed to the Adjutant General of the Army, Washington, D. C.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Oct. 24, 1925.

The Campaign Against Cancer

At the meeting of the grand council of the British Empire Cancer Campaign, it was announced that grants, since the formation of the campaign over two years ago, to existing laboratories, new schemes of research, purchase of radium and commitments, including the formation of the *Journal of Abstracts* and its maintenance, amount to more than $375,000. On the recommendation of the scientific advisory committee, a grant of $5,000 per annum for six years was made to Dr. Thomas Lumsden at the Lister Institute of Preventive Medicine to enable him to relinquish private practice and devote his whole time to continuing his experimental work on serums in connection with seeking a cure for cancer and other allied lines of research. The application of Dr. Mottram, to which a grant has already been made of $4,000, to bring his scheme into line with the recent discoveries of Dr. Gye and Mr. Barnard, was approved. The radiology committee reported that the whole of the $25,000 worth of radium purchased for the campaign for the purpose of cancer research has been allocated to various hospitals. It was reported that Lieut.-Gen. Sir John Goodwin (formerly director general of the army medical service), organizing adviser to the campaign, is completing his plans for the formation of permanent county committees in support of the central campaign.

Osteopathy, Chiropractic and Other Cults

In previous letters, the introduction of osteopathy into this country and the formation of the British Osteopathic Association and its attempt to obtain recognition from the government have been described (THE JOURNAL, June 27, p. 2014). Osteopathy and other eccentric cults have now attracted so much attention from the public that the medical profession cannot entirely ignore them.

Sir Holburt Waring devoted his presidential address to the Medical Society of London to "Osteopathy, Chiropractic and Other Cults and Medicine," because of inquiries he had received from medical friends as to their advantages, disadvantages and dangers. He began by explaining that osteopathy was a system of treatment based on the assumption that all disease was caused by some part of the organism being out of adjustment or alinement, as in the case of a displaced bone, cartilage or ligament, or in the case of adhesions or contractions of muscle resulting in unnatural pressure on, or obstruction to, a nerve or blood vessel. Investigation had shown him that different osteopaths had varying ideas as to what was comprised in the term and what were the limitations of treatment. A later definition seemed to include the use of the term "inhibition" or the relief of pain or muscular spasm by the application of steady pressure. Osteopathic treatment consisted in manipulation to correct the supposed displacement. "Chiropractic" had been defined as a system of adjusting subluxated vertebrae by hand for the restoration of health. Its theory is that disease is the result of pressure on nerves as they emerge from the spine. Diseases of the eye and ear were treated by both osteopaths and chiropractors in a similar manner, although the nerves supplying these organs did not come from the spinal cord.

A number of other cults had sprung from these, of which Sir Holburt referred to only one—"naprapathy." Its exponents asserted that the basal centers of life were located in the medulla oblongata or basal portion of the brain and, therefore, manipulations were applied to the nearest portion of the surface, the nape of the neck. Thus, all these cults based their practice on a theory that was untrue. Patients suffering from severe affections were liable to be seriously damaged by having these methods practiced on them. In a case of appendicular abscess, the treatment was applied and the abscess burst, with fatal result. In many cases the manipulations caused acute dissemination of carcinomas and sarcomas. Sir Holburt had also seen many cases of tuberculous disease of joints, in which serious damage had been caused by forcible manipulation and movement. Some of the reported cures were probably due to suggestion, others to the result of manipulations and the breaking of adhesions between muscles and nerves and the adjacent tissues.

In conclusion, Sir Holburt held that our laws ought to be amended so as to place all medical practitioners on the same educational level, because of the danger to the public of being deceived by plausible theory and unfounded claims. A number of graduates of the schools of these cults in the United States had come to this country and were attracting patients by blatant advertisement. The government should take a strong stand in protecting the health and life of the community.

The Influence of Sunshine and Open Air on Health

At the recent international congress on climatology held at Davos, Prof. Leonard Hill read an important paper on the influence of sunshine and open air on health, a subject which he has made very much his own. He said that there was no evidence that "ionization" of the air had any influence on health, nor were the ozone content and the chemical purity of the air of fundamental importance at mountain and seaside resorts. The existence of ozone at sea level was not proved. The chemical purity of the air, so far as concerned carbon dioxid and oxygen, was not of any importance, and no chemical poison was present in the air of crowded rooms. It was microbic infection by catarrhal diseases that occurred in stuffy rooms. Sedentary work in warm, stagnant air required compensation by vigorous exercise and by sleeping with open windows. The tendency in recent years had been to overheat rooms and to overclothe. Turning to the effects of light, Professor Hill emphasized the value of ultraviolet irradiation and the loss of these rays from smoke pollution, glass windows and clothes. Tuberculosis should not be treated in hot sun boxes, but with cool air and sun treatment in the early morning. Skyshine gave much more ultraviolet radiation than direct sunshine. All children in smoky cities should be given arc light baths twice a week in winter to prevent disease. Hospitals should be built as bungalows out in the country with verandas and open courts for the beds. Patients should be prepared for operation by ultraviolet irradiation, which raises the resistance of the body to infection.

Fatal Explosion in a Boy's Mouth During an Operation

A fatal explosion, of which the cause remains obscure, has taken place in a boy's mouth during an operation. A boy, aged 16, collided with a motor car while cycling. He was taken to the hospital, where his jaw was found to be fractured. In the course of an operation on the jaw, it was found necessary to keep the teeth dry by means of warm air supplied through a dental syringe. Ether and oxygen were the anesthetics used. On the third application of the warm air, an explosion occurred at the back of the boy's mouth. Acute hemorrhage followed, and he died in ten minutes. At the inquest, Mr. Percival Cole, a surgeon and an authority on injuries of the jaw, who performed the operation, said that after the explosion the apparatus used burst into flames. During the war, 1,600 cases of this sort passed through his hands, and what was done in this case was merely routine work. Ether is very inflammable, but there was no naked flame near. In his opinion, the explosion was due to a mixture of vapors. The teeth were smeared with alcohol and had afterward to be made perfectly dry, otherwise the dental cement would not adhere. The anesthetist gave evidence that in 1,200 cases he had never encountered anything similar to what happened in this case. The jury returned a verdict that death was due to accident.

The Post-Graduate Medical Journal

The Fellowship of Medicine and the Post-Graduate Medical Association have issued the first number of a new monthly medical journal, of which the price is 12 cents. Its object is to supply the postgraduate student with details of postgraduate teaching in this country and elsewhere; to supply a medium for the expression of his requirements, and, if need be, the ventilation of his grievances. The first number begins with a foreword from Sir William Hale-White, who refers to some of the difficulties of efficient postgraduate teaching in this country, especially to the dissatisfaction engendered by endeavoring to teach undergraduates and postgraduates together. He advocates the building, in London and other large cities, of medical schools for postgraduates only, with hostels attached to them. The journal will publish a selection of the lectures delivered at the instance of the Fellowship of Medicine, supplemented by specially contributed articles and clinical descriptions. Only such subjects as will from their essential character make a strong appeal to the general practitioner will be published. The first number contains two lectures: one, by Sir Humphry Rolleston, is on the "Medical Aspect of Gallstones." He concludes that there are two factors in the formation of gallstones—the infective and the metabolic, which may operate alone but probably more often operate together. The most common form which the first factor takes is infection of the alimentary canal with *Bacillus coli*, which is carried to the liver and excreted in the bile. The metabolic factor consists of an increase in the cholesterol content of the blood and so in the bile. The second lecture is by Dr. T. Watts Eden, on the "Prevention of Puerperal Sepsis." He points out that puerperal sepsis occurs in all kinds of practice—in the private practice of midwives and physicians, among the well-to-do as well as the poor, and in midwifery hospitals. The causes he regards as obscure. One that he emphasizes is coitus in the last four weeks of pregnancy. Apart from gonorrhea infection, he considers that microbes may thus be conveyed. In regard to prevention, he recommends antenatal care and guarding the patient from all possible sources of infection during and after labor.

Tuberculous Cattle and Environment

In the *Veterinary Journal*, Dr. John Robertson, health officer for Birmingham, has called attention to a serious defect in our treatment of the tuberculosis problem in cattle. He has no hesitation in saying that at most dairy farms we are unwittingly doing our best to propagate tuberculosis. We keep the majority of our dairy cows in dark, ill ventilated sheds; we milk these cows twice or thrice a day—an exhausting process—and in many cases we underfeed them. "Are we not," asks Dr. Robertson, "concentrating too much on testing and slaughter and not devoting enough of attention to the more difficult question of the cow's environment and food?" His main recommendation is that the veterinary profession must be convinced of the necessity for much better cowsheds and that the farmer must be taught the predisposing causes of tuberculosis and must avoid them on his farm. On the subject of tuberculous meat, Dr. Robertson says that while its consumption is repugnant he has never known the diseased meat usually found in slaughterhouses to produce ill effects. He further points out that meat infected with anthrax has been cooked and consumed without bad results and that it is dangerous only in the process of handling before cooking.

Children Killed in Street Accidents

The terrible increase of fatal accidents in the streets, due to the motor traffic, has been pointed out in previous letters. In a small volume, just published by the National Safety First Association, entitled "Safety First for School and Home," the author, Mr. G. A. Christian, gives some valuable hints from his experience as inspector of schools to the London County Council. He tells us that of the appalling number of persons killed in the streets of London last year—866—more than a third were children. Children have one large source of danger special to themselves, that associated with mischief and the playing of games in the street. Many juvenile accidents occur from stealing rides on vehicles and from running into the road after a ball.

Industrial Diseases in France

The official bulletin of the ministry of labor contains information pertaining to industrial diseases in 1923, and their relation to the act of Oct. 25, 1919. Thus far, under the provisions of this act, only lead and mercury poisoning are considered. There were 1,025 cases of lead poisoning in 1923, as against 797 in 1922. The increase may signify merely that, as the law becomes better known, notifications are made more regularly. In 744 cases the diagnosis was simple lead colic. In 114 cases no exact diagnosis was made. The other cases are distributed among the complications of lead poisoning. The period of disability, which ranged from eight to fifteen days, was stated in only half of the cases. One notification read, permanent partial disability; another, probably permanent disability. Nine notices mention hospitalization of the patient, and nine cases were fatal.

The industries that gave rise to lead poisoning were enameling of metals, 278 cases; manufacture and maintenance of storage batteries, 249 cases; manufacture of red lead, 150 cases; metal foundries, 58 cases, lead foundries and plating with lead, 54 cases; painting of buildings, 41 cases; printing, 26 cases, and others.

In 1923, the number of cases of mercury poisoning was reduced to five. The diagnoses were: mercurial stomatitis, one; mercurial trembling, two; nephritis, two. In one case, disability extended over several months.

Taxi Chauffeurs and Mental Affections

Addressing the Société medico-psychologique, April 27, 1925, Toulouse, Dupouy and Schiff pointed out that they had examined the mental condition of thirty-six taxi chauffeurs. They found: psychasthenia, obsessions and impulses without dementia, 12; toxicomania, 2; epilepsy, 2; chronic alcoholism, 5; alcoholism with symptoms of dementia, 2; various dementias, 2; general paralysis, 10. They emphasized the great medicosocial interest that the question presents.

Emergency Treatment of Wounds

Lenormand and Moure, addressing the recent international congress on industrial accidents, discussed the influence of recent war experience on the therapeutics of wounds. They distinguished a first period during which wounds were dressed and patients then evacuated; a second period of débridement and drainage; a third period of continuous irrigation following débridement and succeeded by secondary suturing, and finally a fourth period, which began with the primary suturing of fresh wounds. Primary suturing of wounds, after excision of contused tissues, effects rapid recovery in slight wounds but it is not without danger.

Lenormand and Moure pointed out that the objects sought in treating war wounds and those of civil practice are not the same. War surgery is collective; it seeks to limit the number of losses, without spending too much time with individual cases. The cases in which primary suture did not prove successful were given secondary consideration because the method presented great advantages for the state.

In industrial accidents, however, surgery must sacrifice everything for the safety of the injured individual. Even the slight possibility of loss of life or limb will influence the choice of a therapeutic method.

Lenormand and Moure emphasized the influence of first dressings on the whole evolution of the wound, and the need of complete examination of the patient. They emphasized the importance of the extraction of foreign bodies from punctured wounds. The search for fragments of pins and needles should always be considered a delicate operation, since they may entail considerable laceration and expose the patient to infection. They discussed likewise immediate therapeutic indications in (1) wounds limited to the soft parts; (2) wounds affecting the bones and joints, and (3) crushed and dismembered limbs.

1. Lenormand and Moure explained primary suture of wounds of the soft parts. Its indications seem limited to fresh wounds of the scalp and face and to superficial cuts about the arms and legs. In contused wounds, especially where there are many muscles, it is more prudent not to attempt primary suture. Every case in which a wound is sutured primarily requires close supervision of the local and general condition. The tendons and nerves must not be sutured other than in fresh wounds susceptible of primary suture. Wounds of trunk arteries are subject to conservative operation when an associated fresh wound of the soft parts in itself justifies primary suture. Whenever infection is probable, the two ends of a vessel in the wound should be sutured.

2. As to wounds affecting the bones and joints, in open fractures immediate intervention is required. The object should be to cleanse the traumatized area and to reduce and immobilize the fracture. Only fragments that are completely detached should be removed; all bone splinters that have preserved a connection with the soft parts should be left. When the area of the fracture has been cleansed, the fragments should be adjusted and maintained in place. Plaster-of-Paris casts do not give good results. It is best to use apparatus that combines continuous extension and suspension. Osteosynthesis in complicated fractures should be avoided if possible. Bone union can be best accomplished by means of external apparatus. Internal prosthesis by sutures, plates, clamps, rings and the like is seldom indicated in complicated fractures, and it should never be regarded as permanent. Its sole object is to prevent, for the time being, the displacement of a fragment. It would be exceedingly imprudent, after having cleansed the area of a complicated fracture, to employ osteosynthesis, to close the wound and treat it like a closed fracture. In wounds of the joints, the operative indications vary with the importance of the lesion. In simple punctured wounds of the joints no operative intervention is indicated; compression and immobilization should be the rule. Larger wounds of joints, without bone lesions, are susceptible of primary suture, which constitutes the only means of preventing secondary infection. Joint wounds associated with grave bone lesions require either primary resection or amputation.

3. In dealing with crushed and dismembered limbs, the authors emphasize solely the need and technic of amputation. If the patient is in shock, it is preferable to institute at first active general therapy and to postpone amputation until the general condition of the patient is satisfactory. Sometimes the patient, although he has lost little blood and is still conscious (presenting neither nervous nor hemorrhagic shock) grows steadily weaker in spite of the usual protective and restorative measures employed. In such cases it may be assumed that he is suffering from toxic or from toxic-infectious shock. The only means of saving such a patient is to amputate at once. If a tourniquet has been applied, it should not be removed before amputation. There should be no amputation with flaps and no closure of the wound. The indications for circular amputation at the level of the injury are here the same as in war. General anesthesia should be light and preferably ethyl chlorid or nitrous oxid. Blood transfusion or the injection of physiologic sodium chlorid solution should be extensively used.

Lenormand and Moure discussed also the indications for antitetanus and for antigangrene serotherapy.

BERLIN

(From Our Regular Correspondent)

Oct. 10, 1925.

A Department for Industrial Diseases

Through the action of the Prussian minister of commerce and industry, a department for industrial diseases has been established in the Empress Augusta Victoria Hospital in Berlin. The location of the hospital in the eastern section of the city, in the vicinity of numerous manufacturing establishments, makes it an excellent vantage point for the treatment of industrial injuries. Although Italy, two years before the war, established in Milan the clinic for occupational diseases, under the direction of Professor Devoto, and also soviet Russia has founded richly endowed institutes for the investigation of the relations between industrial work and disease in workmen, Germany has had until now no similar institution. Since July 1, 1925, compulsory medical notification of important industrial diseases, such as lead poisoning, glassmakers' cataract, benzene and anilin poisoning, has been in force. In order that the medical profession may become more familiar with these diseases, which, fortunately, are comparatively rare, lectures and laboratory courses in the field of industrial diseases in general have been organized.

Excess of Deaths over Births in Berlin

In recent years, Berlin has had an excess of deaths over births. However, during certain weeks of 1924, there was a slight predominance of births over deaths, and, during the first quarter of 1925, the births in Greater Berlin exceeded the deaths by almost 600 (in 1924, in the corresponding period, there were 4,400 more deaths than births). This better result was secured, in spite of the fact that, in February and March, infant mortality and death from pulmonary tuberculosis and other respiratory diseases is higher than for the other months. Taking these facts into account, an excess of births over deaths amounting to 6,000 may be expected for the year 1925, as against an excess of deaths over births of 5,000 for 1924. From the reports so far, also the mortality rate for 1925 will be improved, as against the rate for 1924.

The Preservation of Milk

Not only in the medical press but also in lectures and in petitions, there have been of late repeated complaints from physicians, veterinarians and others, on the use of milk preservatives. The employment of these preservatives was due, in part, to the erroneous belief that the addition of alkali carbonates (soda, for example) was permissible.

Under war and postwar conditions, treatment of slightly sour milk with alkali carbonates had to be permitted, since fresh milk was scarce and the supply of milk that reached the places of consumption in a slightly sour condition could not be dispensed with. The partial neutralization of milk slightly sour made it usable. Neutralization, however, had to be carried out with considerable care in order to be successful. Therefore, in 1918, the federal health bureau published directions for the treatment, with alkali carbonates, of whole milk that was slightly sour. Permission to use this method was accorded only to those dairy establishments which were supervised by efficient communal leagues and whose equipment and business management guaranteed that the method would be followed. Only milk with less than 15 degrees of acidity could be subjected to such treatment, the acidity could be reduced only to 6 degrees, and the treatment had to be carried out under the direction of a chemist, who assumed responsibility for errors. Treated milk had to be plainly tagged, and care had to be taken to prevent its use for children under 2 years of age. There is no proof that any injuries resulted from its use, and if the directions for treatment were strictly followed, no soapy taste nor alkaline reaction resulted. In the meantime the supply of milk has increased. Permission to use the neutralization method has therefore been withdrawn. Nor is treatment of milk with hydrogen peroxid now permissible.

The Licensing of Chauffeurs

The city council of Leipzig has passed an ordinance requiring all chauffeurs to pass an examination as to their technical qualifications and mental fitness before they are granted a license. The licensing board, acting in cooperation with Professor Klemm, the director of the department for applied psychology of the Psychologic Institute at the University of Leipzig, has adapted the existing psychotechnical methods to the special purpose in hand and has applied them thus far to about thirty applicants.

GENEVA

(From Our Regular Correspondent)

Oct. 15, 1925.

Criminal and Therapeutic Abortion

In all civilized countries, criminal abortion is forbidden by law and punishment is meted out to offenders. The only exception to the law is when the mother's life is endangered by pregnancy and the only way to save her is by inducing miscarriage. Various legislations admit this exception, and the codes of several of the Swiss cantons contain clauses in which this principle is admitted and provided for.

The drafts of the new criminal code of Switzerland, recently drawn up, sanction the classic rule and include abortion among misdemeanors. The commission appointed to draw up the draft in September last adopted the federal council's point of view, which provides for this therapeutic exception in article 107, which reads:

> Abortion performed with the consent of the pregnant person by a physician is not punishable if undertaken for the purpose of removing a danger impossible to deal with otherwise, threatening the mother's life or portending serious and permanent detriment to her health.

This text was vigorously assailed, and several amendments were proposed to enlarge the limits between which abortion is criminal. Finally, the commission decided to add other exceptions to Article 107, so that if it is finally adopted abortion will be admitted not only when the mother's life is involved, but also when pregnancy results from rape or incest; when at the time of conception the mother was insane, an idiot, unconscious or incapable of resisting—hypnosis, narcosis, etc., or if at the time abortion is practiced, the father or the mother is insane.

Prof. Paul Logoz of the faculty of law of the University of Geneva contested these innovations before the commission, putting forward the following arguments:

In the case of rape. At first sight, this might appear to be perfectly legitimate, but in practice it may not be feasible because it raises the question of proof of rape. To exact a legal sentence in all due form would in most instances render the law permitting the victim to submit to abortion deceptive. Even proof of rape by witnesses—should this be considered sufficient—would be very exceptionally possible; rape is not committed before witnesses, and the identity of the aggressor is not always known. As to the physician whose services are solicited, how can he at this late date (that is to say, when all traces of violence have usually disappeared) establish undeniably the fact that the woman has been raped? Therefore, is he to proceed with abortion simply on the affirmation of his client? What upright physician would venture to risk his professional reputation in these circumstances?

The case of incest. Professor Logoz next shows that in this case the situation becomes still more intricate, because by revealing the origin of her pregnancy, the victim exposes herself to criminal proceedings against her. Now, the commission considered that all that was necessary was to assure an effective control of therapeutic abortions by compelling the physician to inform the proper authorities of the operation about to be undertaken. It goes without saying that no matter what authorities are notified, none are bound by professional secrecy. On the contrary, when unlawful acts are brought to their notice, it is their strict duty to notify the public prosecutor.

Such are Professor Logoz' legal arguments in the case of rape and incest. As to the other hypotheses—impregnation of an idiot, etc., or insanity of the father or mother at the time of the induced abortion—these are strictly questions of eugenics. It is to improve the race that the fetus is destroyed. Professor Logoz is likewise opposed to these reasons, and he points out that it must be unqualifiedly demonstrated that defective individuals invariably engender defective offspring. There are many physicians who maintain that proof of this has never been given and that, on the contrary, the laws of heredity are as yet insufficiently known, so that it is quite impossible to offer an opinion as to the future of the descendants with any degree of certainty.

Dr. F. Naville of Geneva has recently put forward some interesting statistics which somewhat invalidate Professor Logoz' point of view. For example, he relates the history of several consecutive generations of a family in which vagrancy, alcoholism, immorality, prostitution, imbecility, insanity and criminality were family qualities. Of the 310 subjects comprised in the generations whose history could be reliably studied, practically none—children or adults—were spared the defects of their ancestors.

Naville also gives the genealogical tree of five generations descended from a mentally defective female. Of 834 subjects composing this family, there were 709 among whom there were 181 prostitutes, 142 beggars and vagrants, seventy-six criminals (seven being murderers), and sixty-four who had been in prison for various misdemeanors and in all had produced 106 illegitimate offspring. Taken altogether, the members had passed 116 years in prison and had been supported or aided by the state for 734 years, representing a cost of about six million francs ($1,200,000).

Given such data as these and many similar ones from other sources, it is evident that anything that can be done to improve society should be seriously discussed, be it induced abortion or sterilization of defective individuals.

Commi

Francke Huntington Bosworth, New York; Bellevue Hospital Medical College, New York, 1868; professor diseases of the throat, 1882-1898 at his alma mater; professor diseases of the throat 1898-1906 and since 1906 professor emeritus at the University and Bellevue Hospital Medical College; consulting physician to the Presbyterian and St. Vincents' hospitals; past president of the American Laryngological Association, and the American Climatological Association; author of the "Handbook of Diseases of the Throat and Nose," "Treatise on Diseases of the Nose and Throat" and other works; aged 82; was found dead in bed, October 17, of accidental asphyxiation.

William Morgan Case Bryan ⊕ St. Louis; Johns Hopkins University Medical Department, Baltimore, 1902; formerly instructor in anatomy, ear, nose and throat diseases, St. Louis University School of Medicine, and instructor in clinical laryngology and rhinology at Washington University Medical School, St. Louis; member of the American Academy of Ophthalmology and Oto-Laryngology; at one time on the staffs of the Alexian Brothers' and St. Louis City hospitals; aged 50; died, October 9, following a long illness.

Charles Dennison Smith, Portland, Me.; Medical School of Maine, Portland, 1879; member of the Maine Medical Association; formerly professor of physiology at his alma mater; at one time city physician and president of the state board of health; for many years superintendent of the Maine General Hospital; aged 70; died, October 11.

James Moorhead, Marion, Iowa; State University of Iowa College of Homeopathic Medicine, Iowa City, 1893; formerly assistant to the chair of theory and practice, and lecturer on gy at his alma mater; member of the board of formerly a druggist; aged 75; died, October 11, of emorrhage.

Belville Watson, Lock Haven, Pa.; University of nia School of Medicine, Philadelphia, 1863; meme Medical Society of the State of Pennsylvania; of the Clinton County Medical Society; Civil War iged 87; died, October 10, of cholecystitis.

ı **Stewart I. McDowell,** Chicago; Northwestern y Medical School, Chicago, 1891; member of the tate Medical Society; on the staffs of the Washing- and German Deaconess hospitals; aged 67; died, !1, of organic heart disease.

rederick Herbert ⊕ Philadelphia; Jefferson Medical ıf Philadelphia, 1883; ophthalmologist to the Abing-) Memorial Hospital; for several years member of enham Township board of health, and board of edu- iged 65; died, October 12.

l **Woodford Bates** ⊕ Louisville, Ky.; University of e School of Medicine, 1896; served in the M. C., rmy, during the World War; superintendent of the y State Tuberculosis Sanatorium, where he died, 17, aged 51.

:**ar Erni,** New Albany, Ind.; Louisville (Ky.) Medical 1883; formerly professor of general and descriptive , Southwestern Homeopathic Medical College and l, Louisville; aged 68; died, October 17, of heart

J. Haralson ⊕ Forest, Miss.; Louisville Medical 1886; formerly president of the Mississippi State Association and the Scott County Medical Society; of the state board of health; aged 68; died, October

s **Frank Wallis,** Washington, D. C.; University of lvania School of Medicine, Philadelphia, 1895; served M. C., U. S. Army, during the World War; aged 58; ctober 15, at Asheville, N. C., following a long illness.

s **C. Hay** ⊕ Laurel, Neb.; University of Manitoba / of Medicine, Edmonton, 1895; president of the Dixon-Thurston-Wayne-Dakota Counties Medical Society; 4; died, October 12, of pulmonary tuberculosis.

les Meredith Garth, Louisville, Ky.; University of ille School of Medicine, 1906; member of the Kentucky ledical Association; served in the M. C., U. S. Army, the World War; aged 45; died, October 14.

Holly Humphrey ⊕ Endicott, N. Y.; Albany Medical :, 1913; physician in charge of a hospital bearing his served in the M. C., U. S. Army, during the World iged 38; died, October 11, of pneumonia.

cis Willard St. John ⊕ Weedsport, N. Y.; Albany ıl College, 1887; for sixteen years health officer of Weedsport; past president of the Cuyahoga County Medical Society; aged 60; died, suddenly, in October.

Joseph Warren Richardson, Seattle; University of Vermont College of Medicine, Burlington, 1903; member of the Washington State Medical Association; on the staff of the Providence Hospital; aged 45; died, October 8.

George Clifton Hall ⊕ Richmond, Va.; Medical School of Harvard University, Boston, 1890; medical director of the Life Insurance Company of Virgina; aged 57; died suddenly, October 12, of cerebral hemorrhage.

Henry Alexander Gribbon ⊕ Poughkeepsie, N. Y.; University and Bellevue Hospital Medical College, New York, 1899; on the staff of the Vassar Hospital; aged 48; died, October 18, of heart disease.

Edward Giles McConnell ⊕ San Francisco; Cooper Medical College, San Francisco, 1893; member of the American Urological Association; aged 57; died, October 19, of chronic nephritis and uremia.

Charles W. Ely ⊕ Cheshire, Ohio; Starling Medical College, Columbus, 1890; aged 57; died, October 11, of a self-inflicted bullet wound, while suffering from chronic nephritis and heart disease.

James Barbour Boldridge, Winston, Va.; College of Physicians and Surgeons, Baltimore, 1893; member of the Medical Society of Virginia; aged 72; died, October 1, at Culpeper, of angina pectoris.

Anna M. A. Hahn, Chester, Ill.; Homeopathic Medical College of Missouri, St. Louis, 1900; Hahnemann Medical College and Hospital, Chicago, 1901; died, October 12, following a long illness.

⊕ Indicates "Fellow" of the American Medical Association.

Abram Vernon Hicks, Pittsburgh; University of Pitts School of Medicine, 1907; member of the Medical Society the State of Pennsylvania; aged 41; died, Octo pneumonia.

Jacob Read Lincoln, Millbury, Mass.; Medical Harvard University, Boston, 1888; member of chusetts Medical Society; aged 63; died, Septen myocarditis.

Abel Anderson, Denton, N. C. (licensed, North member of the Medical Society of the State of N lina; aged 70; died, October 14, of cerebral hemorrh

John J. Valentini, Baltimore; Baltimore University Sc of Medicine, 1889; formerly a member of the school bo aged 63; died suddenly, October 23, of heart disease.

John Christian Bullitt, Wayne, Pa.; University of P vania School of Medicine, Philadelphia, 1896; aged recently, at Vineyard Haven, Mass., of heart diseas

Earl Thomas, Hoxie, Ark.; Washington Universit School, St. Louis, 1905; member of the Arkansas Society; aged 47; was found dead, October 13.

Lanier Dunn Pole ⊕ Hot Springs, Va.; Univers ege of Medicine, Richmond, 1906; aged 41; died suddenly, October 17, near Staunton, of cerebral hemorrhage.

Abel Braslau ⊕ New York; Medical Department University of the City of New York, 1889; aged 61; suddenly, October 19, of heart disease.

Lee Victor Knapp, Danbury, N. H.; Baltimore Medic College, 1897; member of the New Hampshire Medical Society; aged 59; died, in October.

Lewis Everhard Sisler, Akron, Ohio; Western Reserve University School of Medicine, Cleveland, 1883; aged 65; died, October 19, of heart disease.

William Powers Crane, Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1925; aged 25; died suddenly, October 16.

Dean Gilkey, Walville, Wash.; University of Pennsylvania School of Medicine, Philadelphia, 1918; aged 37; died, October 5, at Eugene, Ore.

William Frank Steer, Cleveland; Cleveland Uni ity of Medicine and Surgery, 1896; aged 56; was killed, C ber 16, in an automobile accident.

H. Powell Luckett, Bastrop, Tex.; University of Louisville (Ky.) School of Medicine, 1867; aged 78; died, October 7, of cerebral hemorrhage.

William T. Pace, Monroe, Ky.; University of Louisville School of Medicine, 1874; aged 78; died, October 16, following a long illness.

Charles Isham, Little Falls, N. Y.; Chicago Medical College, 1865; Civil War veteran; aged 83; died, October 16, at a local hospital.

Clyde Dee Bothwell ⊕ Oelwein, Iowa; St. Louis College of Physicians and Surgeons, 1907; aged 42; died, October 19, of heart disease.

Louis Curtis Wood ⊕ Poughkeepsie, N. Y.; Bellevue Hospital Medical College, New York, 1881; aged 69; died, September 21.

William Knight, Cincinnati; Medical College of Ohio, Cincinnati, 1875; aged 75; died, October 13, at home in Madeira, Ohio.

Victor Noel, New York; University of Paris, France, 1880; died, September 26, at Nice, France, following a long illness.

John C. Bishop, Gainesville, Fla.; St. Louis (Mo.) College of Physicians and Surgeons, 1891; aged 58; died, October 9.

Thomas Ezra Guild ⊕ Boston; University of Vermont College of Medicine, Burlington, 1892; aged 57; died, October 9.

J. Ezra Blanchard, Ozark, Ill.; Eclectic Medical Institute, Cincinnati, 1895; aged 54; died, October 12, of carcinoma.

Clay D. Fellows ⊕ Algona, Iowa; Keokuk Medical College, 1892; aged 57; died, October 13, of heart disease.

Herman J. Groesbeck, Cincinnati; Miami Medical College, Cincinnati, 1873; aged 76; died, in October.

Homer H. Pratt ⊕ Brookfield, Mo.; Rush Medical College, Chicago, 1872; aged 77; died, October 15.

Francis B. Grew, Hoboken, N. J.; L.R.C.S., Edinburgh, Scotland, 1875; aged 75; died, in October.

The Propaganda for Reform

In This Department Appear Reports of The Journal's Bureau of Investigation, of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other General Material of an Informative Nature

HORSE DUNG ALLERGEN-SQUIBB, HOUSE DUST ALLERGEN-SQUIBB, LE PAGE'S GLUE ALLERGEN-SQUIBB AND STREET DUST ALLERGEN-SQUIBB NOT ACCEPTABLE FOR N. N. R.

Report of the Council on Pharmacy and Chemistry

The Council has authorized publication of the following report.

W. A. Puckner, Secretary.

Among the allergic protein preparations of E. R. Squibb & Sons, offered as a means of determining specific hypersensitiveness, are the following: Horse Dung Allergen-Squibb, stated to be the protein from the dung of the horse; House Dust Allergen-Squibb, stated to be the protein from ordinary house dust; Le Page's Glue Allergen-Squibb, the protein isolated from "Le Page's Glue"; Street Dust Allergen-Squibb, stated to be the protein from ordinary street dust.

The composition of house dust varies with the contents of different houses and with their location; therefore the protein obtained from house dust must vary widely. Similarly, the composition of street dust is dependent on the material that goes to make up the dust on streets in different localities. Le Page's Glue is a product of unstandardized composition; hence there is no guarantee that the protein isolated from Le Page's Glue is uniform. As the composition of horse dung, house dust, glue and street dust is indefinite, it is irrational to test the hypersensitivity of a patient by means of a stock preparation; instead, an extract should be prepared from material which is likely to correspond with that to which the patient is sensitive.

In consideration of their indefinite composition, the Council finds Horse Dung Allergen-Squibb, House Dust Allergen-Squibb, Le Page's Glue Allergen-Squibb and Street Dust Allergen-Squibb unacceptable for New and Nonofficial Remedies.

VITANOL NOT A[illegible]ABL[illegible]

Report of the Cou[illegible] Pharmacy

The Council has authorized publication of the statement that follows.

W. A. Puckner, Secretary.

Vitanol (Daub Chemical Company, Brooklyn), "The all-year-round tonic" is stated to have the following composition:

> "Egg Yolk 8%, Lecithin 1.5%, Hemoglobin 1.5%, Ferri Albuminate 1.5%, Cod Liver Oil 25%, Glycerin 9.5%. Vehicle used contains sugar, terpenless oil of lemon, and whiskey giving an alcoholic equivalent of 20%."

This alcoholic "tonic" is exploited with unwarranted therapeutic claims, such as these:

> "Just what the body needs"
>
> "It supplies the human cell what it needs to properly function. In other words, an Ideal Vitamin Emulsion which supplies the physiological and biological requirements of life."
>
> "Bodily functions are greatly stimulated with Vitanol due to the fact that it augments the body heat."

The following recommendations for the use of Vitanol appear on the trade package:

> "Indicated in the treatment of influenza, malnutrition, chlorosis, anemia, general debility, nervous disorders, coughs, colds, pulmonary diseases, lowered vitality and allied diseases."

The information submitted to the Council does not show that the vitamin potency of the mixture is determined or that the quality of the lecithin, hemoglobin, "ferri albuminate" or cod liver oil is controlled. Vitanol, being a complex, irrational mixture of uncontrolled composition, marketed with unwarranted therapeutic claims and in a way to invite its indiscriminate and ill advised use by the public, is inadmissible to New and Nonofficial Remedies.

Correspondence

MORTALITY FROM CANCER

To the Editor:—Referring to the editorial comment (THE JOURNAL, October 17, p. 1224) on my article on cancer mortality in the ten original registration states: In the course of the preparation of the bulletin of which this article is a summary, I, too, was struck by the apparent discrepancy between my conclusions for the ten original registration states and those arrived at by Dr. William T. Howard in his study of the statistics of the city of Baltimore (THE JOURNAL, Jan. 13, 1923, p. 71). This apparent discrepancy led me, of course, to careful study of Dr. Howard's article.

From internal evidence in the article itself, it was apparent that the figures and the rates published were erroneous and, therefore, the conclusions based thereon could not be correct. In his article, Dr. Howard publishes the following table for the city of Baltimore:

Number of Deaths and Rate of Death per Hundred Thousand Living Female Inhabitants 40 Years of Age and Over, from Cancer of the Breast and Uterus, for the Census Years 1880 to 1920, Inclusive

	Total		Breast		Uterus	
Year	Deaths	Rate	Deaths	Rate	Deaths	Rate
1880..............	94	61	37	24	57	37
1890..............	158	76	50	24	108	52
1900..............	161	64.	52	20	109	43
1910..............	199	65	74	24	125	41
1920..............	205	48	80	18	125	30

From his table the following conclusion is drawn:

> From these data, it appears that after 1880 there was no increase in mortality from cancer of the breast, and since 1890 from cancer of the uterus, and from cancer of these two organs taken together. Thus, when rates that approach specificity are obtained, in respect to cancer of these two organs, in which disease in fatal stages is readily diagnosable, an apparent increase in mortality is converted into an actual decrease. Therefore, it seems to be established that during the last forty years, cancer of the breast and uterus (including the other female organs of generation) has shown no real advance in mortality, and that there is a considerable margin of reduction, especially in respect of the latter category, to be placed to the credit of surgical intervention.

On comparing the rates shown in this table with rates that had been computed for cancer of the breast and cancer of the female genital organs for the female population of 35 years and over of the ten original registration states, it was noted that the rates given in Howard's table were abnormally low, only from about one half to one third of the rates found in this population for the registration states of 1900 (e. g., the death rate from cancer of the breast in the female population of 35 years and over of the ten original registration states was 46.4 per hundred thousand in 1910 and 54.0 per hundred thousand in 1920, as compared with the respective rates in Howard's table of 24 and 18). Evidently there was some error in the population figures for females 40 years and over for the city of Baltimore, by which these rates were computed.

The U. S. Census Reports give the following figures for the female population 40 years and over for that city:

Year	Female Population, 40 Years and Over
1880..	40,936
1890..	59,278
1900..	66,811
1910..	80,079
1920..	106,902

Applying these figures to the number of deaths from cancer of the breast and of the uterus, as given for Baltimore by Howard, the following table is obtained:

Year	Female Population 40 Years and Over	Total		Breast		Uterus	
		Deaths	Rate	Deaths	Rate	Deaths	Rate
1800..........	40,936	94	230	37	90	57	139
1890..........	59,278	158	267	50	84	108	182
1900..........	66,811	161	241	52	78	109	163
1910..........	80,079	199	249	74	92	125	156
1920..........	106,902	205	192	80	75	125	117

This recomputation, using enumerated figures, gives much higher rates. In fact, some of them are now apparently too high. For instance, the combined rate for Baltimore in 1910 for cancer of the breast and of the uterus is over twice as high as the computed rate (116.4) for the female population 35 years and over of the ten original registration states.

The following table, which shows the actual deaths in the city of Baltimore for the period 1900-1920, was compiled from the deaths from cancer of the breast and cancer of the female genital organs that were furnished me by Dr. W. H. Davis, chief statistician of the Division of Vital Statistics, Bureau of the Census. The rates were computed for the female population 40 years and over from the population figures given for the city of Baltimore by specific age groups in the reports of the Cenus Bureau, 1900, 1910 and 1920, the intercensal years being estimated by the usual arithmetical method.

Deaths in City of Baltimore, 1900-1920

	Cancer of Breast		Cancer of Female Genital Organs		Total	
Year	Deaths	Rate	Deaths	Rate	Deaths	Rate
1900............	26	39	70	105	96	144
1901............	45	66	69	101	114	167
1902............	45	65	72	105	117	168
1903............	31	44	73	103	104	147
1904............	52	72	74	103	126	175
1905............	43	59	73	99	116	158
1906............	51	68	78	104	129	172
1907............	41	54	91	119	132	173
1908............	44	57	81	105	125	161
1909............	44	56	81	103	125	159
1910............	54	67	95	119	149	186
1911............	52	63	74	89	126	152
1912............	65	76	99	116	164	192
1913............	50	57	104	118	154	175
1914............	65	72	104	114	169	186
1915............	55	59	97	104	152	163
1916............	74	77	105	109	179	186
1917............	42	43	97	98	139	140
1918............	65	64	101	99	166	163
1919............	87	83	122	117	209	200
1920............	65	61	125	117	190	178

On comparing the years 1900, 1910, 1920 as was done by Dr. Howard, using the average of the first two and the last two years, and of the three years, 1909, 1910, 1911,

	Cancer of Breast		Cancer of Female Genital Organs		Total	
Year	Breast	Rate	Deaths	Rate	Deaths	Rate
1900............	35	52	69	102	105	155
1910............	50	62	83	103	133	165
1920............	75	72	123	117	199	189

it is evident that there has been a considerable increase in the death rate from cancer of the breast amounting to 38 per cent., and from cancer of the female genital organs, 15 per cent. The combined rate of increase for these two forms of cancer is 22 per cent. This is, of course, by no means comparable with the much greater percentage increase that has been registered in the mortality figures of the ten original registration states. The situation, however, is far different from the pronounced decline of nearly 33 per cent. in the combined death rate for cancer of the breast and cancer of the female genital organs shown in Dr. Howard's table.

Evidently this explanation clears up the apparent discrepancy between Dr. Howard's conclusions and my own.

J. W. Schereschewsky, M.D., Boston.
Surgeon, in Charge, Field Investigations
of Cancer, U. S. Public Health Service.

"DIATHERMY IN CALCIFIED SUBDELTOID BURSITIS"

To the Editor:—Arthur L. Fisher (The Journal, October 24, p. 1324), San Francisco, takes good exception to the article on "Action of Diathermy in Calcified Subdeltoid Bursitis," by Dr. Joseph F. Harris (The Journal, October 10, p. 1134). In that article Dr. Harris reports only one case. Dr. Fisher also cites the well known occurrence that for some unknown reason the calcification of bursae sometimes disappears without treatment. This could hardly be the situation with Dr. Harris' case, the symptoms of which condition existed seven years.

I have had a few cases of this condition to treat in which diathermy plus static brush discharge has been used, and at the meeting of the American Academy of Physiotherapy in New York during September, 1923, eleven such cases were reported. All the roentgenograms and their diagnoses, both before and after treatment, were made outside my office, some of them having been made at the Presbyterian Hospital, New York. All these cases were of long standing, and it was felt that while diathermy and static electricity did not effect a "cure," they certainly helped awaken a reaction in the body which promoted the absorption of the calcium and assisted the patient in recovering from the condition himself. Physiotherapy in all its branches is very rarely a curative method, but it does seem to convert an inadequate reaction on the part of the individual into one that is adequate to overcome the pathologic condition.

Norman E. Titus, M.D., New York.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

ROENTGEN RAYS AND STERILITY

To the Editor:—Are there any facts to substantiate the belief that roentgenologists are liable to sterility? *Are there any reliable reports* of sterility occurring in roentgenologists in this country and can you give me the references? What procedure should be adopted to determine sterility in the male, if it is suspected? What are the characteristics of the spermatic fluid in cases of roentgen-ray sterility?

M.D., Minneapolis.

Answer.—The general subject of sterility induced by roentgen rays has been dealt with in The Journal from time to time:

Roentgen Rays and Sterility, Current Comment, The Journal, Nov. 11, 1922, p. 1692.
DeVilbiss, Lydia Allen: Roentgen Rays and Sterility, The Journal, Dec. 23, 1922, p. 2184.
Roentgen-Ray Sterilization, Queries and Minor Notes, The Journal, Oct. 3, 1925, p. 1082.

In most cases the sterilization is only temporary. The time of recuperation depends on the intensity of the treatment and on the individual constitution. Neither roentgen-ray nor operative sterilization necessarily affects the libido. There is no specific treatment for roentgen-ray sterility in the male. Absolute removal from the influence of roentgen rays and general hygienic measures are essential.

Furthermore, full discussion of the phases of the subject that interest our correspondent can be found by consulting the book by Sinclair Tousey, "Medical Electricity, Roentgen Rays and Radium," Edition 3, 1921, and by following out the references he gives. However, the following quotation may be of interest in answer to the four questions:

> "Repeated mild exposures of the ovary or testis are quite generally regarded as productive of sterility. In the case of x-ray operators, the loss of the power of motion in the spermatozoa, and in some cases absence of the spermatozoa, has been demonstrated a great many times by the microscope. The fact was first published by Tilden Brown and A. T. Osgood of New York. This is not accompanied by any sexual impotence, and it is doubtless not permanent, but a condition which disappears after the exposures have been discontinued or protection by a proper apron or shield has been adopted. This necrospermia may develop in any one who spends much time in an x-ray room where no precautions are taken to limit the rays to some one particular direction. . . . The author knows of cases in which physicians working much with the x-ray without adequate protection have been found to have complete necrospermia and apparent azoospermia, and in whom a vacation, and the subsequent use of a heavy apron of rubber loaded with baryta, and an efficient shield around the x-ray tube, have been followed by the reappearance of living spermatozoa, and the men have had children."

NEW AND OLD HAINES' TEST

To the Editor:—Is there a table by which a person using a certain number of drops of urine to a given amount of Haines' solution can tell approximately the percentage of sugar?

E. L., M.D., Rockford, Ill.

To the Editor:—What are the directions for the old and new Haines' solutions for testing urine for presence of sugar? How does the new solution differ from the old?

H. E. B., M.D., Ohio.

Answer.—Neither Haines' solution nor Haines' solution modified is adaptable for approximate determinations of sugar by the drop method. Furthermore, the size of drops from different types of delivery tubes varies greatly in amount so that it is much better to employ metric measurement (cubic centimeters) if quantitative data are desired. The directions for the Haines' solution modified (which is a *qualitative* test) are: "Heat about 5 c.c. of the copper solution to boiling in a test tube, remove from the flame, and hold at an angle of 30 to 40 degrees. To this add, by means of a medicine dropper, 10 to 20 drops of the urine (freed from phosphates) in such a manner that a distinct zone of contact is formed between the copper solution and the urine. The tube is then placed in the upright position and the reaction noted. If sugar is present in quantities exceeding 0.1 per cent., a brick-red or yellowish ring will immediately appear at the junction of the two liquids. If the amount of sugar be less than 0.1 per cent., the ring will appear in from a few seconds to slightly less than a minute, the smaller quantities showing slower reactions with a tendency to a more yellowish color of the ring. In urines containing no sugar, no ring of any kind will be noted at the zone of contact" (Haines, W. S.; Pond, G. P., and Webster, R. W.: Improved Test for Detection of Glucoses, Especially in Urine, The Journal, Jan. 31, 1920, p. 301). It will be noticed that the directions preclude the addition "drop by drop," as thereby the two liquids would mix; also the relative degree of pathologic sugar is indicated by the time and color of the ring, and not by the amount of urine employed. It is important that phosphates be removed from the urine in order to avoid wrong interpretations. The A. M. A. Chemical Laboratory has seen instances in which a physician, using this test, reported sugar present when in reality it was absent, owing to not removing the phosphates; the resulting phosphate precipitate was misinterpreted as a positive test for sugar.

In the original Haines' test (qualitative) the technic is different, particularly in that the urine and solution are mixed, then heated and only 6 drops of suspected urine is employed. The directions are: "Four or five c.c. of this solution are placed in a test-tube and gently boiled. Six drops of the suspected urine are added and the upper portion of the mixture brought to a boil and immediately removed from the flame. If sugar be present an abundant yellow or yellowish-red precipitate is thrown down; if no such precipitate occurs sugar is absent. The precautions to be observed in using this test are never to add at the outside more than 10 drops of urine and not to boil the mixture for more than one or two seconds after the addition of urine" (Webster: Diagnostic Methods, Philadelphia, P. Blakiston's Son & Co., 1923, p. 323).

The determination of the sugar quantitatively by means of a pipet or buret is not difficult and much more satisfactory.

The original Haines' solution, which is a modification of Trommer's test, consists of:

Copper sulphate	12 gm.
Sodium hydroxid	32 gm.
Glycerin	90 c c.
Water......to make	1,000 c c.

The composition of the modified Haines' solution is:

Copper sulphate	5 gm.
Glycerin	250 c c.
Sodium hydroxid	14 3 gm.
Water......to make	1,000 c c.

Mississippi June Examination

Dr. F. J. Underwood, secretary of the Mississippi Board of Health, reports the written examination held at Jackson, June 23-24, 1925. The examination covered 12 subjects, and included 96 questions. An average of 75 per cent. was required to pass. Twenty-eight candidates, including two undergraduates, were examined, all of whom passed. Thirteen candidates were licensed by reciprocity. The following colleges were represented:

Oklahoma June Examination

Dr. J. M. Byrum, secretary of the Oklahoma Board of Medical Examiners, reports the written examination, held at Oklahoma City, June 16-17, 1925 The examination covered 12 subjects and included 120 questions. An average of 75 per cent. was required to pass. Thirty-three candidates took the examination and all of them passed. Eleven candidates were licensed by reciprocity, and two were granted reregistration certificates. The following colleges were represented:

College PASSED	Year Grad.	Per Cent.
Northwestern University Medical School	(1924)	89
University of Louisville School of Medicine	(1924)	90

Book Notices

The Medical Follies. An Analysis of the Foibles of Some Healing Cults, Including Osteopathy, Homeopathy, Chiropractic, and the Electronic Reactions of Abrams, with Essays on the Antivivisectionists, Health Legislation, Physical Culture, Birth Control and Rejuvenation. By Morris Fishbein, M.D., Editor of the Journal of the American Medical Association. Cloth. Price, $2. Pp. 223. New York: Boni and Liveright, 1925.

This volume by the editor of The Journal, is a collection of articles published during the last two years in such periodicals as the *American Mercury,* the *Haldeman-Julius Monthly, Hygeia* and The Journal, together with some essays not previously in print. The essays are arranged in chronological order, beginning with the tractors of Elisha Perkins, passing through homeopathy, osteopathy and chiropractic to the Abrams fad, and including also material on health legislation, birth control, animal experimentation, physical culture and the medicine of the press. The volume has been greeted by literary critics with rather general approval. The recognition accorded to the book is an indication of the fact that American journalism today looks to the American Medical Association for authoritative statements in matters of scientific medicine and public health. As an indication, we include statements from current reviews.

The New York *Times* said, in part:

> The rise and fall of the various fads and fancies of medicine as evolved by advocates of preposterous and fallacious theories, some of which were conceived for the purpose of deliberate fraud and others in the uncurbed delusions of fanatics, and all against the "peace and dignity" and the health of the public, are explained with a clarity and convincing logic that leaves little room for argument. . .
>
> It may as well be said at once that in this volume Dr. Fishbein has done a great service to the cause of scientific medicine.

The Brooklyn *Eagle* said:

> The guardian text of the good doctor is that health systems come and go, but the medical doctors go on forever
>
> The practice of medicine made such rapid strides during the war that the public is willing to accept almost anything that appears to have a medical label Dr. Fishbein realizes this. His book is a valuable aid in separating the real from the fake . . . I know of no more readable book of nonfiction

The Chicago *Post* said, in part:

> When the antimedical crowd criticize the medical profession as a trust, they omit one important point; and that is that the medical profession, if it be a trust, is an open one Nobody can be kept out who wants to get in All he has to do is to prove that he has studied the human body, knows therapy, and has a proper educational background The reviewer is a believer in individualism and freedom But the less "medical freedom," in the sense in which the propagandists for it use that phrase, we have, the safer he will feel for himself, his children and his friends.

The New York *Post* said:

> Dr Fishbein writes amusingly and readably; he swings a vigorous club, and when he comes to such absurdities as "The Big Muscle Boys" he scores with every swing Just what good a book of this sort will do is open to question· There will be cults and followers for them as long as mankind lasts But it is interesting reading, and Dr Fishbein has done his part admirably.

The New York *Sun* said:

> In "The Medical Follies" (Boni & Liveright, $2) he sets fire to the shirts of charlatans with tremendous relish and gusto
>
> Everything about his style is in his favor. He is so plain that no intelligent layman will have any difficulty in following him He is so vigorous that the reader is swept along by the flood. Finally, though a book like this is a tremendous public service, it is quite obvious that with Dr. Fishbein it was not primarily written from any solemn sense of duty. Against the frauds who prey upon the public he does not use the weapon of righteous indignation, but the weapon of derision One feels that he waves his battle ax around his head not because it is a service to the state, but because there is a glorious zest in crushing the skulls of quacks This department leaves it to specialists to say whether every statement he makes may be indorsed; but to watch him at his work is as exhilarating as watching a bull fight

The Richmond *News Leader* said:

> The broom is at its most effective point in the essays of "The Medical Follies." The quacks who operate on the shady borderline of the medical profession, taking millions and injuring the cause of authentic science, have never before had to deal with so devastating an offensive

However, not all of the response has been so favorable. One O. O. M'Intyre, conducting a syndicated column, remarks:

> "The Medical Follies," by a Dr. Morris Fishbein, is a stupidly written and unnecessary book It is an old school practitioner sneering at the new schools and its unconscious venom reveals its obvious propaganda As one reviewer notes "Let Dr Fishbein cure whooping cough, then he may impress us more with the surety of his medical views."

An osteopath, W. E. Farbstein, replied to favorable criticism in the *Haldeman-Julius Weekly*, as follows:

> Why didn't Fishbein, if he were an honest man, publish a chapter on Medicine and Surgery Full of Quackery Today? He has criticised every form of therapy but his own, allopathy, which deserve criticism the most.
>
> Medicine and surgery, as practiced today, is 90 per cent. bunk. Cabot, America's premier diagnostician, of the Harvard Medical College, a few years ago stated that 50 per cent of his diagnoses were incorrect, when checked up by postmortem
>
> Osler, the greatest of modern times, was almost a therapeutic nihilist. He said there were less than six drugs of value in the whole Pharmacopeia, also that 80 per cent or more of sick folks would get well just as quick or quicker without any medical treatment.

In the meantime the publisher has made three printings of the volume and it seems to be accomplishing its purpose.

CLINIQUE MÉDICALE DES ENFANTS. Affections de l'appareil circulatoire. Par P Nobécourt, Professeur de clinique medicale des enfants a la Faculté de médecine de Paris Paper. Price, 25 francs. Pp 371, with 122 illustrations. Paris: Masson et Cie, 1925

No greater service can be rendered by a clinician of large experience than to record, after many years of labor among the sick, his observations and deductions This Nobecourt has done in an admirable way in this monograph. He considers the various cardiac affections of infancy and childhood, and each chapter is devoted to a particular phase of the subject. He introduces his clinical treatise by citing the history of several patients, and proceeds with an analytic discussion of the patients and the subject in general. His reference to his own vast experience, as well as to the literature in general, makes the book of added value. There are charts and orthodiagrams. The modern methods of heart diagnosis are presented and stressed, and the suggestions for treatment are rational and valuable. The book will be of great interest to pediatricians and those who treat the cardiac diseases of young life. Not least, the observations and the clinical reflections of a keen and industrious clinician are preserved in the form of a permanent and very readable record.

INTERNAL SECRETION IN HEALTH AND DISEASE By Capt. Y. M. Bose, M D. Cloth. Price, Rs 12 net. Pp 550, with 43 illustrations. Calcutta: Butterworth & Co (India), Ltd, 1925.

This is a curious and disappointing volume on endocrinology. In the preface the author makes the following candid confession: "The writer does not claim any original research and study on the subject, but has tried to put together the important connecting links of the various problems of internal secretion so as to make the subject clearly understood by any busy practitioner or a student." Why a physician who has made no specific research or study on the difficult subject of the endocrines in health and disease should proceed to write a volume on the subject for the information and instruction of students and physicians is certainly not clear. The author says further, "As far as possible all controversal discussions have been avoided." That would lead one to infer that all the matters set forth in the book are accepted, proved and undisputed facts, when, as a matter of fact, the book is full of errors, misleading statements and unproved assertions. The author gives evidence of quite extensive reading in the field of endocrinology; occasionally he shows discrimination and judgment, but more often purile credulity. The book contains the conventional chapters on endocrines and endocrine diseases. There is a chapter headed "Glossary of Endocrine Diseases and their Treatment" from which we quote:

> *Asphyxia* is relieved promptly by adrenalin with saline solution intravenously.
>
> *Cataract* is considered to be arrested by thyroid with adrenal gland and iodides
>
> *Bronchitis* (chronic) responds to thyroid with creosote preparations, in addition to other remedial measures, especially suitable vaccine.
>
> *Eczema* is often the result of defective protein catabolism with correlated endocrine dysfunction and auto intoxication. A week's strict vegetable diet should be followed by thyroid and pituitary.
>
> *Fractures* get easily united when calcium lactate and thymus are given with meals, and strychnine, thyroid and pituitary after meals.
>
> *Mania* is due to hyperendocrin condition.
>
> *Neurasthenia* is relieved by strychnine, thyroid and pituitary.

On page 55 we are told that the "thymus controls the infancy when by its inhibitory action on the other internal secretions the baby is allowed to grow in bulk without much differentiation. . . . The pineal rules the childhood. . . . During the mature period the three important glands, pituitary, thyroid and adrenals, between themselves control the personality, both bodily and mentally, of the man. Senility is due to general endocrin deficiency." On page 58 the author states under the heading Therapeutic Value of Hormones: "It cannot be said that much has been accomplished with organotherapy except in a few instances such as the use of thyroid in myxedema. It is unfortunately common for a present day clinician to take a chance-hit with the much boomed organotherapeutic shot-gun." Then he proceeds to quote with approval Cushing's caustic remarks on the follies of present day organotherapy. And yet in subsequent parts of the book the author completely abandons this attitude and says (p. 481): "The administration of endocrin products by mouth is considered to be practical, for most of these extracts are effective in this way." On page 470 the author states that the administration of the extract of an organ specifically stimulates this organ in the patient, and that this law appears to be general. In other words, he accepts the hypothesis of homostimulation as a demonstrated law. The book cannot be recommended for the information and guidance of either students or practitioners. It is more misleading than informational.

LES SYNDROMES RESPIRATOIRES. Par Émile Sergent, Professeur à la Faculte de médecine de Paris Deuxième fascicule Bibliothèque des grands syndromes Directeur H. Roger, Doyen de la Faculté de médecine de Paris Paper. Price, 20 francs. Pp 489, with 98 illustrations. Paris Gaston Doin, 1925

This is an excellent presentation of the etiology, diagnosis, prognosis and treatment of various disturbances of the mediastinum, the diaphragm, the pleura and the lungs. The section on diseases of the mediastinum covers 150 pages. The section on the diaphragm is briefer; the section on the pleura and that on the lungs cover 100 pages each. Seventy-six of the illustrations are reproductions of roentgenograms of patients illustrating the various types of disorders. Great emphasis is laid on the roentgen ray in diagnosis of the disorders treated Comments on therapy are very brief. The volume is a serious and valuable study on the diseases of the chest.

VITAL CAPACITY OF THE LUNGS A Handbook for Clinicians and Others Interested in the Examination of the Heart and Lungs Both in Health and Disease By J. A Myers, M.S, Ph D, M D, Assistant Professor of Preventive Medicine and Public Health, Medical and Graduate Schools, University of Minnesota With introduction by S Marx White, B S, M D, F A C.P., Professor of Medicine and Chief of the Department of Medicine, University of Minnesota Cloth Price, $3 25 Pp 140, with 32 illustrations. Baltimore: Williams & Wilkins Company, 1925.

Internists, teachers of physical education, and investigators will welcome this concise, accurate and conservative monograph. The author has attempted to bring together the chief facts which we now possess concerning the normal vital capacity and its variations in health and in disease, making these data available without the use of any mathematical calculations or an understanding of the mathematical formulas from which the tables are derived. The six chapters deal in turn with the history of the study of vital capacity; factors other than disease which influence the normal capacity; the influence of disease on the vital capacity; some limitations of the vital capacity as a clinical test for disease or as a test for physical fitness; measurements and instruments used in the vital capacity test, and, finally, normal vital capacity standards. The presentation is clear, concise and conservative. No one will take issue with the following conclusion (p. 81):

> I do not wish to leave any reader with the impression that the vital capacity test is infallible or that it should replace any part of the physical or x-ray examinations as they are used today. But the laboratory, physical and x-ray examinations are all subject to error. In fact, diagnosis of disease rarely should be made on a single phase of an examination, but all possible information should be obtained from every available source before a patient is told that disease does or does not exist in his body. In such a complete examination the vital lung capacity test is fully entitled to a place.

Médicaments et médications cardiaques. Par H. Vaquez, Professeur a la Faculté de médecine de Paris. Leçons recueillies par M. Théodoresco. Cloth. Pp. 302. Paris: J.-B. Baillière et Fils, 1925.

There are twelve lectures by Vaquez reported by his intern Théodoresco. Several drugs are discussed, digitalis, strophanthus and quinidin being considered quite fully. The clear style and orderly arrangement make for easy reading. The historical introductory pages add much that is of value. In the first half of the volume the approach to the subject is by way of the drug. In the last half it is by way of the different diseases, there being considered the treatment of such affections as the acute cardiopathies, the arrhythmias, hypertension and angina pectoris. While Vaquez is rather optimistic as to therapy and while one may not always agree with his views, no one can read the book without a lively interest and without receiving many valuable suggestions as to the practical treatment of diseases of the heart.

Textbook of Differential Diagnosis of Internal Medicine. By M. Matthes, M.D., Professor of Medicine and Director of the Medical Clinic, University of Königsberg. Authorized translation of the fourth German edition with extensive additions, by L. W. Held, M.D., and M. H. Gross, M.D. Cloth. Price, $12. Pp. 908, with 176 illustrations. Philadelphia: P. Blakiston's Son & Co., 1925.

Differential diagnosis is obviously one of the most important phases of medical practice. It demands a broad knowledge of numerous diseases. In the review of the second German edition of Matthes' textbook, The Journal recommended an early English translation because of the systematic, concise presentation and the completeness. The English edition is made from the fourth German edition, bringing the literature quite up to date. Moreover, the translators have added to the sections on influenza, circulatory diseases, roentgen-ray diagnosis and chronic appendicitis, so as to give full value to recent American observations in these fields. The additions by the translators and editors of this volume make what was, in the German edition, a superior book, in the American edition, a superlative one.

Théorie des vitamines et ses applications. Essais de vitaminologie. Par Jean Lorenzini, Docteur en chimie appliquée de la Faculté de Pavie. Avec préface de Charles Richet. Paper. Price, 8 francs. Pp. 88, with 28 illustrations. Paris: Masson et Cie, 1925.

This is an excellent critical summary of the present status of the vitamin problem. The author is catholic in his familiarity with the literature in all languages. The bibliography, however, is incomplete. There are some good photographic illustrations of typical vitamin deficiencies in man and in animals. In the preface to the volume, the physiologist Richet of the University of Paris states that the present volume is really complementary to the volume on the vitamins published by Dr. Berg in Germany three years ago. Dr. Berg in his monograph dealt particularly with the relation of the vitamins to mineral metabolism. Lorenzini's volume deals also with this problem but, in addition, sums up briefly our present knowledge concerning the rôle of the vitamins in all phases of nutrition and metabolism. The volume is a useful and valuable contribution to medicine.

Medicolegal

Phosphorus Poisoning an Accidental Injury

(Victory Sparkler & Specialty Co. v. Francks (Md.), 128 Atl. R. 635)

The Court of Appeals of Maryland, in reversing a judgment for $22,500 recovered against the defendant company for the benefit of a young girl who had contracted phosphorus poisoning while employed in the making of fireworks for the company, says that the lower court held the disease of phosphorus poisoning to be an injury outside the purview of the workmen's compensation act of Maryland; and that the employer was liable, for this injury, at common law. But the court of appeals holds that the girl had sustained an injury arising out of and in the course of an extrahazardous occupation, and that her sole remedy was under the terms of the workmen's compensation act.

The most that was warranted to be inferred from the allegations of fact in the declaration was that the phosphorus poisoning alleged was the gradual result of the negligence of the employer. As this negligence was a breach of duty to her, it was not to be foreseen or expected by the worker as something which would occur in the course of her employment. The fact that she continued at her place of labor, in the doing of her common and regular task, made it clear that the phosphorus poisoning happened without her design or expectation, and so her injury was accidental. It was by chance that the employer did not use due care, and by chance that the vapor of phosphorus was where its noxious foreign particles could be inhaled by the girl. It was by chance that the inspired air carried these particles into her system, sickening her, and causing a necrosis of the jaw after fortuitously finding a lesion. The injury thus inflicted on her body was accidental by every test of the word, and its accidental nature was not lost by calling the consequential results a disease.

Nor could the fundamentally accidental nature of the injury be altered by the consideration that the infection was gradual throughout an indefinite period, as this simply implied a slow development of the malady, or that, instead of a single accidental injury, there was a succession or series of accidental injuries culminating in the same consequential results. The introduction of phosphorus into the human body is none the less accidental, if through the medium of a pimple point, an unsound tooth, a scratch, a lesion, or of ingestion or in breathing. Nor is the accidental nature of this introduction lessened by the length of time intervening between the reception of the poisonous substance and the first manifestation of the resultant poisoning, as its progress may be slow, moderate or rapid, according to the form it assumes. The infection is the accidental injury, and whatever follows in causal connection are but consequences, which measure the duration and effect of the injury. The phosphorus poisoning of the employee as described in the declaration was therefore not a disease incident to the industry, but was an injury in causal connection with her employment, within the meaning of the act defining injury to "mean only accidental injuries arising out of and in the course of employment and such disease or infection as may naturally result therefrom."

Relatives of Patient as Accomplices of Practitioner

(People v. Albrexstondere (Calif.), 235 Pac. R. 87)

The District Court of Appeal of California, Second District, Division 1, says that the defendant contended that the several members of the family of the patient, having prior knowledge of the fact that the defendant was not a licensed medical practitioner within the state, and they with such knowledge having cooperated with him in the treatment of the patient, these facts brought them within the rule that one who in any manner, knowingly and with criminal intent, aids and abets another in the commission of a criminal act is as guilty of the offense as is the person who actually commits it, and consequently that the members of the family who, with such knowledge of the facts, assisted the defendant in the treatment of the patient were accomplices of the defendant, and

> I do not wish to leave any reader with the impression that the vital capacity test is infallible or that it should replace any part of the physical or x ray examinations as they are used today. But the laboratory, physical and x ray examinations are all subject to error. In fact, diagnosis of disease rarely should be made on a single phase of an examination, but all possible information should be obtained from every available source before a patient is told that disease does or does not exist in his body. In such a complete examination the vital lung capacity test is fully entitled to a place.

Médicaments et medications cardiaques. Par H. Vaquez, Professeur a la Faculté de médecine de Paris. Leçons recueillies par M. Theodoresco. Cloth Pp. 302. Paris: J. B Baillière et Fils, 1925.

There are twelve lectures by Vaquez reported by his intern Théodoresco. Several drugs are discussed, digitalis, strophanthus and quinidin being considered quite fully. The clear style and orderly arrangement make for easy reading. The historical introductory pages add much that is of value. In the first half of the volume the approach to the subject is by way of the drug. In the last half it is by way of the different diseases, there being considered the treatment of such affections as the acute cardiopathies, the arrhythmias, hypertension and angina pectoris. While Vaquez is rather optimistic as to therapy and while one may not always agree with his views, no one can read the book without a lively interest and without receiving many valuable suggestions as to the practical treatment of diseases of the heart.

Textbook of Differential Diagnosis of Internal Medicine. By M. Matthes, M.D, Professor of Medicine and Director of the Medical Clinic, University of Königsberg Authorized translation of the fourth German edition with extensive additions, by L W. Held, M D, and M. H. Gross, M.D. Cloth. Price, $12. Pp. 908, with 176 illustrations. Philadelphia: P. Blakiston's Son & Co, 1925.

Differential diagnosis is obviously one of the most important phases of medical practice. It demands a broad knowledge of numerous diseases. In the review of the second German edition of Matthes' textbook, The Journal recommended an early English translation because of the systematic, concise presentation and the completeness. The English edition is made from the fourth German edition, bringing the literature quite up to date. Moreover, the translators have added to the sections on influenza, circulatory diseases, roentgen-ray diagnosis and chronic appendicitis, so as to give full value to recent American observations in these fields. The additions by the translators and editors of this volume make what was, in the German edition, a superior book, in the American edition, a superlative one.

Théorie des vitamines et ses applications Essais de vitaminologie Par Jean Lorenzini, Docteur en chimie appliquee de la Faculté de Pavie Avec préface de Charles Richet. Paper Price, 8 francs. Pp. 88, with 28 illustrations Paris: Masson et Cie, 1925.

This is an excellent critical summary of the present status of the vitamin problem. The author is catholic in his familiarity with the literature in all languages The bibliography, however, is incomplete. There are some good photographic illustrations of typical vitamin deficiencies in man and in animals. In the preface to the volume, the physiologist Richet of the University of Paris states that the present volume is really complementary to the volume on the vitamins published by Dr. Berg in Germany three years ago. Dr. Berg in his monograph dealt particularly with the relation of the vitamins to mineral metabolism. Lorenzini's volume deals also with this problem but, in addition, sums up briefly our present knowledge concerning the rôle of the vitamins in all phases of nutrition and metabolism. The volume is a useful and valuable contribution to medicine.

Phosphorus Poisoning an Accidental Injury

(Victory Sparkler & Specialty Co. v. Francks (Md.), 128 Atl. R. 635)

The Court of Appeals of Maryland, in reversing a judgment for $22,500 recovered against the defendant company for the benefit of a young girl who had contracted phosphorus poisoning while employed in the making of fireworks for the company, says that the lower court held the disease of phosphorus poisoning to be an injury outside the purview of the workmen's compensation act of Maryland; and that the employer was liable, for this injury, at common law. But the court of appeals holds that the girl had sustained an injury arising out of and in the course of an extrahazardous occupation, and that her sole remedy was under the terms of the workmen's compensation act.

The most that was warranted to be inferred from the allegations of fact in the declaration was that the phosphorus poisoning alleged was the gradual result of the negligence of the employer. As this negligence was a breach of duty to her, it was not to be foreseen or expected by the worker as something which would occur in the course of her employment. The fact that she continued at her place of labor, in the doing of her common and regular task, made it clear that the phosphorus poisoning happened without her design or expectation, and so her injury was accidental. It was by chance that the employer did not use due care, and by chance that the vapor of phosphorus was where its noxious foreign particles could be inhaled by the girl. It was by chance that the inspired air carried these particles into her system, sickening her, and causing a necrosis of the jaw after fortuitously finding a lesion The injury thus inflicted on her body was accidental by every test of the word, and its accidental nature was not lost by calling the consequential results a disease.

Nor could the fundamentally accidental nature of the injury be altered by the consideration that the infection was gradual throughout an indefinite period, as this simply implied a slow development of the malady, or that, instead of a single accidental injury, there was a succession or series of accidental injuries culminating in the same consequential results The introduction of phosphorus into the human body is none the less accidental, if through the medium of a pimple point, an unsound tooth, a scratch, a lesion, or of ingestion or in breathing. Nor is the accidental nature of this introduction lessened by the length of time intervening between the reception of the poisonous substance and the first manifestation of the resultant poisoning, as its progress may be slow, moderate or rapid, according to the form it assumes. The infection is the accidental injury, and whatever follows in causal connection are but consequences, which measure the duration and effect of the injury The phosphorus poisoning of the employee as described in the declaration was therefore not a disease incident to the industry, but was an injury in causal connection with her employment, within the meaning of the act defining injury to "mean only accidental injuries arising out of and in the course of employment and such disease or infection as may naturally result therefrom."

Relatives of Patient as Accomplices of Practitioner

(People v Albrexstondare (Calif.), 235 Pac. R. 87)

The District Court of Appeal of California, Second District, Division 1, says that the defendant contended that the several members of the family of the patient, having prior knowledge of the fact that the defendant was not a licensed medical practitioner within the state, and they with such knowledge having cooperated with him in the treatment of the patient, these facts brought them within the rule that one who in any manner, knowingly and with criminal intent, aids and abets another in the commission of a criminal act is as guilty of the offense as is the person who actually commits it, and consequently that the members of the family who, with such knowledge of the facts, assisted the defendant in the treatment of the patient were accomplices of the defendant, and that their testimony was subject to the statute which required that before the defendant could be convicted on the testimony of accomplices it was necessary that it be corroborated by evidence which tended to connect the defendant with the commission of the offense.

It is apparent that if the members of the family of the patient in good faith believed that the defendant was a physician and licensed by the state board of medical examiners to act as such, their cooperation with him in treating the patient would not have been criminal. Their knowledge of his lack of statutory qualifications in the premises was prerequisite to any constructive criminal intent on their part. Assuming such actual knowledge by the members of the family, and constructive knowledge on their part that the law forbade any one to treat the sick without having a valid unrevoked certificate of license from the board of medical examiners, it would seem probable that they occupied a position not differing in the law from that occupied by any person not a member of the patient's family who assisted in such treatment. However, while evidence should have been admitted touching the complicity of several of the witnesses with the defendant in the commission of the offense, and in such event the jury properly instructed regarding such evidence, because of the fact that the remaining evidence in the case was so strong that in the absence of any contradictory evidence, without a violation of their oaths, the jury could not do otherwise than find the defendant guilty, his appeal in that regard must be considered as though such errors had not occurred. Moreover, whether or not he received any consideration in compensation for his services as a physician was of no consequence, so far as establishing the violation of the terms of the penal statute was concerned.

On a judgment of conviction being affirmed, the defendant petitioned to have the cause heard and determined by the Supreme Court of California. The latter court, in denying the petition, says that it neither approves nor disapproves the conclusion of the district court of appeal that under the circumstances outlined in the opinion the members of the patient's family would be accomplices, if they had knowledge of the fact that the defendant did not have a license to practice medicine. The supreme court does not deem it necessary to express an opinion on that question at this time.

Joint Liability of Surgeons in Sponge Case—Evidence

(Spears et al. v. McKinnon (Ark.), 270 S. W. R 524)

The Supreme Court of Arkansas says that the gist of the complaint was that after an operation for ectopic pregnancy, performed on plaintiff McKinnon at a hospital, the defendants, who were the operating surgeon and his assistant, left in the abdominal cavity a sponge or gauze which dropped into the culdesac, where it began to rot the tissue and membranes until it found its way to a point about 5 inches above the anus, where it sloughed into and out through the rectum nine months after the operation. The sufficiency of the evidence to sustain the verdict was challenged on several grounds, but, in giving the strongest probative force to the testimony of the plaintiff, all reasonable possibilities must be taken into account, and when that was done the evidence was sufficient to support the verdict in her favor.

None of the witnesses remembered having made a personal examination of the grade or size of the mesh of the gauze used in the operation, and while there was some difference between that which passed from the plaintiff and that generally used in the hospital, it might be that on the occasion of this operation the hospital had run out of the kind it generally used and procured and used the kind that passed from the plaintiff. From the circumstances in the case the jury might have so inferred. As the gauze passed out of an abscess which emitted a large quantity of pus, it could not be said, as a physical fact, that the blood stains would have remained on the gauze during its passage through rotting, sloughing tissue from the abdomen into the rectum. It was contended that the gauze would have traveled the route of least resistance, which would have been through the wall of the vagina instead of through the wall of the rectum; but, as the court interprets the testimony of the physicians, they all admitted that the route of the passage of the gauze from the abdomen to the rectum was a possible way but hardly a probable route. Before the judgment and verdict for the plaintiff could be set aside on this ground, the undisputed testimony would have to show that the route of elimination through the wall of the rectum was an impossible route.

This court cannot agree with the contention that because one of the defendants was assisting the other and was not instructed by the latter to search the abdomen for sponges after the operation, he was exempt from liability if gauzes were found in the abdomen. The record revealed that the assistant's part in the operation was to insert and withdraw the sponges. If through carelessness or negligence he failed to withdraw any of them, he could not escape liability on the ground that he was an assistant. Such a rule would have the effect of acquitting one of civil liability growing out of his own negligence.

Again, it was the contention of the defendants that no liability rested on them as physicians and surgeons on account of sponges or gauzes being left in the abdomen of the plaintiff, because the duty of counting them before and after the operation was imposed on the attendant nurse who was in the employ of the hospital where the operation was performed. In other words, that it was a rule or custom of the hospital and among physicians for the attendant nurse to ascertain by count whether any sponges or gauzes had been left in the body of the patient, which count entirely relieved operating surgeons from such responsibility, and consequently from liability growing out of a failure to remove sponges and gauze from the openings or cavities in the body. But there was no error in a refusal of the trial court to give requested instructions which expressed this idea. Nor was error committed in excluding testimony offered by the defendants tending to establish a rule or custom of the hospital or of physicians making the count by the attending nurse of sponges conclusive evidence that all of them used in the operation had been accounted for and that none of them had been left in the wound or body of the patient.

The jury found for the plaintiff the sum of $3,500 against each of the defendants. This action was against them jointly to recover damages against them as tort-feasors. There was only one operation and one damage. Both of the defendants participated in it and, according to the verdict, both were liable. Under the testimony they were liable as joint tort-feasors, if at all, and the verdict must be construed as a finding of joint and not several liability. The only way that this could be done was to construe the verdict as a joint finding against the defendants for $3,500, and the trial court should have so interpreted the verdict and rendered a joint judgment against the defendants for $3,500; and a judgment for $3,500, instead of $7,000, is here rendered against them.

COMING MEETINGS

American Pharmacological Society, Cleveland, Dec. 28-31. Dr. E. D Brown, University of Minnesota, Minneapolis, Minn, Secretary.
American Physiological Society, Cleveland, Dec 29-31. Dr. W. J. Meek, Science Hall, Madison, Wis, Secretary.
American Society of Biological Chemistry, Cleveland, Dec. 28-30. Dr. D W. Wilson, University of Pennsylvania School of Medicine, Philadelphia, Secretary
American Society for Experimental Pathology, Cleveland, Dec. 28-30 Dr. E B Krumbhaar, Philadelphia General Hospital, Philadelphia, Sec'y.
District of Columbia, Medical Society of, Washington, D. C, Dec. 2 Dr C. B Conklin, 500 Medical Science Bldg, Washington, D. C, Sec'y
Federation of American Societies for Experimental Biology, Cleveland, Dec 29-31. Dr. Walter J Meek, Science Hall, Madison, Wis, Sec'y
Philippine Islands Medical Association, Manila, Dec. 16-19. Dr. Isabelo Concepcion, College of Medicine and Surgery, Manila, Secretary
Porto Rico, Medical Association of, Coamo, Dec. 14-15. Dr. R. M. Suarez, Box 314, Santurce, Secretary.
Radiological Society of North America, Cleveland, Dec. 7-11. Dr. Robert J. May, St Luke's Hospital, Cleveland, Secretary.
Society of American Bacteriologists, Madison, Wis, Dec. 29-31. Dr. James M Sherman, Cornell University, Ithaca, N. Y., Secretary.
Southern Medical Association, Dallas, Texas, November 9-12 Mr. C P. Loranz, Empire Bldg, Birmingham, Ala, Secretary.
Southern Surgical Association, Louisville, Ky., Dec. 15-17. Dr. Hubert A. Royster, 423 LaFayette Street, Raleigh, N. C, Secretary.
Western Surgical Association, Wichita, Kan, Dec 18-19 Dr. Harry P. Ritchie, Lowry Building, St. Paul, Minn., Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal for a period of three days. No foreign journals are available prior to 1920, nor domestic prior to 1923. Periodicals published by the American Medical Association are not available for lending, but may be supplied on order. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested).

Titles marked with an asterisk (*) are abstracted below.

Chemical Composition of Spinal Fluid; Diagnostic Value. H. B. Wilcox, J. D. Lyttle and J. A. Hearn, New York.—p. 513.
*Gastric Digestion in New-Born Infants. C. Griswold and A. T. Shohl, New Haven, Conn.—p. 541.
Importance of Considering Body Mechanics of Children. L. P. Sutton, New York.—p. 550.

Caloric Bases of Milk Mixtures.—The constitution of a great number of the milk mixtures commonly used in infant feeding is expressed by Powers in terms of the percentage of each energy-producing nutrient in the total energy value of the food as fed. This method of food evaluation has been the means of extricating these heterogeneous mixtures from a maze of quantitative relationships which are metabolically meaningless, and has made them available for comparative study on a significant basis in terms of the standard unit of nutritional currency—the calory—and without regard to water content. In this simple way, a host of apparently dissimilar milk mixtures have lost an artificial individuality and have been classified in seven distinctive groups. Here individual differences may be studied where they actually exist, that is, in mineral content, chemical and biologic values of protein, carbohydrate and fat, degree of denaturization and water content. Powers says that it is a striking fact that the vast majority of successful milk mixtures used in infant feeding are unlike human milk, which stands apart from all other foods; indeed the popular mixtures are as unlike human milk as they are unlike unmodified cow's milk.

Ketosis Accompanying Infections in Children.—A study was carried out by Tallerman on a series of children presenting ketosis associated with infection. A derangement of carbohydrate metabolism, as evidenced by abnormal blood sugar curves, has been noted. In the majority of the cases, this appeared to be associated with hepatic inadequacy, as shown by the levulose tolerance test. It is probable that hepatic function is temporarily deranged as a result of the toxemia of certain infections, and ketosis results from a failure to utilize carbohydrates. Another possibility is that the abnormal blood sugar curves, especially the initial high values, are due in part to overaction of the sympathetic nervous system associated with fever. A low food intake must be mentioned as a probable contributory factor.

Skin Temperatures in Normal Children.—Skin temperature readings in five normal children were made by Talbot et al. with the thermo-electric couple, so far as possible under uniform conditions. It was found that the temperature of the skin under clothing varied, that of the trunk being higher than the extremities and exposed parts of the body. The same group of children were exposed to room temperature, and when the clothing was removed, there was an immediate fall in the skin temperature. In some instances the skin temperature continued to fall definitely during a half hour without any change in rectal temperature, while in others there was very little, if any, fall after fifteen minutes. This seems to indicate that the skin as an organ has some power of regulating the rate in which the heat is transported to it, and is able to prevent heat loss just as it is able to accelerate heat loss by perspiration.

Skin Temperatures and Basal Metabolism During Fasting.—Talbot et al. found that during fasting, the rate of heat production in the body, as measured in the child cot chamber, usually diminishes. It fell more in a fourteen day fast than in an eight day fast. The skin temperature became lower during the fast, and, in general, presented a curve similar to that of the basal metabolism; the longer the fast the greater the fall in the skin temperature of these patients. The pulse rate was usually lowered, and the blood pressure sometimes definitely lowered. This is associated with a tendency for the skin to become pale or slightly cyanotic if not well covered with clothing or blankets.

Blood Chemistry of New-Born.—Comparative data on the blood chemistry of new-born infants (twenty-three cases) on the first, third and fifth days are presented by Sherman et al. In so-called inanition fever there is a marked increase of blood urea nitrogen and amino-acids. There is marked acidosis, as shown by the marked decrease in carbon dioxid combining power. There is no decrease in the percentage water content of the blood, as measured by the total solids. These so-called inanition fevers apparently are not due to increased salt concentration of the blood.

Light as an Antirachitic Factor.—From the investigations made by Bloch and Faber and considerations thereon it appears that light and particularly ultraviolet rays have a stimulating effect on the organism, which chiefly benefits those functions that are depressed. The curative action of light on rickets and tetany can be explained by such a stimulating effect. It is certain, however, that cod liver oil has the same healing action on rickets and tetany as light has, although the former, in the quantities that can be given to children, acts more slowly and less surely than light. As this effect is not due to the vitamin A substance, there must be a stimulating factor in cod liver oil similar to that in ultraviolet light, in addition to the vitamin A substance. This proves that the nonspecific stimulating factor must be the ultraviolet rays. Evidently the hypothetic antirachitic vitamin does not exist.

Gastric Digestion in New-Born Infants.—Griswold and Shohl assert that the gastric contents of unfed new-born infants consist of gastric juice which contains free hydrochloric acid. The average p_H is 2.6. The buffer value is 9.4 c.c. The volume is 4.5 c.c. At 5 days of age, test meals removed in one hour show an average acidity of p_H 2.5, a buffer value of from 10 to 12 c.c. and a volume of 6.5 c.c. Similar values were obtained in the tenth day. The capacity for gastric digestion is greater in new-born infants than later in infancy. Gastric digestion of 50 c.c. of partly skimmed cow's milk is practically complete in one hour. It would seem logical to feed new-born infants a more concentrated and a more alkaline food.

Penetration of Fruits and Vegetables by Bacteria.—The experiments described by Mills, Bartlett and Kessel bear directly on the question as to whether any uncooked vegetable or fruit is safe to eat, and under what conditions. It is stated that normal uninjured fruits and vegetables do not contain living bacteria within their tissues. Finely divided particulate matter, such as carbon, corresponding in size to bacteria, protozoan cysts and helminth ova, does not penetrate the stem-end of fresh vegetables to any appreciable extent. Bacteria do not penetrate the unbroken skin of fruits and vegetables kept under market conditions. Bacteria, pathogenic to man, may gain entrance to fruits and vegetables through injured and decayed portions, where they may spread to a very limited extent, and may remain alive for from seven to forty-two days. They may also contaminate the cut-end of vegetables and remain viable for a similar length of time. It is, therefore, advisable to remove such portions before attempting sterilization. Pathogenic bacteria may persist on the surface of fruits and vegetables kept under moist conditions for fifteen days or more. The gradual loss of moisture through the covering of fruits and vegetables would tend to keep them viable longer than would be possible on perfectly dry surfaces. When such foodstuffs are freshened with water, the viability would be influenced by the saprophytic flora, normal to such an environment. Chlorination freed the surface of vegetable matter from pathogenic bacteria in every instance, but was not effective against cysts or ova. Dipping fruits and vegetables for ten seconds into boiling water or water which remains above 80 C. during the immersion, is the only method thus far discovered which will uniformly kill all pathogenic bacteria, protozoan cysts and helminth eggs which might be found contaminating such food products, and render them safe for human consumption in an uncooked condition.

Hemolytic Proteus Bacillus in Bone Marrow in Pernicious Anemia.—A marrow smear was made by Kline at necropsy of a case of severe anemia having all the clinical manifestations of pernicious anemia, forty-six hours post mortem, and found to contain, in addition to the usual cytologic picture, a large number of proteus bacilli. A culture was obtained after charring one end of a rib in the free flame by expressing through this end a small amount of marrow. A few loopfuls of this material were shaken up in 2 c.c. of broth and the suspension streaked on Endo and blood agar plates. The next day hundreds of colonies were noted, apparently a pure culture of proteus bacillus. This organism grows well on ordinary mediums, has a fairly characteristic sugar reaction and unusually great hemolytic power. The blood picture was followed in eighteen inoculated animals, smears showing the appearance in the circulation of a moderate number of nucleated red blood cells, usually within forty-eight hours. Megaloblasts, also in moderate number, were occasionally observed. Animals, inoculated with repeated, increasing doses of the organism, over a period of a few weeks, developed a siderosis, more marked in the spleen and bone marrow, moderate in the liver. A hyperplastic bone marrow was found in the majority of the inoculated animals.

Proteus Culture.—The hemotoxin of a culture of *Proteus*, isolated from human bone marrow, was studied by Ecker and Brittingham. The toxin rapidly hemolyzed human, sheep, dog, cat, guinea-pig and rat erythrocytes. The production of *Proteus* hemotoxin varied greatly with the strain employed. The lytic principle was independent of the life of the organism. The organisms were killed by etherization. The cultures remained toxic after cell death. The lytic principle was retained in the filtrate of cultures passed through a Berkefeld candle. The hemotoxin was thermolabile. Even as low a temperature as 37 C. weakened it. At 45 C. its power was greatly reduced and at 55 C. it was completely destroyed. Ultraviolet light greatly retarded its power, depending on distance and length of exposure. Normal rabbit serums, if given sufficient time to act on the toxin, prior to the addition of the cells, will protect. Antihemotoxic (rabbit) serums, however, demonstrated a definite neutralizing power, if the serum and toxin were first mixed and the cells then added to them. Under similar conditions normal rabbit serums failed to protect. These antihemotoxic serums did not protect against the action of tetanolysin.

Scarlet Fever Spread by Ice Cream.—An epidemic of scarlet fever occurred in Flint, Mich., during July and August, 1924. A rapidly developing epidemic in hot weather, when scarlet fever is out of season, immediately suggested dissemination through some food product. The results of detailed investigations confirmed these suspicions, and definitely fixed the responsibility for the epidemic on an ice cream maker who continued working while he was clinically a scarlet fever patient. He made all of the ice cream sold by his company over the week end of July 26, a pleasant, warm Saturday and Sunday, which invited ice cream consumption. Of the 116 patients, sixty-two, or 53.45 per cent., were attacked within three days of this Sunday, and an additional thirty-six, or 31.03 per cent., during the following week. Milk supplies were found to have no relation to the outbreak.

Adiposity as Cause of Diabetes Mellitus.—The predominant effect of adiposity as a predisposing cause of diabetes is indicated by the figures quoted by Anders and Jameson. They believe that the phenomenal rise in the diabetes death rate and incidence among women in recent years is not due solely to their greater and more general adiposity.

Operation for Cerebral Tumors.—Elsberg suggests that instead of the major operative procedure used in these cases the following method be adopted as a regular procedure: An incision is made through the scalp under local anesthesia, in a location and direction that it may form part of the line of incision for the outlining of an osteoplastic flap, if that be later required. Through this primary short incision, a button of bone is removed with the trephine and a small incision, sufficient to permit the passage of a blunt brain puncture needle, is made in the dura. If no tumor is found directly under the opening in the dura, the subdural space is carefully explored in various directions with a broad, flat probe made of German silver and bent so that it can be passed underneath the dura. For this purpose, the blunt cannula devised for puncture of the corpus callosum can be used. If a distinct, firm resistance is felt by this subdural exploration—as would occur in the presence of a meningeal tumor—then the surgeon at once proceeds to anesthetize a large area to divide the scalp and to make a large osteoplastic bone flap. If no resistance is met with, the brain itself is punctured in several directions with a blunt ventricular puncture needle. If a cavity which contains the typical yellow fluid which occurs in a gliomatous cyst is entered, the fluid is emptied by aspiration, air is injected in order to obtain a roentgenogram of the cyst cavity, and the small incision in the scalp is then closed by suture and the patient sent to the roentgen-ray room. If, on the other hand, no resistance to the passage of the blunt needle is encountered (and this is often the case), the small plugs of brain tissue obtained by aspiration are carefully preserved in liquor formaldehydi for histologic examination. The direction in which the needle was passed and the depth to which it was inserted is carefully noted, and the operation is concluded for the time being. The further course of the procedure will depend on the results of the roentgen-ray and the laboratory examinations.

Infectious Jaundice in Philadelphia.—Two cases of infectious jaundice are reported by Sailer in each of which *Leptospira icterohemorrhagica* was found. It is believed that they are the first cases occurring spontaneously to be recognized in Philadelphia and its environs.

Tintometer for Analysis of Skin Color.—From a large number of plaques representing artists' reproductions of skin color from approximately 100 normal and pathologic subjects a tintometer has been constructed by Rowntree and Brown which apparently covers adequately the entire range of color variations encountered in human skin in health and disease. The tintometer consists of multiple color scales, each composed of ten plaques, representing progressive increase in color, each plaque of which has been analyzed qualitatively and quantitatively and expressed in three dimensions of hue, value and chroma. The normal range of variations has been first determined. A separate color scale has been constructed for jaundice, cyanosis, erythrosis and brown pigmentations, each resembling somewhat the Tallqvist scale employed in the clinical determination of hemoglobin. By means of these tintometers direct comparisons with the color of the skin are made.

Giardiasis.—Lyon and Swalm report and analyze the clinical data in twenty cases of giardiasis in adult patients. The disease is most often found clinically associated with disease of the gallbladder, bile ducts and duodenum. It is unusually resistant to all forms of treatment.

Tropical Sprue in Child.—A case of tropical sprue in a child, aged 6 years, including animal inoculation and isolation of *Monilia psilosis* both from the animal after necropsy had been done and from photomicrographs of the parasites as stained in tissue, is reported by Johnson and Breidigain together with the treatment given and the results.

Anemias of Pregnancy and Puerperium.—Seventeen cases are recorded by Larrabee of anemia occurring in pregnancy and the puerperium, all of severe grade. The blood picture may be that of secondary anemia, pernicious anemia, or aplastic anemia, or it may be atypical. All seven patients with the secondary blood picture recovered. Transfusion seems a question of expediency rather than necessity. Eight patients presented the pernicious blood picture. Of four not transfused, three died. Four recovered after transfusion. One patient with aplastic anemia died in spite of transfusion. In a highly typical case recovery ensued after splenectomy, repeated transfusions having been unsuccessful.

Nonfatal Carbon Monoxid Poisoning.—Alpers reports a case of proved carbon monoxid poisoning in which exposure was not sufficient to cause death, but in which the symptoms corresponded to the anatomic distribution of the lesions found in more severe cases. By means of this also a closer correlation of clinical and pathologic findings is possible, for a careful study of the former in a patient not succumbing to the gas will reveal where and to what extent certain brain areas are affected in the less severe cases, and whether these cases show a progressive degeneration in the areas affected. Aside from this, the progress of a patient who has been sufficiently injured by carbon monoxid to produce definite symptoms of brain destruction without causing death is in itself a matter of interest, particularly since very few such cases have been put on record.

Spleen Extract and Bone Marrow in Tuberculosis.—Twenty-three cases of active pulmonary tuberculosis are reported by Dunham in which this medication was employed; two showed no improvement in the blood picture; three were slightly improved; seven moderately improved and eleven were markedly improved, making a total of twenty-one cases, or 91 per cent. improved. Spleen extract and bone marrow will definitely increase the production of erythrocytes and hemoglobin.

Infecting Organism in Pyelitis of New-Born.—The infecting organisms in Graham's series were *Staphylococcus aureus*, a nonhemolytic streptococcus and *B. coli*, each in two cases. The time of onset suggests an invasion by the bacteria at the time of birth in most instances. One case suggests a congenital infection. Leukocyte counts ranged from 11,000 to 16,000. Blood cultures were negative. These patients responded to alkalis and large quantities of water.

Neutral Red Test of Gastric Function.—Piersol, Bockus and Bank assert that neutral red can be looked on only as an imperfect test for gastric function, since it furnishes no information as to the motor power of the stomach.

Eosinophilia with Splenomegaly.—A case of extreme eosinophilia is described by Bass occurring in a girl, aged 6 years. During the two and a half months in which the child was under observation she showed a moderately enlarged spleen; slight general adenopathy; leukocytosis varying between 14,800 and 25,600; eosinophilic polymorphonuclear cells varying between 37 and 64 per cent., and eosinophilic myelocytes present up to 6.3 per cent. Four somewhat similar cases in adults are reported from the literature, two with necropsy. The relation of this condition to leukemia is discussed.

Recklinghausen's Disease.—The study of four cases by Schneiderman failed to reveal any endocrine dysfunction in the etiology of Recklinghausen's disease. He supports, however, the theory of an embryonic disturbance in the ectoderm as the cause of neurofibromatosis. Furthermore, Recklinghausen's disease has a distinct hereditary tendency in the great majority of cases, if not in all. Many patients with this anomaly deny the presence of cutaneous tumors in other members of the family because some other member happens to have the so-called abortive type of Recklinghausen's disease, having only one or two small tumors, and a predominance of nervous symptoms. These patients are not only unrecognized by the family, but by the physician as well. In the light of experimental revelations, it is more probable that the anomalies represented by Recklinghausen's disease are due to a physical, chemical or nutritional disturbance in the environment of the developing embryo at the stage when the ectoderm is forming the nervous system and are transmitted to the following generations according to the mendelian law.

History of Syphilis.—Capper is convinced that syphilis did not exist in the Old World before 1493, except, perhaps, in Eastern Asia, and particularly along the Pacific coast. Syphilis did exist in America before Columbus arrived there. The origin of syphilis in America could perhaps be traced by way of the Bering sea from Japan or from any other part of Eastern Asia. Syphilis was imported into Europe from the New World by the crew of Columbus in 1493. The epidemic that was raging in Europe following the return of Columbus was due either to some disease or diseases other than syphilis or to syphilis plus the other diseases, syphilis, however, playing a minor rôle in the ravages resulting from the epidemic.

Sodium Chlorid in Treatment of Bromism.—Stevenson states that sodium chlorid given in appreciable amounts intravenously or by mouth hastens the excretion of bromid from the body. This action is not due to dieresis, but to the chlorid replacing bromid by mass action. If given by mouth, sodium chlorid may well be administered in phenol salicylate coated tablets or pills, 60 grains once a day. The bromodermas rapidly regress under this treatment. Nephritis is a contraindication to this therapy.

Typhoid Infections of Kidney.—Two cases of pyonephrosis due to *B. typhosus* are reported by Patch, and eight cases from the literature are reviewed. In both of Patch's cases, the disease was unilateral. There is nothing to indicate the exact time of onset in either case. In the first case, there was no history of an attack of typhoid. The woman may have been a typhoid carrier, in the gallbladder or in the intestine. Infection in the kidney may at any time have been precipitated by any localizing incident in the kidney. In the second case, there was nothing in the case history to indicate when the renal infection began. It may have been contracted in either one of two attacks of typhoid in 1911 and 1920. Masses of calculi were found scattered in the calices of the first case. Patch believes that typhoid infections of the kidney are more common than has been generally believed. They must be regarded as of hematogenous origin.

End-Results in Renal Infections.—Quinby states that a kidney is capable of withstanding a very considerable amount of infection without loss of all its factor of safety in renal tissue. The course of infections of the kidney is usually of long duration, symptoms of a general sort being often slight and to be found only on careful investigation, intermingled by exacerbations of greater or less severity, which attacks are not rarely erroneously attributed to "grip," "lumbago" or "biliousness." Localizing symptoms, either of kidney or of bladder, are frequently absent, especially in the earlier months of the infection and between the acute attacks. The possibility of restoring a kidney to a state of healthy activity and of preventing continuance of renal damage should be better appreciated by both the family physician and the surgeon. In many an instance there is abundant opportunity for a much earlier diagnosis than is usually made. Institution of treatment at a time preceding that at which the kidney has become badly crippled in its structure and overwhelmed by infection will avoid many nephrectomies. For this purpose the method of frequent renal lavage through the inlying ureteral catheter, which at the same time relieves stasis, is of great benefit.

Blood Transfusion in Genito-Urinary Surgery.—Boyd's experience with transfusions of blood lead him to advocate very strongly their use in genito-urinary surgery. Not only are they of value for the purpose of saving life in an extreme emergency, but also to assist in carrying patients safely through operations by giving them needed blood before operation, and to mitigate the symptoms due to a loss of blood and shock.

Incision for Tumor of Kidney.—The transverse incision combined with a vertical midline incision is regarded by Cabot as the method of election for attack on tumor of the kidney. The incision should be started well back in the loin near the anterior border of the erector group. It should be planned to pass not far from the lower border of the twelfth rib, inclining slightly downward until it reaches the midline of the body in the region of the umbilicus. The course of this incision does not traverse any nerve trunks of importance and will not result in paralysis of the rectus or of any important amount of the oblique muscles. It is then met by an incision in the midline carried upward to any necessary extent. This can do no damage to nerve supply or to any other important structure. It allows the raising of a triangular flap which gives direct access to all of the structures of the upper quadrant. Through this incision the costal margin may be lifted as freely as is ordinarily necessary. The peritoneum is lifted from the posterior wall, carrying with it the colon and its mesentery, which may be turned inward as far as the midline. This flap of peritoneum with its intestinal and mesenteric content has the effect of keeping the other intestines out of the way and gives a wholly satisfactory view of the field.

Bladder Neoplasms.—MacKenzie analyzes 228 cases, of which 118 were malignant. There were thirty-nine papillomas, seventy papillary carcinomas, eight carcinomas and one sarcoma. Hematuria was the chief complaint in 75 per cent. of cases and usually the cause for seeking relief. Frequency was the chief complaint in 25 per cent. of cases, and was an associated complaint in from 40 to 60 per cent. Dysuria was the chief complaint in 10 per cent. of cases; and an associated symptom in from 15 to 20 per cent.

Cutaneous Lesions in Leprosy.—Rodriguez asserts that not all the cutaneous lesions of leprosy are anesthetic. Sixteen per cent. of infiltrations do not show any disturbance of the cutaneous senses. The character of the anesthesia depends on whether it is located in a macule, an infiltration, or a skin free from lesions. In macules there is, as a rule, early loss of epicritic sensibility; in nodules and infiltrations the anesthesia is very variable; and in a skin free from eruptions a partial dissociation of the syringomyelic type is effected. These differences suggest the possibility that the cutaneous nerves may be involved in various ways, depending on the character of the overlying skin lesion. The anesthesia shows definite improvement under ethyl ester treatment although, as is to be expected, it is not as well marked as the improvement in the cutaneous lesions. Although the absence of anesthesia does not exclude leprosy, the touchstone in doubtful cases, from the clinical standpoint, is its presence in some cutaneous lesion or in some skin area. The final confirmation of the diagnosis is the presence of the specific organism in the lesions or on the nasal septum.

Fresh Pancreas in Treatment of Diabetes.—The data obtained by Carrasco-Formiguera in one case studied carefully show that, in a patient who had never before received insulin and was on a constant diet, raw fresh pancreas, administered in the form advised by Hollins, and even with an additional dose at dinner time, thoroughly failed to diminish a glycosuria (it was rather increased), which was very quickly reduced to traces on the next day by a very moderate dose of insulin, and completely disappeared on the fifth day of insulin treatment. All duly controlled experiments, recent as well as ancient, show that the oral administration of raw fresh pancreas has no beneficial immediate effect on glycosuria in diabetic patients. Thus far, there are no known facts supporting the very faint theoretic possibility that this form of pancrotherapy might have any kind of delayed beneficial influence in the treatment of diabetes.

Death Follows Passing of Stomach Tube.—Allan relates the case of a man who complained of pains in the epigastrium and behind the shoulder coming on soon after the taking of food and accompanied by flatulence, in addition to much shortness of breath on exertion. Every effort to find a cause for this condition proved futile. Finally, a further test meal was given to determine whether there was any alteration in the gastric acidity. When the tube was passed to remove the stomach contents, the patient had an attack of coughing and a dram or two of fluid was ejected from the tube. He suddenly became very pallid and the tube was immediately withdrawn, but he died almost instantaneously. There was no external bleeding. The only explanation that could be offered was that the patient had had an attack of syncope or angina set up reflexly by the passing of the tube. Necropsy was not permitted.

Recurrent Hair Ball of Stomach.—Harris relates the case of a woman from whose stomach five hair balls had been removed on five separate occasions, in 1911, 1920, 1922, 1923 and 1924. Apart from her hair-eating habits, this woman was quite normal mentally. She seems to have suffered no permanent ill effects from her repeated operations.

Splenic Anemia with Splenectomy.—Kingston's patient, aged 5½ years, had had twenty-two attacks of melena, and six of hematemesis, nearly all being severe enough to blanch the child and keep her almost constantly in bed. She was tapped eleven times at weekly intervals, from 4 to 7 pints of clear straw-colored fluid being removed on each occasion. The spleen was removed. It weighed 1 pound. Five months after the operation the child was much stronger, had gained 14 pounds in weight and was much improved in general health.

Death from Hemorrhage in Scarlet Fever.—The hemorrhage in Calder's case occurred on the thirty-fourth day of the disease, from the external jugular, which ruptured and the child died. Incident to a very severe sore throat a great deal of sloughing resulted exposing the vein and the carotid artery to view.

Fundus Oculi in Kala-Azar.—Observations made by Ling on the fundus of five cases of kala-azar suggest a definite relationship between the occurrence of retinal hemorrhages and the low degree of secondary anemia in this disease. Of four patients with retinal hemorrhages two were observed long enough to show complete absorption. In one case complete absorption took fully four months. In a second case it took about five months. The gradual absorption of hemorrhage goes hand in hand with the improvement of the anemia.

Hongkong Foot.—Hongkong foot is an infectious disease of mycotic origin found in North, Central and South China. In Peking, during the summer months, it is commonly seen and occurs with equal frequency among Chinese and foreigners. The initial symptom is a persistent, intolerable itching of the hollow of the sole, or of the toes and the interdigital spaces. This symptom does not disappear with the development of cutaneous lesions. These manifest themselves in one of two forms, or more frequently in a combination of the two. The first and more common consists of small, deep-seated, epidermal vesicles, which contain a clear serum. These are usually situated on the inner margin of the hollow of the sole; on or between the toes, especially the third, fourth and fifth digits at their proximal extremities; and on the plantar surface near the toes. The great and second toes are conspiculously avoided by the infection. With evolution of the vesicular lesions their coverings become thinner and usually rupture, discharging a sticky, serous fluid, after which rapid desiccation and exfoliation ensues. New lesions continue to form throughout the active period of the disease. With the onset of cold weather the process has a tendency to subside. Not uncommonly through traumatism and lack of care, secondary pyogenic infection complicates the picture. The vesicular type is found on the hands, concomitant with or independent of, similar lesions of the feet. Hongkong foot is not peculiar to China. Under the name of eczematoid dermatitis of the extremities, ringworm of the hands and feet, Dhobie itch of the toes, epidermophytosis, etc., the disease has been described in Europe and America (where it is quite common) and in tropical countries.

Operation for Superficial Varicose Veins.—The operation employed by Price is as follows: the patient is anesthetized and the leg allowed to hang over the table, thereby distending the veins, or a tourniquet may be applied. The surgeon with heavy silk threaded in a curved skin needle, passes a number of sutures through the skin, under the vein, and out through the skin at a point on the opposite side of the vein from the point of entrance. These sutures are placed from one-fourth to one-half inch apart and as many may be used as desired. The ends of the sutures are caught with forceps and when all are in place they are tied tightly, usually from above downward, in bowknots on top of the skin. Occasionally, the needle punctures a vein but this accident makes no difference, for other sutures on each side of the puncture will close the vein. After all sutures are tied the leg is wrapped loosely in a sterile cloth, secured with safety pins. A bandage will cause great pain. The patient is kept in bed. On the seventh day after operation the sutures will be found to have become loose. They are untied and tied again tightly. This is somewhat painful but not excessively so. On the fourteenth day the sutures are removed and the patient is allowed out of bed. The vein will have been obliterated.

Toxicity of Carbon Tetrachlorid.—Of forty-nine cats which were given 0.5 c.c. of carbon tetrachlorid per kilogram, only four survived; of twenty-seven which were given 0.25 c.c. per kilogram, three survived; and of twelve given 4 c.c. per kilogram, all died. Ten of the twelve which were given 4 c.c. vomited within about half an hour. Altogether, eight cats out of the eighty-seven died on the day following treatment, thirty on the second day, twenty-three on the third day, seven on the fouth day, and four on the fifth day; five were killed when in a dying condition, and seven survived. Chandler and Chopra cut sections of the liver and kidney of all these cats, and sections of the spleen, suprarenal, and intestinal wall of many of them. No significant changes were found in the spleen, and in only a few instances was found the necrosis reported by Phelps and Hu. The intestinal wall in some instances showed the villi severely congested and occasionally denuded of the epithelium. The really important lesions were found in the liver and kidneys. The liver in every instance showed the central necrosis which is so characteristic of carbon tetrachlorid, and usually a very extensive fatty degeneration was present. From 25 to almost 100 per cent. of the liver tissue was damaged, even in cats which received only 0.25 c.c. per kilogram. Most remarkable, however, were the lesions found in the kidneys; in many, if not in most, instances, Chandler and Chopra believe that the renal rather than the hepatic damage was the actual cause of death and that the susceptibility of this organ in cats accounts for the much greater toxicity of carbon tetrachlorid for cats than for dogs. The convoluted tubules showed extensive fatty degeneration and frequent necrosis, but the collecting tubules were as a rule little affected; there was often desquamation—sometimes very extensive—of Henle's loops. The Bowman capsules were frequently infiltrated with blood, and the glomerular endothelium was swollen and the vessels dilated. In every instance in which it was possible to obtain urine at necropsy there was albumin present, often in great quantity, and there was frequent evidence of blood.

Air Embolism.—A few small bubbles of air injected into a vein at a slow rate are apparently harmless, and the same also appears to apply to a small continuous column of air, judging from the results of D'Abreu's experiments. In one experiment, 24 ounces of air was sufficient to produce the death of a bull weighing approximately 500 pounds, so that a man weighing from 140 to 154 pounds would proportionately take about 6 or 7 ounces as the lethal dose.

Action of Disinfectants on Microbes.—The interesting point in the experiment made by Grosh is that the microbes seem to be killed by a certain dilution of the disinfectant up to the first five hours of contact but divide and multiply when placed in fresh medium after twenty-four hours. It is possible that most of the microbes are killed by the disinfectant effect of the chemicals used; others, more resistant, get attenuated and lose the power of division and multiplication for a certain period, during which time they show no growth even when placed in a fresh medium. This period may be called a period of shock to the bacteria. Later, as the time of contact increases, this condition of shock passes off, and they adapt themselves to the environment and begin to multiply again, and on inoculation into new medium show abundant growth.

Internal Strangulation by Spermatic Cord.—In Chetti's case, the abdomen was distended like a drum and tender all over. The pulse rate was 90 per minute, the respiration 30 and the temperature was normal. The patient, on examination, had just commenced to vomit. Although nothing pointed to any trouble in the scrotum, this was examined. The skin of the scrotum was loose. The testis with its sac was felt to be tense, but no tenderness was elicited. There was no evidence of bulging of the inguinal canal or enlargement of the external ring. The usual signs of an ordinary inguinal strangulated hernia were absent. There was absolutely no pain over the ring. An incision was made over the external ring both above and below. A small sac was exposed and incised, and a small quantity of brownish-red fluid was emptied out. The testicular substance was a dark purple and was found to be tightly gripped at the external ring above the globus major. An attempt was made to pull the testis downward without success. The external ring was gently and gradually incised; when it was sufficiently cut, the testis went into the abdomen with a snap. There was nothing else in the sac or in the inguinal canal. An attempt was made to search for the lost testis inside the abdomen through the internal ring, but it failed. The usual operation for hernia was performed and the patient was put back to bed. Chetti emphasizes the importance of careful examination of the scrotum in all cases of acute intestinal obstruction.

*The Oculocardiac Reflex. Fribourg-Blanc and Hyvert.—p. 512.
*Mitral Stenosis with Angina Pectoris Symptoms. L. Telia.—p. 531.

Intermittent Claudication in an Old Syphilitic.—Letulle and his co-workers observed a case of intermittent claudication in a man, aged 72, with syphilis of over fifty years' standing.

Necropsy showed that the lameness which had started two years before, was due to arteritis obliterans affecting the abdominal aorta, both iliac arteries and particularly the tibial arteries. While in diabetes the inflammatory lesions are localized in the tunica intima, in this case the middle and outer coats were chiefly involved. Infiltration of the arterial walls with cholesterol was less manifest than in diabetes.

Electrocardiograph Record of the Oculocardiac Reflex.—Fribourg-Blanc and Hyvert's research was made on 174 patients with nervous or mental disease. Compression of the eyeballs not only changed the heart rhythm, but also increased the oscillometric index in 97 per cent. of the cases. The rise in this index did not parallel the retarding or acceleration of the pulse. Increase of the systolic tension as well as reduction of the diastolic tension seemed to be connected with the rise of the oscillometric index. Electrocardiographic curves taken during the compression of the eyeball indicated an increased amplitude of intra-ocular tension in persons without functional disturbances of the myocardium. This corresponded to an exaggerated excitability of the myocardium with stronger contractions of the ventricle. Rise of the oscillometric index revealed peripheral vasoconstriction of sympathicotonic origin. Oscillometric curves, preceding and following the compression of the eyeball, demonstrate the condition of the arterial circulation in the subject.

Syndrome of Angina Pectoris with Mitral Stenosis.—Telia reports three cases which explain the mechanical origin of the pain in cases of mitral stenosis. His patients were between 17 and 27. Necropsy findings in one case showed that the attacks were traceable to the left coronary artery compressed between the left auricle and the pulmonary artery. The special precordial pain with mitral stenosis—the aortalgia—is explained by compression of the aorta and aortic plexus by the enlarged left auricle. Bloodletting (from 300 to 500 gm.) is suggested to relieve the attacks.

Vaccination of Very Young Subjects Against Diphtheria.—Zoeller states that the results of his experimental vaccination against diphtheria, made during several recent months, seemed to confirm the clinical findings. Two injections of 0.5 c.c. of anatoxin, with a fifteen days' interval, were given to two new-born guinea-pigs, and 1 c.c. to three older guinea-pigs. All these animals were given a lethal dose of diphtheria toxin three months afterward. None of them died. A characteristic local reaction was manifest in the younger, but was absent in the older guinea-pigs, thus proving the greater resistance to antidiphtheria vaccination in the very young.

Cholesterol in the Bile in Gallstone Cases.—Chiray and his co-workers' conclusions are based on thirty-seven observations. In healthy subjects the amount of soluble cholesterol in the bile was not modified in visceral diseases, without changes of the liver, and not even in affections of the gallbladder, except cholelithiasis. The usual decrease of soluble cholesterol in the bile was not always present with gallstones. The fact may be explained by the two phases of the disease, the stage of formation of the gallstones, and the stage of mechanical and infectious complications. The alternation of these stages induces formation of concentric deposits on the gallstones, each layer corresponding to a lithogenetic stage. It is possible that the colloidal instability of the cholesterol is due to an insufficient secretion of biliary salts, and that the cholelithiasis is due rather to a disturbed liver secretion than to a primary affection of the biliary tract.

Injection of Graafian Follicle Liquid.—Brouha and Simonnet observed that an injection of an extract of the follicle fluid prolonged the estrual cycle in mature rats, but did not modify the periodicity. The extract had no apparent influence on gestation. No changes were manifest in the mammary gland. The castrated female rats seemed to be more responsive to the follicle extract than the immature females.

Cytodiagnosis in Colitis and Pyorrhea.—Classification of the cells in pus from the stools showed that ulcerative and other forms of colitis belong to the group of chronic bacillary dysentery. The cell findings in twelve cases of alveolar pyorrhea were identical with those from normal gums. This seems to indicate that pyorrhea is not an infectious disease, but is caused by invasion of the alveolar cavity, after separation of the gum, by bacteria usually present in the mouth. Alexeieff adds that pyorrhea—for the etiology of which 350 different theories have been advanced—seems to be merely an exaggerated physiologic leukocytorrhea.

Sensitiveness of Galleria to Trypanosomes.—Injection of trypanosomes did not affect the transformation cycle of *Galleria mellonella* larvae. The fecundated insects continued to lay their eggs after the injection. Mice died in two to four days after hypodermic injections of trypanosomes that had passed through the galleria.

Immunization of Galleria.—Chigasaki's experiments demonstrated that *Galleria mellonella* is easily immunized against Danysz' bacterium in each of its three metamorphosis stages. The acquired immunity of the caterpillar is transmitted to the chrysalis and the moth.

Formation and Rôle of Tonsil Capsule.—Argaud and Viéla's research on the embryo, the new-born, adults and elderly persons showed that the capsule of the tonsil develops from the pharyngeal epithelium. It not only protects the organ, but exerts a mechanical action on the expulsion of secretions.

Immunization Against Tetanus.—Ramon and Lafaille easily induced an active immunity against tetanus in guinea-pigs and rabbits by one or two injections of anatoxin, at a twenty day interval. The same results were obtained with an injection of anatoxin given after simultaneous injections of tetanus antiserum and anatoxin. Injection of tetanus anatoxin-antitoxin mixture did not confer immunity; it seemed to hamper the immunizing action of the anatoxin, injected afterward.

Rôle of Vagus in Sensitization to Protein Shock.—Garrelon and Santenoise's further experiments on ninety dogs confirmed their conclusion that sensitization to protein shock depends on the vagus and its action on the thyroid gland.

Albuminuria from Injection of White of Egg.—Garnier and Schulmann induced albuminuria in rabbits by injections of the white of egg. The renal lesions were analogous to those from injection of different poisons. The toxic element of the white of egg did not vary under heating as long as the temperature was below that of albumin coagulation.

Antiscorbutic Property of Preserved Orange Juice.—Vagliano fed one series of guinea-pigs on a scurvy ration and another on the same diet to which a syrup made from orange juice had been added. The syrup was prepared six months before with four parts of orange juice, two of sugar and one of water, heated to 120 C. for half an hour. While all the animals of the first series died from scurvy within twenty-five days, the other group remained perfectly healthy. Obviously neither the prolonged heating nor the age had affected the antiscorbutic property of the orange juice. The conservation of vitamin C may have been due to the action of the sugar, which also insures the conservation of the antiscorbutic property of condensed milk.

Radium Emanation has No Affinity for Cancer Tissue.—Ferroux and Lacassagne's experiments on five rats with implanted cancer indicated that radium emanation, injected by any route, is chiefly found in the eliminating organs. There was no evidence of any affinity of the emanation for cancer tissue.

Gain of Weight Under Organ Extracts from Fattened Animals.—The treatment was applied by Carnot and Terris in two cachectic women, aged 69 and 52, weighing, respectively, about 62 and 67 pounds. Aside from visceroptosis there were no grave lesions. Extract of liver from a fattened pig was injected in an oil vehicle. Twenty-six injections of the solution, corresponding to 0.18 gm. of a dry extract, induced in the older woman a gain of weight by about 8 pounds in thirty-six days. In the younger woman, still under treatment, ten similar injections were followed by a gain of 2 pounds in sixteen days.

Action of Radium Emanation on Tetanus Toxin.—Ferroux and Mutermilch's tests in mice revealed that the toxicity is completely destroyed in tetanus toxin by exposure to radium emanation. Further experiments demonstrated that the antigen property is destroyed simultaneously with the toxicity under the emanation. This contrasts with the well known fact that physical and chemical agents destroy the toxic elements of toxins first. Toxins thus transformed to toxoids or anatoxin retain their antigen property, and can therefore be utilized in experimental vaccination.

Absence of Bacteriophage in the New-Born.—Pierret and Bilouet examined the meconium of eight new-born infants up to 4 days old. No bacteriophage for Shiga's, colon or typhoid bacilli could be detected even in meconium rich in microorganisms. The bacteriophage content was excessive in the stool of an infant, aged 12 days. The fact may be explained by absence of bacterial growth in the first few days of life.

Improved Pasteurizing Apparatus.—Marmier describes a pasteurizer in which sterilization is performed automatically. No supervision of the apparatus is required.

Bedside Test for Urea in Blood.—The Augustes say that only one drop of the whole blood is needed. After xanthydrol precipitation by the usual technic, the reading is made the third minute. The test is accurate enough for ordinary purposes. The fluid is limpid or more or less turbid.

Common Feature of Golgi's Apparatus, the Cell Nucleus and the Mitochondria.—Hirschler emphasizes that these three are each enclosed in a membrane which is capable of reduction of osmic acid.

Fate of Typhus Virus in Bird Body.—Selivanoff inoculated lice, guinea-pigs and rabbits with brain from birds infected with typhus virus. The findings proved that the vitality and toxicity of the virus diminished during its sojourn in the bird's body. The serum from the infected birds did not contain antibodies.

Action of Atropin on Heart Block.—Meyer's research was on men and dogs injected intravenously with atropin. The dromotropic action of atropin on atrioventricular conductivity, during the stimulation phase, is due to its sympathicotropic action; it exerts besides a direct effect on His' bundle. In two cases with block of His' bundle, no improvement of the atrioventricular conduction was obtained with 1 mg. of epinephrin, while a marked influence was manifest with small doses of atropin. These findings suggest, he says, a more rational treatment of heart block.

Permeability of the Erythrocytes.—Blum and his co-workers found that under the action of carbon dioxid, acids penetrate into the erythrocytes, while bases pass from the erythrocytes into the plasma.

Action of Carbon Dioxid on Development of Hen's Eggs.—Rogalski noted that carbon dioxid injures hen's eggs and interferes with their development. The lesions are the more pronounced the longer the eggs remain in contact, and the higher the temperature of the eggs. The lesions are similar to those from roentgen rays or aging.

The Suprarenals in Epilepsy.—The necropsy findings in two cases of epilepsy showed reduction or absence of lipoid in the cortex of the suprarenal capsules. Popea and Eustatziu assume that the lipoid is utilized for neutralization of toxins produced by the excessive muscular contractions in the epileptic seizures. This would confirm anew the antitoxic action of the suprarenals.

Cholesterolemia in Epileptic Seizures.—Popea and Vicol observed during seizures a diminished cholesterol content of the blood in each of sixteen epileptics. The cholesterol may have been used up during the excessive functioning of the nervous and muscular systems or in destroying the toxins from the exaggerated muscular contractions. Since the seizures were frequent in these cases, the cholesterolemia persisted low in the intervals.

Protein Shock May Restore Vegetative Tonus to Normal.—Obregia and his co-workers induced protein shock, by milk injections, in forty insane patients. The vegetative tonus became normal when it had been previously augmented or diminished. It did not vary if it had been normal before. He queries whether to ascribe this fact to the functional activity of the cell protoplasm and the colloid balance of the body fluids or to assume that the improvement in the vegetative tonus had restored the colloid balance of cells and humors.

Action of Calcium Ion on Vegetative System in Man.—With small doses of calcium (from 0.1 to 1 gm.) injected intravenously, Popescu-Inotesti induced phenomena of sympathetic excitation, namely, tachycardia, hypertension, mydriasis, hyperglycemia or sometimes tachypnea. Injection of large doses (from 1.5 to 4 gm.) caused excitation of the parasympathetic, with bradycardia, miosis, bradypnea. The hypertension in this instance is due to a direct stimulation of the muscle fiber of the vascular wall.

Influence of Nervous System on Action of Toxic Substances.—Roger injected strychnin in frogs in stupor from the electric shock induced by a Leyden jar. Spasmodic muscular contractions did not appear until thirty-four minutes, and tetanic spasms only after one hour while in the controls this occurred in five and fourteen minutes. When an injection of veratrin was given after the sciatic nerve had been severed, the action of the poison on the gastrocnemius muscle on that side appeared later and was less pronounced than in the muscle of the other side. When the normal muscle has ceased to respond to even very strong excitation, the denervated muscle continued to contract for a few hours. Analogous phenomena were manifest after section of one half of the spinal cord; the muscles of the paralyzed side resisted the action of the poison longer. Obviously, the nervous system exerts a considerable attenuating influence on the action of toxic substances. This may be due to reduction of the sensibility of the muscle to the poison, or to the impeding of the passage of the latter from the blood into the tissues, entailed by the exclusion of the nerve.

Anatomic and Clinical Aspects of the Artery of the Sino-Auricular Node.—Géraudel gives an illustrated description of this artery, emphasizing the connection between functional changes in Keith and Flack's node and a disturbed blood supply. He believes that the artery of the sino-auricular node is a terminal artery, without anastomoses, analogous to arteries in the brain.

Catarrhal Jaundice Not An Infectious Disease.—The onset of the catarrhal jaundice in Marcou-Mutzner's seven cases resembled a colloidoclastic shock. The sudden appearance of fever, joint pains, urticaria, vomiting and asthenia coincided with an intense bile output in the stools. This was followed by bile pigments in the urine. He asserts that the phenomena can be ascribed neither to angiocholitis nor to retention of bile in the biliary ducts. An exaggerated insufficiency of assimilation of protein substances, under various intoxications, induces overproduction of bile in the liver as a defence reaction. Acute swelling of the liver, which occurred in these patients within a few hours, was evidently due to hypertrophy of the overworking hepatic cells. The treatment should aim to arrest the resorption of products of proteolysis; carbohydrates, lactic ferments, curdled milk or yoghurt may influence the intestinal fermentations. Vitamin deficiency should be avoided. Sodium sulphate in small doses in Vichy water seemed to have a favorable action in his experience.

Diet Treatment of Ulcer of the Stomach and Duodenum.—Jarotzky insists that milk should be suppressed in the cases of gastric hypersecretion. White of egg and unsalted butter, given separately, form his special diet for treatment of peptic ulcer. A raw white of egg, not whipped, is given without salt, alternating with fresh unsalted butter. During the eight or ten days of the course the use of water is prohibited. The patient keeps in bed for the time of the treatment. One white of egg in the morning and a tablespoonful (29 gm.) of butter in the afternoon are given the first day. The ration is daily increased by one white of egg and 20 gm. of butter, till ten whites and 180 gm. of butter are given per day. No other food or drug is allowed. The diet appeared more efficient than fasting after gastric hemorrhage. Relief of pain, subsiding of gastric contractions, allowing better chances for healing of the peptic ulcer, followed this diet treatment. Various cereals, vegetables and fruits, cooked in water without salt and passed through a sieve, are given after the eighth or tenth day. This treatment has been successfully applied in several Russian hospitals since 1910, and he says that it has been used in the United States, citing Altshuler and others.

*Research on Gastric Secretion. A. Ciminata.—p. 549.
*Recurring Tubal Pregnancy. E. Momigliano.—p. 792.

The Gastric Secretion.—Ciminata devotes 242 pages to his review of previous research on the secretory function of the stomach and his own experiments on dogs, thirteen with a Pawlow stomach pouch. There seems to be a direct connection, he says, between the water content of the food and the amount of gastric juice secreted. The secretion is most profuse with milk and meat, and it occurs earlier. Water alone stimulates secretion, but only for a short time. The acidity seems to depend on the rapidity of the secretion and not on the kind of food, but the peptic potency seems to be determined by the nature of the food—highest with bread, less with meat, and least with milk. The food always contains substances which stimulate secretion, but these substances are locked up in the food. They are released only by the gastric juice, so that gastric digestion requires that the secretion be already under way when the food reaches the stomach. This is usually provided by the psychic gastric secretion, aided further by water, which starts a brief secretion. These two factors release the secretion-inducing substances, and these continue with greater intensity the task of stimulating production of gastric juice. Without "appetite secretion" and without water, food, such as bread, which is not digested so readily as meat and milk, may lie even in the healthy stomach for hours without a trace of digestion. The more intense the psychic gastric secretion, the earlier and more completely the food will be digested. The acidity of the gastric contents depends on the degree of neutralization by mucus, and this in turn depends on the speed of the secretion. With bread, for instance, which has only a comparatively weak and slow secretogenous action, there is time for much mucus to form and thus neutralize the acid. The more rapid the digestion, the sooner the stomach evacuates its contents. There can be no gastric juice, he adds, when chlorin is lacking. The splitting of hydrochloric acid and hydrates seems to occur specifically in the secreting cells.

Recurring Tubal Pregnancy.—Momigliano analyzes sixteen cases of recurring tubal pregnancy operated on at the Rome clinic. One of the cases seemed to be a bilateral tubal pregnancy but the operation demonstrated tubal abortion of an older date on one side, probably several months before. In most cases, the first tubal abortion had caused no appreciable symptoms, or so vague as not to be recognized. In the 314 cases of extra-uterine pregnancy at the clinic since 1913, inflammatory processes or gynecologic operations had preceded it in 65.3 per cent. In 1.9 per cent. there was hypoplasia of the genital organs. No cause for the anomaly could be discovered in 32.4 per cent.

*Sign of Toxic Nature of Rheumatism. S. Libarona Brian.—p. 264.

Posttraumatic Heart Block.—A physician consulted on account of an attack of influenza had found the pulse of the man, aged 43, practically normal. A year later, after a fall from a horse, injuring the left side of the chest, he was unconscious for a day and a half, and there was much coughing, pain and blood stained expectoration for a time, with persisting dyspnea on exertion. Three months after the accident, symptoms of auricular fibrillation and heart block developed, and this condition has persisted for the four months to date.

Differential Diagnosis of Rheumatism.—Libarona Brian states that an infectious rheumatism can be distinguished from a chronic rheumatism of toxic origin by the absence of the exacerbation which the latter usually presents with a change to damp and cold weather and the improvement in dry and warm weather or environment. The rheumatic disturbances in gout are the only exception to the reliability of this barometric differential sign of toxic as distinguished from toxinic rheumatism. In toxic rheumatism the patients are always inclined to be chilly. He has treated a number of patients of the toxic rheumatism type with systematic alkaline injections, and he claims excellent results.

A Nervous Form of Malaria.—Alvarez relates that a man, aged 55, was brought to the hospital in a comatose condition. He had presented chills and fever for the preceding three weeks, of the tertian type. Then he suddenly lost the power of speaking and of moving his arms and legs. The paresis was accompanied by pronounced exaggeration of the tendon reflexes. There was also trismus, with incontinence of anus and bladder, and dilated pupils. A lumbar puncture was negative, but the blood showed *Plasmodium malariae*. The symptoms began to improve at once after the second injection of quinin. He left the hospital in a month apparently completely cured, but there was retrograde amnesia.

Ovarian Function, Blood Ions and Vegetative System.—Schultze confirms that there are certain relations between the ovarian function and the potassium and calcium content of the serum. This suggests some influence of the corpus luteum on the sympathetic. Without this influence, especially in the amenorrhea of young girls, a predominance of the vagus may appear, with a shifting of the ratio between the ions. The potassium content of the blood serum was in some of these patients as low as 14 mg. per hundred cubic centimeters. An increase of the calcium concentration is less common. He assumes with Dresel that the lowering of the potassium level in the blood serum is associated with an increased concentration of the ion in the tissues.

Water Metabolism in Pregnancy.—Runge and Kessler measured the osmotic (oncotic) pressure of the plasma colloids in pregnancy and the puerperium, using the Schade and Claussen method. The results were compared with the refraction and viscosity of the plasma. The osmotic pressure of the plasma colloids rises in the beginning of pregnancy. It gradually becomes lower after the fourth month, rises suddenly during labor, and falls in the first days after delivery. The changes of the protein concentration of the plasma are only to a certain extent parallel; the specific viscosity varies partly in the opposite sense.

Site of Placenta, Shape of the Uterus, and their Mechanical Import.—Demme describes a characteristic flattening of one side and a convex outline of the other side of the uterus, which are visible through the abdominal wall. If the back of the fetus is situated in the convex part, a coiling of the umbilical cord may be expected. He describes the mechanism of this complication, and reports his investigations on the site of the placenta.

Action of Thyroglobulin in Pregnancy.—Mahnert injected intravenously from 0.03 to 0.05 gm. of iodin-thyroglobulin in pregnant women. Those with edema responded usually with diuresis and marked increase in the elimination of uric acid, urea and chlorids. The blood cholesterol became lower.

Blood Volume in Pregnancy.—Bohnen and Borrmann used Griesbach's congo red method. The blood volume in normal controls averaged 6.4 per cent. of the body weight. In the first half of pregnancy, 7.7 per cent.; in the second half, 7 per cent. The decrease in the second part is chiefly due to the increase in weight.

Painless Labor in Hypnosis.—Franke describes the technic for obstetric hypnosis. Several preliminary hypnoses are necessary before amnesia is obtained. He recommends a combination of hypnosis in labor with administration of 3 c.c. of chloroform. The good or bad example of the other pregnant women influences the results. He obtained in 80 per cent. of the cases a complete success, with absolute amnesia.

Cardiovascular Changes from the Menopause and Castration.—Strassmann found an average increase of 20 mm. of mercury in the blood pressure of women in the menopause or with myomas of the uterus. In 15-20 per cent. of the former group and in 40 per cent. of the latter, it leads to an enlargement of the heart. Frequent hemorrhages lower the blood pressure. Enucleation of the myomas did not influence it. Surgical castration is followed at first by a lowering of the blood pressure—depending on the gravity of the operation. Later on, the pressure rises (average 32 mm. systolic and 15 mm. diastolic) in women who had been previously menstruating. It has no permanent influence in the menopause. Roentgen amenorrhea after an ovarian dose produces no hypertension—probably because the internal secretion of the ovaries continues. Only the deep irradiation in malignant tumors raises the blood pressure and causes enlargement of the heart.

The Nervous System and Metabolism.—Oswald finds that only the patients whose nervous system is disturbed react with hyperthyroidism to administration of iodin or thyroid extracts.

Cause and Treatment of Peptic Ulcer.—Katzenstein reviews the clinical and experimental evidence supporting the theory of a disturbed balance between pepsin and antipepsin. He explains some contradictory findings by pointing out that only a very active gastric secretion can digest living tissue. A loop of intestine sewed into the stomach of dogs is not digested if the activity of the secretion is kept low by a practically meat free diet or by atropin. He advises to give ulcer patients internally a preparation of antipepsin in alkaline solution. A blood transfusion is the best remedy in hematemesis. He says that it acts as a hemostatic, and contributes to the healing of the ulcer by increasing the antipepsin content of the blood. Although a surgeon, he recommends to try medical treatment first, even in indurated ulcers. The best surgical treatment is the Billroth I resection.

Hunger Sensation and Gastric Acid.—Müller found in the majority of patients with a sensation of hunger or hunger pains, a low gastric acidity.

Cholagogues and the Duodenal Tube.—Taschenberg and Hofmann tested the action of various cholagogues (phenylcinchoninic acid derivatives, magnesium sulphate, oil of peppermint and sodium glycocholate), using the duodenal tube. They confirm the action of the remedies, but emphasize the fact that neurotic subjects are wholly unsuitable for these experiments. The secretion is soon arrested in such cases.

The Blood Sugar in Rabbits.—Lévai and Waldbauer found great spontaneous changes in the blood sugar concentration in rabbits. The difference in samples taken on different days from the same fasting animal amounted to 64 per cent. Hence the inconstancy of insulin units determined on rabbits.

Pathogenesis of Dysoxidative Carbonuria.—Collazo found an increased amount of lactic acid in the blood from avitaminotic pigeons and dogs. The urine of these dogs contained lactic acid. This was especially pronounced after exertion. He concludes that lactic acid is one of the components of dysoxidative carbonuria.

Influencing of Diuresis by Hypnosis.—Heilig and Hoff made the diuresis experiment in hypnosis, suggesting pleasant and unpleasant sensations. The former decreased the elimination of water, chlorids and phosphates; the latter increased it. They explain this as secondary to the changes of gastric secretion (hyperchlorhydria with pleasant and hypochlorhydria with unpleasant suggestions).

Action of Atropin and Epinephrin on the Evacuation of the Stomach.—Petrović found more stomach contents after ingestion of 600 c.c. of water and an injection of atropin than with the water alone or combined with an injection of epinephrin.

Calcium Treatment of Dysentery.—Teodosijevits reports excellent results of calcium chlorid in dysentery. He injected 10 c.c. of a 10 per cent. solution twice daily, and added morphin subcutaneously.

Frequency of Cancer of Lungs.—Staehelin confirms the increased frequency of primary cancer of the lungs since 1912, in Basel, while the general incidence of cancer has not changed. He suggests that tarring of the streets may be one of the possible causes.

Hexose-Phosphoric Acid of the Blood.—Lawaczeck found about 1 mg. of hexose-phosphoric acid per hundred cubic centimeters of blood. Injection of epinephrin causes a lowering of the acid followed by an increase. Insulin increases its concentration, yet a decrease follows. He regards the second phase as the reaction of the organism: secondary insulinemia in the first and epinephrinemia in the second instance. One group of diabetic patients react like normal subjects; the other group in the opposite way. This latter group also shows a paradoxic influence of injections of epinephrin and insulin on the blood sugar. He believes that it represents only a functional diabetes due to a pathologic equilibrium between insulin and epinephrin—not necessarily to insufficiency of the pancreas.

Experimental Inhibition of Exudation by Pituitary Extracts.—Saxl and Donath found that an injection of pituitary extract or of neo-arsphenamin inhibited the exudation due to instillation of mustard oil in the conjunctiva of rabbits. They explain this by the action of these substances on the reticulo-endothelial system.

Fermentation Acids and Digestive Disturbances in Infants.—Catel found that enterococci produce in vitro much more lactic acid than volatile fatty acids. Colon bacilli act the reverse. Lactic acid and its sodium salt do not irritate the bowel, while the other acids cause a strong peristalsis, especially in the small intestine.

Lactic Acid Elimination in Carcinosis.—Glaessner injected mice intravenously with glucose, using about 1 per cent. of their body weight. Mice inoculated with carcinoma responded with an elimination of lactic acid by the urine. The acid was absent in the urine from healthy and sarcomatous controls.

Hematology of Rats with Rickets.—Maurer, Diez and Berendt found constantly myelocytes and normoblasts in rats with experimental rickets.

Potassium and Calcium of the Blood in Hypertension.—Kylin and Myhrman found a slight increase in the potassium content of the serum in 100 patients with essential hypertension. Since the calcium content is lower in these subjects, the K/Ca ratio is increased. Instead of the normal 1.70-2.15, the figures obtained ranged from 2.08 to 2.97. The same change was observed in asthma, gastric ulcer and other vegetative neuroses.

Extracts from Bilberry in Pancreatectomized Dogs.—Eppinger, Mark and Wagner succeeded in lowering the blood sugar and glycosuria in pancreatectomized dogs by oral administration of an extract from bilberry leaves. The action depends, however, on some other circumstances, for the blood sugar increased at times.

Herpes Zoster and Chickenpox.—Lauda and Silberstern had negative results with complement fixation in herpes zoster when using an antigen from chickenpox. They suggest that the positive results obtained by French workers might be due to an epidemic of zoster of chickenpox origin in Paris.

Syphilis and Tuberculosis.—Liek had been irradiating without results a man diagnosed by an authority as suffering from tuberculosis of the skin. The patient had a negative Wassermann reaction and a negative history, but recovered under arsphenamin treatment. A young girl of good family, referred for irradiation of supposedly tuberculous lymph glands in the neck, had a primary sclerosis on the labium majus, which was soon followed by a roseola. He quotes other similar cases of diagnostic mistakes, especially in children with real or supposed surgical tuberculosis.

The Rockefeller Institute. W. Levinthal.—p. 1480. C'cn.
Tuberculosis of Female Sex Organs. O. Pankow. Supplement.—pp. 1-43.

Increasing Prevalence of Thyroses in Vienna.—Wiesel finds an increased frequency of goiter (especially exophthalmic) and of hyperthyroidism in Vienna. He attributes many of the cases to the indiscriminate use of iodin. He has noted that symptoms of exophthalmic goiter are frequently combined in young girls with chlorotic blood changes.

Pharmacology of Mineral Waters.—Wiechowski observed changes of temperature, coagulation time, and of the reaction to inflammatory stimuli and magnesium anesthesia in animals drinking Carlsbad water over a long period. It is possible that such waters act by changing the mineral metabolism of the organism.

Insulin Treatment of Exophthalmic Goiter.—Richter recommends small doses of insulin in treatment of exophthalmic goiter. He injects 5 units twice daily, later 2.5 units.

Fattening of Nondiabetics with Insulin.—Bauer and Nyiri had excellent results, in underweight persons, with insulin injections. They administered on the first day 5 units twice daily; on the second day 10-15 units, and, beginning from the third day, 20 units. In the second week, 3 injections of 20 units were given daily, together with food representing 60 calories per kilogram of body weight. The average diet contained usually over 100 gm. of proteins; 100-150 gm. of fat, and 250-400 gm. of carbohydrates. The appetite soon began to increase.

Influence of External Application of Ice on Gastric Secretion.—Von Friedrich found that an ice bag applied externally for three hours did not modify the secretion in the stomach.

Transmission of Herpes Virus to Mice.—Luger and Erdstein produced easily encephalitis in mice by intracerebral inoculation of herpes virus. The degeneration of the oxychromatin was perhaps more distinct than in rabbits.

Treatment of Skin Diseases.—Pinkus deals with so-called interdigital eczema. It is in reality a mycosis, as Kaufmann found, although Sabouraud had preceded her in showing that a large proportion of the so-called dyshidrotic eczemas are parasitic affections. He advises drying the skin between the toes, and washing only with diluted alcohol.

*To Facilitate the Alexander-Adams. H. Friedrich.—p. 2212.

The Reaction of the Vaginal Secretions During Pregnancy.—Heinlein's research failed to confirm the alleged cyclic fluctuations of the acid titer, but he found wide variations at different times in the same person.

The Alexander-Adams Operation.—Friedrich lays a forceps on the median line, to touch the symphysis' upper margin. A second forceps is then placed over the upper margin of the superior ramus of the os pubis, the tips of the instruments touching at the median line. They form a right-angled triangle, and he makes his incision exactly through the center, beginning 1 cm. from the angle of the triangle. By this means the inguinal ring is opened up without fail, and ample access is obtained for the Alexander-Adams operation. The incision is continued to the limit of the hair. The incisions are thus symmetrical, immaterial whether the women are lean or stout.

Criticism of Gye's Discoveries. R. Kimla.—p. 1379. C'cn, p. 1414.
Survey of Czech Literature on Microbiology. G. Gellner.—p. 1381.

High Closure of the Vagina in Operative Treatment of Vesicovaginal Fistula.—Müller advises to return to high colpocleisis in cases of extensive communication between the bladder and the vagina if the capacity of the bladder is reduced. Supravaginal amputation of the uterus or roentgen castration might be added, to prevent formation of calculi.

Venous Pressure.—Tatterová and Šerf obtained in fifty-six patients practically identical results with Pruche's indirect method and with the direct method. Venous hypertension was observed in auricular fibrillation, mitral disease, exophthalmic goiter, syphilitic aortitis and nephritis. Patients with arteriosclerosis of the kidneys had no increased pressure. Electrocardiograms showed in venous hypertension with mitral disease or exophthalmic goiter a predominance of the right ventricle; in nephritis, the left ventricle predominated.

Influence of Semicircular Canals on Gait. P. de Haan.—p. 1238.
Appendicitis in Right Femoral Hernia. Gouwe.—p. 1247.

Bacteriophage Action by Trypsin.—Wolff states that trypsin loses its bacteriophage-like action when diluted to 1:200, while the bacteriophage is still active at this dilution, even after adsorption by kaolin. Heating trypsin abolishes the bacteriophage-like action, while heating scarcely modifies the true bacteriophage action. Other tests have all given concordant findings, he says, suggesting that the bacteriophage-like action of trypsin is due in reality to the actual presence of the bacteriophage in the trypsin. This has been d'Herelle's contention from the first, while others have hailed this action of trypsin as evidence that the bacteriophage is of ferment nature.

Muscle Tonus and the Foot Reflexes.—Langelaan presents arguments to show that the muscular contraction is due to a reflex mechanism, and that the foot reflex is independent of the sympathetic fibers innervating the muscle. The foot reflex persists even after corresponding ramisection. This conception of the mechanism of the foot reflex allows estimation of the latent period and formulation of certain purely physical constants from study of the living muscle.

LEUKOPLAKIA BUCCALIS

OBSERVATIONS BASED ON A STUDY OF FORTY CASES *

HOWARD FOX, M.D.
NEW YORK

While much has been written on leukoplakia buccalis, there is still some difference of opinion regarding certain of its features. The subject was discussed before this section in 1922 by Hazen and Eichenlaub,[1] and since then has been reviewed by Maderna[2] in Italy and by DeForest[3] in this country. My object in again introducing the subject is to give the results of personal experience, especially in their relation to its etiology. The relationship of syphilis as a precursor of the disease and of cancer as a possible complication are perhaps the most important points to consider. Although leukoplakia affects other mucous membranes besides those of the oral cavity, the latter alone will be considered in this communication.

SYMPTOMS

Leukoplakia varies greatly in appearance according to its age and development. In the early stages, the process is superficial and, as a rule, the patient is not aware of its presence. It may appear in the form of minute points, streaks or more often smooth patches of irregular size and shape. It is generally bluish white or slaty, or may suggest the appearance of mucous membrane touched with silver nitrate. Eventually the patches become noticeably thickened, whitish, rough and stiff. The surface may be exfoliated, fissured or ulcerated and the borders more or less inflamed. Bleeding may occur on slight trauma. Subjective symptoms are now in evidence, and interference with speech and eating may occur.

The favorite sites for leukoplakia, according to Maderna, are the dorsum of the tongue and mucous surface of the lips and gums, and only in exceptional cases the hard or soft palate or under surface of the tongue. My experience coincides largely with these statements. In my series of forty cases, the disease affected the tongue in twenty-eight cases, the commisures in twenty-six, and the cheeks in twenty-one cases. Frequently the patches were present on two or three of these regions. In nine cases, the lips (including the mucous surface and vermilion border) were affected, and in two cases the soft palate. When the tongue was involved, the favorite site was the anterior half of the dorsum or sides. The disease was noted eight times as often on the anterior as on the posterior portion. In a single case, it affected the under surface of the tip of the tongue, while in none of my patients were the gums involved. When seen on the buccal mucosa, the disease was generally bilateral. In eight cases in which it was unilateral in all except one, the right side was affected.

A complete absence of subjective symptoms was noted in eighteen of my cases. While present in twenty-one cases, they were generally of a mild type and occasioned by the ingestion of very hot or highly seasoned food or by the use of tobacco. In two cases, the subjective symptoms disappeared after treatment by arsphenamin, although the lesions themselves were unaffected.

ETIOLOGY

Age.—Leukoplakia is essentially a disease of adults. When first seen by the physician, the patient has frequently reached middle age. This was certainly true in my cases, in which the average age at the time of the first visit was 48.4 years. The average duration of the disease, as far as the patients were aware, was 8.7 years.

Sex.—Leukoplakia, while not exclusively a disease of men, shows a striking predilection for the male sex. Cumston[4] states that out of a total of 848 cases collected from the literature, including ten of his own, "there were only thirty females." In my own series, there were thirty-eight men and two women.

Race.—The full blooded negro, I am convinced, rarely suffers from leukoplakia. For the last twelve years, I have had unusual opportunities at the Harlem Hospital to study skin diseases in the negro. In spite of constant watchfulness, I have seen only four undoubted cases of leukoplakia in this race, only two of these patients being full blooded. One of these was observed at Camp Upton in the course of an examination of negro troops. In my statistical study of skin diseases in the negro,[5] a photograph of leukoplakia is included which was taken many years ago by my father, Dr. George Henry Fox. I had never seen the patient myself. In Hazen's[6] study of skin diseases in the American negro, leukoplakia was observed in five white persons and in two negroes.

Occupation.—It would not appear that occupation plays any part in the causation of leukoplakia, with the rare exception of workers such as glass blowers or those habitually exposed to dust and smoke, in whom a direct source of local irritation is evident. In my own cases, twenty-three different occupations were represented, including professional and business men leading a sedentary life, and artisans and others doing manual labor or living outdoors.

Syphilis.—The question of the relationship of syphilis to leukoplakia has been the cause of much difference of opinion. The contention is that syphilis acts in some unknown manner as a predisposing cause to the formation of leukoplakia. That the latter disease is not a direct syphilitic manifestation is evident from its histologic structure and its failure to be influenced by antisyphilitic treatment. The essential pathologic process is a hyperkeratinization of the mucosa and a gradual sclerosis of the derma, changes that are not characteristic of syphilis.

There is a mass of evidence in the literature showing that leukoplakia is preceded in a large proportion of cases by a syphilitic infection. The statistics of Fournier[7] show that of 324 patients suffering from leukoplakia, 80 per cent. had previously been infected with syphilis, and in the remaining 20 per cent. this disease could not be absolutely excluded. Max Joseph,[8] on the other hand, found a much smaller percentage (35.2 per cent.) in 100 cases of leukoplakia. Opinions of American textbook writers on dermatology differ concerning the etiologic relationship of syphilis to leukoplakia. Thus, Highman states that "leukoplakia buccalis is almost invariably syphilitic," and Sutton considers that "syphilis is an important factor in many instances." Ormsby says, "It is believed that syphilis may be one of the indirect causes," while Pusey and Stelwagon think the relationship of the two conditions is questionable. Hazen and Eichenlaub consider that "syphilis represents an accidental rather than a causative factor in this disease."

In 65 per cent. of my cases, a previous syphilitic infection was judged to have occurred from the history, Wassermann reaction or presence of tertiary manifestations. While my percentage is not as high as that of some other observers, it is too high to ignore the relationship of the two diseases. It is quite possible that my figures show a smaller proportion of syphilitic infections than was actually present. For instance, in six of the cases giving no history of syphilis, the Wassermann test had unfortunately not been performed. Furthermore, in many cases of syphilis of long duration, the blood Wassermann test is found to be negative. In nineteen of my cases with negative Wassermann tests, the average duration of syphilis had been twenty-two years.

Tending to show that the syphilitic infection had antedated the leukoplakia, eighteen of the known syphilitic patients stated that their leukoplakia had been present on an average about half as long as their syphilis. This, it must be admitted, is not entirely conclusive, as the leukoplakia may have been present, unknown to the patient, for a considerable time.

Whatever effect syphilis may have had in my cases in predisposing to leukoplakia, its action was largely unhampered by treatment. In twenty-six of the syphilitic patients, the treatment administered previous to the appearance of the leukoplakia had been very inefficient. In six cases, there had been no treatment whatever; in sixteen, the treatment had been inefficient and fairly energetic in only four cases.

Desiring to learn the incidence of leukoplakia in a large number of known syphilitic patients, I recently visited the syphilitic clinic of Dr. M. B. Parounagian at Bellevue Hospital. Here the opportunity was offered of carefully examining the buccal cavities of 280 patients in a single afternoon. To my surprise, nine of them showed evidences of leukoplakia, mostly of a mild degree in the commisural region. While even this proportion may seem large, it is astonishing to hear the results of examination of fifty cases of neurosyphilis by Elliott and Stookey.[9] They report that in these cases the "changes in the buccal and lingual mucosa have been as constant a finding as any abnormality of the pupils," and further state that "only one case showed a normal mucosa of the entire buccal cavity."

While there is much evidence to show the frequent relationship between syphilis and leukoplakia, there is excellent proof that many cases of the latter occur without any such association. From a careful study of this subject, Raillet[10] concluded that in at least 15 per cent. neither acquired nor congenital syphilis could be held responsible. Cases are also on record in which persons with long standing leukoplakia have contracted syphilis.

Tobacco.—The synonym "smokers' patches" is frequently used for leukoplakia buccalis and suggests a predisposing cause that is without doubt of the greatest importance. There is such a general agreement on this score that it would be useless to quote much of the literature. Joseph goes so far as to say that he had never seen a patient whom he had learned to know, who at some time had not been a smoker. He also considers that the "severity of leukoplakia depends upon the greater or less use of tobacco."

All of the patients in my series, with the exception of the two women, had been more or less addicted to the use of tobacco. Thirty-five were habitual smokers, twenty-five of these using tobacco to excess, some of them since boyhood. Two of the patients smoked moderately and one occasionally. In addition, four of them chewed tobacco. Cigars, cigarets and pipes were used about equally.

A significant relationship between leukoplakia and the use of tobacco is that the affection is chiefly seen in men, who in general consume much more tobacco than women. The irritating effects of smoking, it may be mentioned, are due not only to the nicotin but to various products of combustion, such as carbonic acid gas, ammonia and creosote.

Alcohol.—The immoderate use of alcohol may be one of the predisposing causes of leukoplakia, especially when it gives rise to marked gastro-intestinal disturbances. In my series of patients, eight used alcohol to excess; nineteen drank moderately and seven occasionally, while five were total abstainers.

Food.—Highly seasoned or very hot food is another source of irritation, which has been thought to play a part in causing leukoplakia. There can be no doubt about the discomfort which this produces in some of the more advanced cases. In answer to the question regarding the use of highly seasoned food, eight of my patients admitted such a predilection.

Teeth.—The irritating effects of decayed teeth, with jagged edges, etc., are emphasized by Hazen and

Eichenlaub as an important cause of leukoplakia. Bloodgood,[11] in a series of twenty-seven cases, found "dirty, rough" teeth in all but one. According to James,[12] leukoplakia may be due to "dental infection" alone, the writer stating that in some of his cases "no other cause could be found." In thirty-eight of my cases, notes concerning the condition of the teeth were made. In eighteen cases, it was recorded as good or fair and in a similar number as poor or bad. In two cases, all of the teeth had been extracted.

Gastro-Intestinal Disturbances.—Disturbances of the gastro-intestinal tract are considered by many to have an influence in the causation of leukoplakia. Of my patients there were twenty-two who suffered from more or less indigestion, chronic constipation, badly coated tongue, etc.

COMMENT ON ETIOLOGY

Leukoplakia is not itself a syphilitic process. Syphilis, however, precedes the appearance of leukoplakia sufficiently often to conclude that it may be one of the factors in its production. I cannot agree with Hazen and Eichenlaub, who consider syphilis to be "an accidental rather than a causative factor" in this disease. It is undoubtedly true that, in a minority of the cases at least, leukoplakia may occur independently of syphilis. The real cause of leukoplakia, as Maderna states, is still unknown. Whether syphilis may or may not have preceded the appearance of leukoplakia, some local source of irritation can generally be discovered. Such irritants include smoking, chewing of tobacco, the excessive use of alcohol, gastro-intestinal disturbances, the presence of decayed or jagged teeth, and indulgence in very hot or highly spiced food. By far the most important local irritant, in my opinion, is tobacco. This opinion is shared by many other observers and is certainly corroborated by my own experience. Rough and jagged teeth may play a part in causing leukoplakia through mechanical irritation. I feel, however, that too great emphasis has been placed on this form of irritant by Hazen and Eichenlaub, who consider that rough teeth "inaugurate the disease in the vast majority of cases." In the opinion of DeForest, "tobacco and syphilis must be regarded as the most important factors in etiology." He considers that "where syphilis exists, it is probably true that less smoking is necessary to develop leukoplakia." I feel convinced that in the majority of cases one of these two factors is concerned in the causation of leukoplakia buccalis.

RELATIONSHIP TO CANCER

The most important feature of leukoplakia from the practical standpoint is its well known tendency to develop malignancy. This does not mean that the majority of cases will terminate in cancer, especially when the sources of irritation are removed. Many cases of leukoplakia persist for years or even decades without even causing any appreciable discomfort to their possessors. The disease is, however, a continual menace and, if sufficiently irritated, has a potential power for harm. It is eminently proper to class it among the "precancerous" affections. Mantilla[13] has tabulated 566 cases from the literature, reported by some eleven observers, and has found that in 32 per cent. cancer eventually developed. Bloodgood considers that leukoplakia is second only to bad teeth as a cause of cancer of the mouth. In 160 cases of cancer of the tongue in men, Bloodgood found that in forty-one cases leukoplakia had been present and known to the patients for years before the appearance of the cancer. In four of my cases of leukoplakia, undoubted clinical carcinoma was noted. In one, the diagnosis of carcinoma was recorded as probable and in three others as possible.

TREATMENT

It has been stated that leukoplakia occasionally disappears spontaneously, though it has never been my fortune to observe such a favorable outcome. The disease is notoriously rebellious to treatment, as shown by numerous remedies that have been recommended, many of which are hopelessly inefficient. Antisyphilitic treatment in the vast majority of cases will not cause the disappearance of leukoplakia, though it may benefit the subjective symptoms. It is quite possible that the condition may even be aggravated by such drugs as mercury, bismuth and the iodids, through their tendency to produce stomatitis.

Prophylaxis is all important and consists in removing, as far as possible, all causes of local irritation. It would certainly be best to prohibit entirely the use of tobacco. At least, its consumption should be reduced to the lowest possible amount. When the habit of smoking cannot entirely be given up, cigar and cigaret holders or long stemmed pipes should be used. The teeth should be put in order, especial attention being given to the removal of rough edges, badly fitting plates, etc. Alcohol should be used in moderation or prohibited, and a warning sounded against the ingestion of very hot or highly spiced foods. Gastro-intestinal disturbances should receive proper attention. In addition, the frequent use of a bland mouth wash is advisable. The elimination of sources of irritation will not cure the leukoplakia, it is true, but the subjective symptoms will be benefited or completely relieved and the chances of future malignancy will be vastly lessened.

For years, I have taken a decidedly conservative stand regarding the active treatment of leukoplakia. Where prophylactic measures are faithfully carried out and the patient kept under observation, the milder types of leukoplakia require no active intervention. As a matter of fact, few of these patients apply for treatment in the earlier stages, as they are generally unaware of the presence of leukoplakia. Again, in the very extensive cases involving considerable area of the tongue and buccal mucosa, radical treatment is out of the question. I have been pleased to learn the opinion of Bloodgood regarding active treatment in this disease. He states that "as long as the leukoplakia shows no tendency to crack or peel off or form an ulcer there is no indication for any treatment other than the removal of the causes —tobacco, teeth and syphilis." He adds, however, "the moment a patch of leukoplakia splits, scales or desquamates and leaves an ulcer, the area should be excised with the cautery."

Of the many methods recommended for the active treatment of leukoplakia, chemical caustics are among the least satisfactory. The frequent practice of using such a superficial caustic as silver nitrate cannot possibly accomplish any good and is liable to do harm. Among the various physical agents which have been recommended may be mentioned electrolysis, carbon dioxid snow, superheated air, endothermy, the actual cautery, the roentgen ray and radium. The roentgen ray has not proved satisfactory, partly because of the natural difficulty in applying it to the buccal cavity.

The two most widely used agents at present are probably radium and the electric cautery. MacKee[14] states that he has "been disappointed with both x-ray and radium in the treatment of this affection." He adds that "small patches can be cured with radium, but they can be cured with greater certainty (although with more discomfort) by means of the galvanocautery." Maderna is one of the warm advocates of radium, the favorable action of which he thinks is heightened by preliminary treatment with arsphenamin. He makes the rather surprising statement regarding radium that "with a few treatments and weak doses," he has cured all his patients. With both radium and the electric cautery, I have had disappointing results in some cases, recurrences taking place after the patches had supposedly been destroyed. In five of my series of cases, radium had previously been used, in three cases by men of experience. In none of them had the result been permanent. Levy[15] concludes that "the results of treatment are unsatisfactory."

CONCLUSIONS

1. Leukoplakia occurs chiefly in men, especially of middle age. It is rare in women and in full blooded negroes.
2. The essential cause of leukoplakia is unknown.
3. Syphilis acts as a predisposing cause in the majority of cases. In a minority of cases, such a relationship can be definitely excluded.
4. Various sources of local irritation act as predisposing causes, including tobacco, alcohol, rough teeth and gastro-intestinal disturbances. Of these, tobacco is undoubtedly the most important.
5. Leukoplakia is a frequent forerunner of cancer, though it may exist for years or decades before the appearance of any malignant change.
6. In the treatment of leukoplakia, prophylaxis is all important.
7. The permanent cure of leukoplakia is difficult, the best agent for this purpose being apparently radium or the actual cautery.

ABSTRACT OF DISCUSSION

Dr. Otto H. Foerster, Milwaukee: In the relationship of syphilis to leukoplakia, recurring mouth lesions of syphilis must be recognized as of considerable importance. In resistant or insufficiently treated cases of syphilis, they may account for some of the cases of later leukoplakia. Furthermore, hot foods, particularly hot fluids, taken into the mouth injure the mucous membrane and this is a factor in the production of leukoplakia, either the sole factor in some cases or the additional factor of injury acting on structures previously altered by syphilis. My experience in connection with carcinoma of the tongue and leukoplakia has been that carcinoma has occurred only when the leukoplakia was extensive, when it was associated with deforming interstitial syphilitic glossitis, and when there was a definite history of injury. In some of the cases verrucous leukoplakic patches had been present which, by rasplike rubbing against opposing surfaces, had caused injury of the base. Darier described chronic small angular ulcerations occurring in leukoplakic patches, which apparently do not have the potentiality for malignant change found in the fissures of leukoplakia. The floor of these ulcers is smooth and red, is raised to the level of the leukoplakic patch, and is separated from it by a deep folded-in furrow. I agree with Dr. Fox that antisyphilitic treatment for leukoplakia is useless. In the presence of leukoplakia in an evidently syphilitic patient, antisyphilitic treatment should be given or withheld only after consideration of the therapeutic requirements of the patient in general and not of the tongue or mouth alone. Electrothermic coagulation, endothermy, appears to offer a method of treatment which in my limited experience has been satisfactory. I wish to express a word of caution to the effect that any local treatment in leukoplakia, unless it be by a powerful and thoroughly destructive agent, is meddlesome and dangerous and should not be employed.

Dr. J. Frank Schamberg, Philadelphia: I can fully endorse every statement made by Dr. Fox. We ought, however, to differentiate between the terms leukoplakia, which represents smooth, whitish patches, and leukokeratosis. The former has often a preceding change and remains relatively harmless. It is when deeper changes occur in the mucous membrane that the condition becomes dangerous in respect to ensuing cancer. Syphilis is the largest factor in the leukodermias in the mouth. I think we may conceive that the spirochete is lodged in the tongue, as in the skin, and there remains and by reason of being there plays a rôle as the dominant irritant. In the way of irritants, I think smoking plays the greatest part. Hot food may be a factor, but when we see the tremendous number of cases in men over those seen in women we must conclude that tobacco plays a large rôle. We have all seen many cases that clear up when smoking is stopped and recur when it is resumed. We must remember that other conditions in the mouth may be confused with leukoplakia, such as lichen planus and also certain chronic inflammations which may lead to whitish patches, with some thickening of the outer layer.

In regard to treatment, I agree that antisyphilitic treatment has little effect. I have seen some little improvement under syphilitic medication, but have never seen a complete disappearance of the patches without prohibition of smoking. It is most important to prohibit smoking completely because of the danger of cancer. Every case of leukokeratosis of the mouth may be regarded as a precarcinomatous condition. I am inclined to believe that in many cases the carcinoma runs a more benign course than when it is of other origin. I know of one case in which the growth was destroyed by electrodesiccation and the man is well at the end of five years. I agree with Dr. Fox that the roentgen ray and radium should not be employed in the treatment of leukoplakia. They lower the resistant power of the tongue because of the vascular changes. Electrodesiccation is a proper treatment if well carried out, and, in some instances, one may with the electrocautery knife decorticate the tongue. I have had excellent results in one or two cases from this procedure. We should impress on the public the necessity of seeking medical care when these white spots appear on the tongue. As has been stated, they frequently are not observed by the patient. The dentist may see them and refer the patient to a physician, and then a positive Wassermann reaction will be found. The condition may escape recognition for a long time and, if the tongue becomes thickened, it becomes a menace to the patient.

Dr. Henry H. Hazen, Washington, D. C.: I cannot agree with the statement that leukoplakia is very frequently of syphilitic origin, and yet in making this statement we must take care to define very carefully what we mean by leukoplakia. I agree with Dr. Fox that the great majority of cases *involving most of the dorsum of the tongue are syphilitic*, probably over 50 per cent. of the cases, if that constitutes leukoplakia alone. But, on the other hand, if we make a routine examination of the mouth, we shall find that many of the patients of advanced years have a certain degree of leukoplakia on the buccal membranes; if not a definite leukoplakia, a leukokeratosis. I can see no difference between these except one of degree. If one will study these lesions still more closely, one will find that in every case they coincide with the tooth lines, where the buccal mucosa rubs on the teeth. I think this is a most striking thing. If we make a Wassermann test and study these patients for syphilis we shall find that practically none of this group will show syphilis, although a large percentage of those cases showing extensive leukoplakia on the dorsum of the tongue do show syphilis. Another factor that may be partly responsible for the difference is that the series of cases which Dr. Eichenlaub and I published some three years ago were private cases.

[15] Levy, Robert: Leucoplakia Buccalis et Lingualis, Laryngoscope 25:539 (Aug.) 1915.

Another factor of considerable etiologic importance is the possibility of either Vincent's infection or a streptococcus infection in the gum. I have seen a number of cases within the last year in which there was a very definite leukoplakia surrounding Vincent's infection on the gum, and as soon as the teeth were extracted or cleaned up the leukoplakia disappeared. In regard to leukoplakia in the negro, I do not remember whether both of our cases were in full blooded negroes or not. I know one was, and I think both were.

Dr. Herman Goodman, New York: In cases of syphilitic leukoplakia the attending physician finds a four plus positive Wassermann reaction. He institutes antisyphilitic treatment and may push it to the limit. It is not unusual in such instances for the leukoplakia to become much worse. Whether this is due to the syphilis plus the added irritation of the arsenic in the arsphenamin is not known to me. At least one patient under my care passed from an operable condition of the oral cavity to an inoperable one while undergoing the therapeutic test with arsphenamin for syphilitic leukoplakia with beginning degeneration. I have often wondered whether others have seen similar instances.

SOME PROBLEMS IN PUBLIC HEALTH ADMINISTRATION *

MATTHIAS NICOLL, Jr., M.D.
New York State Commissioner of Health
ALBANY, N. Y.

When we take into consideration the comparatively short time that official care of the public health has been recognized in America, with certain noteworthy local exceptions, as a problem of fundamental importance to the citizenry, it is not surprising that the rapid strides that have taken place in this field, especially during the last decade, should be accompanied by difficulties inherent in any widespread campaign that seeks the adoption of a program frequently opposed to customs and habits of life inherited from individualistic forebears. Today the American people as a whole, when the value of rules and regulations affecting public and personal health habits have been convincingly demonstrated, show remarkable willingness to comply with their provisions, even though such compliance may entail a good deal of discomfort and not infrequently physical and mental suffering. There are no other countries in which the almost autocratic powers of constituted health authorities are so generally upheld by the higher courts and sustained by the force of enlightened public opinion. That a noisy and troublesome minority is to be found in practically every community, which, through ignorance, malice or alleged personal conviction, is with difficulty made to comply with well established and fundamental principles underlying the preservation and promotion of public health is a matter for regret but by no means for discouragement.

The influence on the public of the teachings and practices of false prophets and charlatans under a variety of high sounding titles, of unscrupulous, badly informed, commercially minded editors and publicists is indirectly proportionate to the efficiency with which official and unofficial health work is administered and its value convincingly demonstrated; so that the best, indeed the only, weapon with which to fight effectively these opponents of public welfare is good public health work and effective, sane publicity regarding its accomplishments and aims.

A certain number of people even in enlightened communities have always worshiped false gods, and even in this age of scientific progress that number is by no means inconsiderable; but we may be confident that truth will ultimately prevail and that the teaching and practices of those who cannot or will not recognize and acknowledge it will become negligible as a factor in the proper conduct of public health administration.

The difficulty experienced by states and local communities in securing qualified health administrators and adequate staffs of co-workers and subordinates is dependent on a number of well recognized conditions: First is the comparatively recent recognition by the medical profession and public of the fact that public health work as a career is a true specialty for which training, experience and certain fundamental personal qualifications are essential to success. Universities and medical schools are now placing much more emphasis on the importance of a knowledge of hygiene and sanitation as part of the equipment of every well grounded physician, and a number of special schools are industriously turning out men and women technically trained in public health, but the demand for qualified men with a reputation of having made good, especially in the more important positions, is far greater than the supply. Administrative ability in public health and other fields is not a common human attribute. It is usually inborn, but is susceptible of being acquired only in the rough school of experience. Contrary to a frequently expressed opinion, I believe that it is no more uncommon among members of the medical and allied sciences than other professional groups; but the fact remains that, among a large number of persons who by intelligent application may become technically proficient in various branches of public health work, only a very small percentage will prove to possess a high degree of administrative ability, for which reason—in order that the demand for such persons may not only be met but also maintained—public health work must attract a far greater number of persons than is the case at present, and not only a greater number but more of the right type. This cannot be brought about until certain fundamental drawbacks are eliminated or largely reduced. Of these, I may point out the inadequate financial return accorded to the higher grades of public health workers, which averages far less than is available in the private practice of medicine and in the practice of most other learned professions.

It is perfectly true that official public health salaries are showing a distinct tendency to be revised upward, largely for the reason that there is a popular demand for efficient public health work, and a gradual dawning on the consciousness of the public and of state and local governing officials that certain qualifications are essential to its performance, and that the attainment of such qualifications involves the expenditure of a great deal of time, large financial outlay, and often much personal sacrifice, which are justly entitled to an adequate return.

He who elects to devote the fruits of study and experience to the service of public health as his sole or principal life work thereby takes a step which it is difficult or impossible to retrace, should he wish to do so. In this country, the chief administrative health official is usually a physician. His training has been, in the majority of cases, in the general practice of medicine or one of the many specialties. But though knowledge of the medical sciences is the basis on which the qualifications of an efficient health officer rests, a good physician will not necessarily make a good health officer; and, conversely, official health work fully entered on by no means enhances the prospects of suc-

---

* Read before the Section on Preventive and Industrial Medicine and Public Health at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

cess in medical practice, but, as shown by experience, actually decreases it. In this respect, the health officer's position is quite unlike that of other administrative officials whose tenure of office usually entails little or no sacrifice of business or profession, or only a temporary one, and who has been under no expense of time or money to qualify himself for holding office. Indeed, many of them derive much benefit from the reputation and associations afforded by public service. Yet, notwithstanding these undeniable facts and the overwhelming importance to the welfare of a community of the work of an efficient health officer, when we use our efforts to have an adequate salary granted to him, how frequently are we met by the statement: "Why, we can't pay the health officer as much as the mayor, governor or other official," or "We need the money for parks, lighting, paving, the police and fire department," or "We can't compete with private business."

The health officer giving full time to his work has practically no other means of supplementing his income. He should not be supported in luxury, but in all justice and for the general interest of public health work throughout the country, be granted, as Mr. Hugh Frayne has so well expressed it in regard to labor, not only a living but a saving wage, that he may support himself and family in reasonable comfort, and when incapacitating illness or death ends his earning capacity, have something left for his dependents, besides life insurance, which is unfortunately not usually the case.

Another important deterrent to entrance on public health work is uncertainty of tenure of office, and freedom from political interference with the authority of the health officer. Until the American people with their surpassing genius for efficiency in the conduct of private business insist that a like efficiency be exhibited in the management of national, state and local affairs, which is strictly a business and requires the services of those who are qualified, other than by political and personal affiliation, the health officer will continue to be regarded, as he now so frequently is, as just a member of the great army of office holders, good, bad and indifferent, toward whom the public is so prone to assume an attitude of extreme cynicism, if not suspicion. But that same public, absolutely responsible for the character of its official representatives, seldom takes the trouble by organized and efficient effort to make its influence felt, even in matters so vital to its interest as the preservation and promotion of the public health.

It is not surprising, therefore, that public health service is frequently hampered by the ignorance and selfishness of partisan politicians who are too shortsighted to realize the responsibility they assume in interfering with the machinery for protecting the health and lives of the people. If a deserving health officer cannot count on the organized support of the community that he serves, he is pretty certain sooner or later to find that his office is desired by some one backed by political or personal influence, or both.

Though laws and regulations regarding tenure of office have been enacted in several states and communities, it may be truthfully stated that in the absence of effective public support a health officer may be, and not infrequently is, compelled to relinquish his office because he is persona non grata with certain political or commercial interests, who by constant nagging, interference with his duties and his official staff, and efforts to discredit his work, make it impossible for him to do his work effectively. It is true that if he has made good he can always find another position; but his going means a loss to his community, frequently a good deal of personal sacrifice, and the necessity to work amid strange surroundings in which he is not familiar with the local problems and the attitude of the people toward public health. It takes time for a health officer to establish himself and to do effective work, and the interchange of health officers constantly going on throughout this country between states and cities for one or more of the reasons that I have mentioned makes for general inefficiency in public health work.

A word regarding civil service. I believe that with its well recognized defects, but few, if any, state health officials would voluntarily dispense with the civil service system. In order, however, that it may help and not hinder efficient public health work there should be provisions, certainly in the case of technical appointments, that only such persons should be admitted to examination as are qualified according to the regulations of some responsible central health organization, as, in the state of New York, by the public health council.

While no one will deny the desirability, for various reasons, of appointing to office residents of a state, and, if possible, in the case of local appointments, of a community, it so frequently happens that they are not available that for the higher positions, at least, examinations should be thrown open to nonresidents, if not to noncitizens who are properly qualified. Too much weight should not be placed on the written examination, and there always should be granted to the appointing power a period of tryout of several months by means of provisional appointment. Furthermore, the appointing power should not be restricted to the first man or woman on the list, but be given some choice in selecting the candidate. In general, if civil service officials, both state and local, perform their work with a single eye to efficiency in public service, it will be found, certainly so far as health officials are concerned, that they will be granted full support and cooperation.

CONCLUSION

If I have seemed to dwell too pessimistically on public health service as a career, it is not for the reason that the department over which I preside and which for so many years was administered by my distinguished predecessor, Dr. Hermann M. Biggs, has suffered from the conditions that I have endeavored to outline. Quite to the contrary, since its reorganization and for the last ten years it has not only been left absolutely free to do its work without interference, political or personal, but has had the fullest support, sympathy and cooperation of the various governors and legislatures, irrespective of party affiliations. It is because I know that such a condition of affairs is possible, though not present in many states and local communities, including some in the state of New York, that I have the utmost confidence that its prevalence throughout the whole country is merely a matter of time, which, judging by the progress that is now being made, should not be long deferred.

ABSTRACT OF DISCUSSION

Dr. A. J. Chesley, Minneapolis: Dr. Nicoll's statements are best appreciated by administrative officers who periodically face the people who make appropriations for state, provincial or city health work. In public health work certain objectives are sought, well tried procedures are used, and the results that may be obtained under given conditions are known. When people better understand public health work, they will support it and more willingly suffer the inconveniences Dr. Nicoll mentions in order to obtain better health. But reduction of expenditures rather than better health work seems to be the chief idea of those who make the appropriations. Funds to aid victims of a great disaster or for the control of an epidemic are easily secured, when funds for prevention have been denied. A health officer must keep in mind that he is health officer for the people as a whole and not for only those who approve his methods. He must modify his program according to the availability of resources and to the possibility of results. When he considers health work as a career, he reflects that some of our best health officers have been replaced purely by the political preference of some one who does not even understand the work. As Dr. Nicoll said, a knowledge of local conditions has a great deal to do with success, and even our best qualified men must acquire such knowledge to succeed. The majority of state and city health officers have risen from the ranks. Medical students give attention to preventive medicine and public health, but they learn little of the practical difficulties familiar to those who have survived the school of experience. The student instruction is necessary and valuable, but knowing the whole situation from experience, one hesitates to recommend public health work as a life work. The cults that guarantee everything apparently have more influence with legislative bodies than well qualified medical men, scientists or sanitarians. What wonder we become pessimistic when considering public health work as a life work.

DR. JOHN A. FERRELL, New York: It is exceedingly unfortunate that the evil influences of politics continue to be so destructive to the maintenance of high standards in the field of health. Although we are only in the fifth month of this year, three state health officers who have been rendering creditable service have been removed by governors. In certain instances it has been alleged that the promotion of the political aspiration of the governor prompted removal. In two states, the governor vetoed legislation designed to upbuild the state health service and to increase its usefulness. Four state health officers who have rendered exceptional service fear removal this year. It seems that the time is ripe for the health forces to endeavor to bring about legislation that will give security of tenure to men who equip themselves to serve effectively in public health positions. Another important point has been mentioned. It was my pleasure only two or three weeks ago to accompany a commission of foreign health officials to visit three or four state health organizations. In two small cities and two counties I found that the local health officers are actually receiving larger salaries than are the state health officials, and there is a tendency in some of the counties where city and county are combining resources to pay larger salaries than the states are paying. It would be logical if the salary scale could be so arranged that advancement from the local position to the state position would carry increased compensation. The situation is not satisfactory in many states. Measures that will give security of tenure to competent men and women are needed. Merit in the field of public health should be recognized on a basis commensurate with the training and ability required to meet the requirements.

DR. J. A. HAYNE, Columbia, S. C.: I have been in service fourteen years. I have been referred to this year by a senator from my state as a "flat-tire politician." He has referred to the state board of health as "an eating sore on the treasury of the state." The situation is a very serious one. I have to lecture every year to the senior class of the medical college and point out the beauties and the desirability of entering the public health service as health officers, either municipal or county, or state. The important question to these students is, What is the remuneration? As a man now under our admirable system of medical education cannot probably graduate until he is about 28 or 30 years of age, and usually has a wife and three or four children before he graduates in medicine, the question of remuneration is much more important than it used to be when I graduated. I do not know of any remedy, unless it is that we pledge ourselves in a sort of secret organization that when one fellow goes out of a position we will see to it that a position is opened to him in some other part of the country. That is about the only satisfactory solution. Whether this can be done or not, I do not know, but I am heartily in favor of it.

DR. JOHN E. MONGER, Columbus, Ohio: In regard to the situation under which we operate in Ohio: In 1917 our state board of health was succeeded by a public health council, which was a nonpartisan body of four men; the tenure of office of each member is four years. Two members of this council must be physicians. In 1917 the appointment of the health commissioner was placed in the hands of the public health council. We were very fortunate in having Dr. Allen Freeman in Ohio, who put our perfectly wonderful law in operation. In reorganization of the state government in 1921, Dr. Freeman was displaced from politics and made director of health. The tenure of office is coincident with that of the governor, two years. In public health matters we must teach politicians. We must realize that politicians are always going to control state government, and ideals, whatever they may be, will only in rare instances rule. A health department is not a political asset, but distinctly a political liability and if we can teach the politician that the health department is not a liability but a distinct asset, then we shall go a long way to remove from public health the burden it is under.

DR. A. T. MCCORMACK, Louisville, Ky.: We have permitted ourselves to get at the wrong angle of this discussion. Unfortunately, and necessarily, the remuneration of a health officer is an essential feature, but from the point of view of ourselves and of public interest, the important thing to instill into a young man who desires to enter into this branch is the opportunity for rendering service. If he has not the desire to render service, he ought not to enter the public health field. Necessarily in this age of economic attrition this eliminates a large number of men who would make a desirable addition to our specialty. At the same time, it must be recognized that it is developmental; and if he brings to it the spirit of service, he will secure from it from year to year public confidence and therefore public remuneration. In the meantime, as in every battle and warfare, there will be casualties, and the only regret is that some of the outstanding casualties, like those in war, are among the most effective and efficient of the general officers in the service. They cannot be avoided. I think it rather fortunate that there should be attacks on the health officer, such as will put him in the spotlight and enable all the people to see all the virtues he has. As a rule, the attack of the minority is of violent character because it is political and attempts to influence the public by machine methods and thus defeats its purpose.

DR. MATTHIAS NICOLL, JR., Albany, N. Y.: I was a little surprised by Dr. Monger's remark that public health is not a political asset. This is true only in the sense that the administration of public health in the nation, state and community should be absolutely free from political interference. On the other hand, there is no greater asset to a state or local administration than an efficient, independent health department. In the state of New York the political complexion of the governors and legislators changes about as frequently as the constitution permits, and yet since the reorganization of the state health department in 1914 and up to the present time there has been no governor or legislature that has not supported and encouraged the work of the state department of health, and, in my opinion, greatly to the satisfaction of the people of the state and to the enhancement of their own reputation as their representatives. Unfortunately, this is not usually the case in regard to the conduct of public health in local communities, where it is too frequently regarded as simply a cog in the political machine. Local politicians are notoriously short sighted, usually inclined to act in accordance with what they believe are their immediate political necessities and with but little regard for the welfare of the people and their present and future needs. In regard to the pay, tenure of office and dignity of the position of health officer, we in this country have much to learn from England, where, to be sure, they have had a much longer experience with official public health than we. As an example, and by way of contrast, those who read the *Medical Officer* will recall that not long ago the governing council of an important English city advertised for a health officer at a salary considerably below the rate which the office had been accustomed to receive. As a result the association of English health officers practically blackballed this city, so that it could not possibly obtain an efficient health officer, except on the terms previously allowed. Furthermore, the health officer in England is assured of a life tenure of office while he is able to give efficient service, and no political consideration has any possible bearing on his administrative acts. This is a state of affairs to attain which we must all look forward in this country. It is not impossible of realization by any means, and I think all will agree that there is a decided trend throughout the whole United States in that direction. In the bringing about of this happy state of affairs, some national body such as the American Public Health Association can be of the greatest service. Too little publicity is given to the frequent removals from office, for no other than political reasons, of efficient health officers of large cities and states.

MAXILLARY SINUSITIS

THE PROBLEM OF COOPERATION *

CARL W. WALDRON, M.D.
MINNEAPOLIS

Authors of textbooks on oral surgery and rhinology are at variance on points of etiology, operative procedures and postoperative treatment of infections of the maxillary sinus. These differences of opinion and practice have been reflected in the opinion and procedures of a large number of members of both the medical and the dental professions. Such a condition of affairs is greatly to be deplored.

There is unquestionably a feeling of uncertainty among the majority of members of the dental profession regarding the proper handling of all conditions relative to the antrum of Highmore. Others specializing in exodontia and minor oral surgery confidently undertake the treatment of maxillary sinusitis with a lack of knowledge of the fundamental points of etiology and pathology. Frequently, the possibility of associated infections of the overlying sinuses is not considered, and nasal obstruction as a factor in the causation of sinusitis, or reinfection, is disregarded.

On the other hand, medical opinion and practice present no greater uniformity. A considerable number of rhinologists in their daily practice fail to take into account the fact that dental infection quite frequently causes maxillary sinusitis, or prevents its resolution. Many, however, consider it of some importance, yet merely refer the patients to their dentists for examination and treatment; without taking the trouble to talk the case over with the dentist concerned in order to assure full understanding and complete cooperation. A very small number of rhinologists lay great stress on the importance of dental infection and the possibilities of resolution and cure of chronic maxillary sinusitis by the eradication of dental infection alone, relegating to sinus and nasal surgery and other intranasal treatments a relatively minor rôle. A considerable number of physicians are of quite neutral opinion regarding this problem. It is surprising how often one hears of the advice of the medical man to have the dentist remove a tooth and establish antral drainage through the tooth socket.

On first consideration, these marked differences of opinion seem hopeless of solution, yet I am sure that more thorough teaching of the fundamental facts concerning the development, anatomy, physiology, histology and pathology of the maxillary sinus will provide a basis for better understanding and cooperation.

I know of no better agency for the furthering of this end than the members of the Section on Stomatology. A large number of us are qualified and licensed to practice both medicine and dentistry and, consequently, are in close contact with physicians, rhinologists, dentists and exodontists. Many of us are responsible for the teaching of this borderline subject to dental students, and our responsibility and duty to present the fundamental points clearly and fairly should be fully realized. We are also responsible for the promotion of efficient cooperation between dentist and physician. A few members of our section actively practice rhinology and are in a position to enlighten the nose and throat men concerning the modern methods of dental diagnosis and the handling of dental infection beneath the sinus floor. By this means, increased cooperation is assured.

The most important fundamental is a clear understanding of the development, anatomy and physiology of the maxillary sinus. That it is essentially a paranasal structure from developmental and histologic standpoints should be clearly understood. The frequency of the very close proximity of root ends and antral floors should be thoroughly demonstrated to the dental student in order to encourage careful handling of infection in this region. This may be accomplished by a detailed study of cross sections, dry specimens, roentgen-ray films and clinical observations in the exodontia and oral surgery clinics. A knowledge of the rich circulatory anastomosis of the vessels of the periosteal layer of the antral mucosa, the vessels of the spongy bone of the maxilla and the vessels covering the alveolus and the roots of the teeth, as demonstrated by Strubell, should impress one with the possibilities of spread of infection from the dental area to the sinus, and vice versa.

The gross anatomy of the maxillary sinus, the position of its ostium, its walls, variations in size, its average cubic content and the average surface area of mucosa should be matters of common knowledge. The relationship of the antrum and other nasal sinuses should be studied. Its vulnerability may thus be appreciated.

The appearance of the normal antral mucosa should be known and its histologic structure well understood. With this foundation, a study of the gross and microscopic appearances of infected sinus mucosa will provide a sound basis for the consideration of the various methods of treatment.

The symptoms of acute inflammation of the sinuses should be well known to dentists and physicians. Dentists finding infection of the upper bicuspids and molars should be able to question the patient regarding nasal and other symptoms indicative of sinus infection. By so doing many patients may be referred to the nose and throat specialist. Phelps [1] considers extreme variability in the amount and character of the nasal discharge from day to day to be diagnostic of dental etiology.

The etiology of maxillary sinusitis has been a matter of extraordinary difference of opinion. Dental causation has, for instance, been credited with from 5 to 100 per cent. of the cases by different observers. A brief survey of the literature impresses one with the probable influence of prejudice and personal opinion on the positive statements set forth. The oral surgeon treats many cases of apparent dental origin, whereas the rhinologist sees a majority showing close relationship to nasal

---

* Chairman's address, read before the Section on Stomatology at the Seventy Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

obstruction and recurrent coryzas, or following influenza, and each in turn magnifies or minimizes the importance of dental infection. The percentage statistics so positively expressed are obviously not based on modern methods of dental and alveolar diagnosis. Thorough vitality testing, thermal, electrical (exploring with the dental burr, if necessary) and dental roentgenography, as perfected today, were not sufficiently correlated with maxillary sinus treatment to warrant statistical conclusions. Until a group of well trained men can combine to diagnose carefully, treat, follow up and recheck such cases, statistics had better be kept under cover. They fulfil no useful purpose and mislead members of both the medical and the dental professions. The patients consequently receive less efficient treatment. Therefore, these published statistics may well be forgotten, and in their stead a liberal, broad-minded summary of our present information should be thoroughly taught dental students and the dental and medical professions at large. What does it matter whether dental infection be responsible for 15 or 50 per cent. of antral infections? The important thing ever to keep in mind is the intimate, anatomic and circulatory relationship of the teeth and investing tissues and the maxillary sinus, and the consequent reciprocal relationship of infections in either dental or antral regions. Cause and effect may be a matter of uncertainty in many cases. This is of little moment and should not materially affect the plan of treatment. Thorough examination and diagnosis of the sinus and the underlying dental region should be the rule. Coincidental infection of the antrum and teeth, without definite causal relationship, must be more common than we suspect.

Oral surgeons undertaking the treatment of maxillary sinusitis should appreciate the frequency and importance of nasal origin, septal obstruction and secondary infection of the antrum from disease of the overlying frontal and ethmoidal sinuses. This paves the way to efficient rhinologic cooperation.

Are we giving sufficient attention to the prevention of infections of the maxillary sinus? I think not. Along with the larger problems concerning the prevention of dental caries, pulpal infection and dental periclasia, we must consider the ever present problem of the dentist extracting teeth beneath the antral floor. I am convinced that the average dentist has received but casual training, if any, in the handling of operative exposures of the sinus cavity. Here, as elsewhere, the essentials of good surgical procedure are the careful handling of tissues under direct visual control, and the reduction of trauma to the minimum. How rarely are these fundamentals observed. Many dentists on discovering an accidental perforation of the antrum are unduly alarmed. Others blindly explore and curet the opening or sinus itself, without rule or reason, and in most instances postoperative observation and care are sadly lacking.

Lyons,[2] from a detailed study of a hundred cases of empyema of the antrum of Highmore secondary to the extraction of teeth, concluded that in most instances penetration occurs, first, as a result of the rocking movement of extraction, which tears into the antrum at the point immediately above and in contact with the root, and, secondly, as a result of the failure to extract all the root, with subsequent displacement of the root tip into the antrum on attempting its removal. The average duration of the antral infections and fistulas in his series was 349 days, and the average length of time of previous treatment was estimated to be 170 days. An analysis of this series brings out the facts that the dentists were not equipped to handle the situation, nor sufficiently concerned regarding the persistence of alveolar fistulas. The average duration of treatment was little short of six months, and the various forms of treatment carried out showed a lack of understanding with regard to the pathologic condition and the surgical principles involved in cure. Most cases were treated through the alveolar fistulas, and the various forms of treatment stimulated the formation of an epithelial lining and the consequent permanent opening.

We cannot ignore this situation nor dodge our responsibilities in the matter of the training of dentists to handle these conditions correctly. As long as root ends bear a close relation to the antral floor, accidental perforations will not be infrequent. More or less uniform and standardized methods of taking care of infected teeth should be taught in dental schools. The use of procain should be advocated in order to afford sufficient time for careful operative work under direct vision with good illumination. The necessity of taking steps to reduce traumatism to the minimum, avoiding the fracture of alveolar process or root ends, should be emphasized. Some degree of buccal alveolar process resection is indicated to facilitate the extraction of the tooth and give better access to the diseased area beneath the antral floor. Careful drying of the root sockets will permit accurate visualization of the periapical area, and thorough removal of infected tissue by curettage is made possible. All unnecessary removal of alveolar process beneath the floor of the sinus should be avoided. Forcible irrigation of the sockets should not be done. Gentle irrigation or mopping should be the rule. The dentist carrying out such technic sees what he is doing and is master of the situation when root tips are broken off or the sinus floor is penetrated. He can recovêr the fractured root end, remove the affected tissue, and assure the closure of the perforation by adjusting the gingival margins and suturing. An edge to edge closure is not necessary nor desirable. The operator must recognize the importance of keeping such cases under observation for a week or so, and the patients should be instructed to avoid sucking at the extraction wound.

Dentists should keep constantly in mind the desirability of protecting the sinus from the bacterial flora of the mouth. Tooth socket treatment of an infected sinus is universally condemned. Should temporary drainage or treatment through the alveolar opening be indicated, every effort should be made to seal it between treatments.

Should the dentist be equipped to take care of the cases of acute maxillary sinusitis that do not respond to nasal palliative measures, such as shrinking the mucosa, inhalations, oil sprays, suction and elimination treatment? Probably in cities and towns where rhinologists are in practice, the need of dental cooperation in relieving such conditions would never arise. In certain districts, however, the dentist would seem better able to establish drainage through the canine fossa than is the physician to puncture the antronasal wall. I feel that dentist should be able to cooperate in such conditions when indicated. If, in spite of such careful handling of the dental condition, an acute maxillary sinusitis supervenes or a quiescent chronic condition lights up, the dentist should be well acquainted with the symptoms in order to enlist the services of the rhinologist and secure prompt treatment.

---

[2] Lyons, H. R.: Empyema of the Antrum of Highmore Secondary to the Extraction of Teeth, J. A. M. A. 78:486 (Feb. 18) 1922.

A consideration of the treatment of chronic maxillary sinusitis opens up another controversial field. One should in fairness give credit to those who differ with us, particularly if one is teaching the subject to students or practitioners. Phelps has called attention to the beneficial effect on many chronic sinus conditions of careful elimination of underlying dental infection. Whether such dental conditions are primary, secondary, or only coincidental matters little. They should be thoroughly taken care of as a routine measure according to the method previously outlined. Realizing the importance of underlying dental infection, the rhinologist should be vitally interested in the method used for its elimination and should refer his patients to the dentist who will operate according to the best oral surgical practice. The time for taking care of the dental infection may be decided after a consultation of the dentist and the physician.

In most cases of chronic maxillary sinusitis, it would seem advisable first to remove the dental infection and postpone other than simple sinus treatment, for the time being, to await results. A few antral irrigations or a Krause window resection to improve aeration and drainage may establish a cure with complete relief of sinus symptoms. Operative relief of nasal obstruction by submucous resection of the septum may be indicated before radical treatment of the sinus is contemplated. If discharge persists for a month or so, polypoid degeneration of the antral mucosa has presumbaly taken place, and prolonged irrigations or other nasal treatments are futile. Removal of this hopelessly infected mucosa is indicated.

The method of choice will depend on the operator. Many can efficiently remove the infected tissue by means of angular curets by the intranasal route. I myself prefer the modified Caldwell-Luc technic carried out under procain-cocain anesthesia. This permits most efficient visualization, affords good ventilation and drainage, and shortens the postoperative treatment. In discussing operative treatment, many writers have been most unfair in criticism. All intranasal procedures are condemned by some, and wildly exaggerated word pictures of the lamentable plight of patients so treated are frequently drawn. Such criticisms may be justified when directed against ruthless resection of the inferior turbinate, and excessive window resections, but are entirely unwarranted when discussing modern rhinologic practice, which rarely interferes with turbinal structure or physiology. Communications between the inferior meatus and antrum, made low and somewhat posteriorly, are free from any postoperative discomfort. A high anterior opening may involve the nasolacrimal canal.

The canine fossa approach has been severely criticized from the standpoint of tooth injury. If the bony opening is not made too large or too low, the pulpal blood supply should in no way be interfered with, and any nerve impairment should be of a temporary nature and inconsequential. This has been confirmed by recent anatomic studies by Neivert.[3] In many cases teeth beneath the involved sinus are missing, or their removal is indicated, and any possibility of dental discomfort need not be considered. Chronic antral infection of nasal origin with normal and complete underlying dentition should, of course, demand the utmost care if treated by the Caldwell-Luc method. In these cases effort should be made to clear up the condition by intranasal methods.

Some writers opposing the nasal opening beneath the inferior turbinate advocate surgical enlargement of the natural ostium. This would surely interfere with the main blood supply and venous return of the antral mucous membrane.

It becomes obvious that we must be broad-minded in our consideration of this whole subject. Pathetic descriptive statements and appeals have no place in the discussion of the various methods of treatment. We must be liberal and fair to others in order that some common ground may present the opportunity for greater uniformity of opinion and practice. To further this end this contribution is submitted.

La Salle Building.

ABSTRACT OF DISCUSSION

Dr. T. L. Gilmer, Chicago: Dr. Waldron spoke of cooperation between the rhinologist and the oral surgeon in sinus diseases. That is very important. If the disease originates in the nasal fossa, then it is a case for the rhinologist. If it has its origin in a tooth, then it is a case for the oral surgeon. It may be necessary, in order to determine this positively, that a consultation be had with the rhinologist. Teeth are often the cause of maxillary sinusitis. I examined a large number of skulls of cadavers some years ago, and found that a large percentage of them showed signs of maxillary sinusitis, and a considerable proportion were directly associated with infected teeth. Some chronic cases originating in the nose may be treated by the rhinologist by irrigation, but one should hesitate about puncturing the sinus from the nose or elsewhere in the acute stages. If, however, there is chronic infection, whether it is caused by the teeth or whether the disease comes through continuity of tissue from the nose, and if curettement is indicated, the latter is best not done through the nose but through an opening made in the buccal wall of the jaw, the Caldwell-Luc operation. The opening should be sufficiently large that one can see into and readily explore the sinus. An opening through a tooth socket is not a good approach to the sinus. It affords insufficient room to observe the condition of the entire sinus; besides there is greater thickness of bone to be cut away. If the Caldwell-Luc operation is done, a mucoperiosteal flap is first lifted and then the sinus is opened. The buccal wall is easily penetrated by drills and enlarged by burrs, a much easier and more delicate operation than if chisels and gouges are used. After the sinus has been cleaned out, a large opening is made through the inferior meatus of the nose for permanent drainage; it is packed with iodoform gauze, the gauze being brought out through the opening into the nasal fossa. The opening in the buccal wall is at once closed by suturing the mucoperiosteal flap back in place. It seems to me that is the best possible treatment for maxillary sinusitis requiring curettement.

Dr. Robert H. Ivy, Philadelphia: I should like to support Dr. Waldron in what he says about the little damage that is done the teeth in these radical operations for maxillary sinusitis. Assertions have been made that the teeth are damaged by the incisions and the cutting away of the bone around the roots of the teeth. If the bone is removed high enough so as not to expose the roots of those teeth, in most cases no damage is done to them. About two years ago, with the cooperation of Drs. Ridpath, Skillern, Coates and other rhinologists in Philadelphia, I was enabled to make some studies of patients who had had radical operations on the maxillary sinus. Tests that I conducted on the teeth showed that, while the nerve supply might have been interfered with temporarily, yet after a certain number of months, or even less time, sensation almost invariably returned. The assertion that a tooth is dead because the nerve supply is cut off is not true. Injury to the ulnar nerve may cause numbness of the fingers, yet they are not dead; they have a blood supply. The blood supply of the teeth is not cut off in these operations because of the rich anastomosis. In any case, even if the teeth are occasionally destroyed by this operation, it is the only procedure that I know of that will cure these chronic sinus conditions.

[3] Neivert, H.: Morphologic Variation as a Factor in the Symptomatology of Paranasal Sinus Disease, Arch. Otolaryngol. 1: 367 (April) 1925.

Dr. Carl W. Waldron, Minneapolis: One point I want particularly to make is that this arguing about percentages is futile. The thing to remember, along with a fundamental knowledge of the physiology and vascular relationship, etc., is that infection may spread from one point to another. It must also be remembered very clearly that infection may be coincidental, with very little relationship. Dr. Phelps and I were trained together in nose and throat work. We had, one might say, the radical form of training. Most of our patients with maxillary sinusitis had been treated previously by rhinologists by intranasal and the more conservative methods. We almost invariably performed the Caldwell-Luc operation. Dr. Phelps became associated in Minneapolis with a rhinologist who was particularly impressed with the importance of dental infection. Today Dr. Phelps performs the Caldwell-Luc operation very rarely. He feels that taking care of dental infection will give the patient that opportunity to take care of the infected antrum that has been irritated from time to time. In most cases, of course, he carries out a few intranasal irrigations, possibly a window resection. The results have been very promising. When he changes his opinion so markedly, I feel that there is certainly something in the premise that dental infection will cause the recurrence of nasal sinus infection, or will be the turning point in preventing coryzas (that may develop on account of septal obstruction) from going on to resolution. So, we must remember that sinus infection may be present and yet not be associated with dental infection, and that if there is dental infection beneath an antral floor, good common surgical sense demands its removal.

PATHOLOGIC PHYSIOLOGY OF LIVER IN RELATION TO INTOXICATION AND INFECTION *

EUGENE L. OPIE, M.D.
PHILADELPHIA

[Editorial Note.—This paper, together with the paper of Dr. McClure, Dr. Mendenhall, and Mildred Huntsinger, and that of Drs. Lyon and Swalm, which follow it, conclude the symposium on "Liver Function." In our last issue we published the papers of Drs. Carlson, Mann and Greene.]

The physiology of the liver is in large part concerned with the remarkable capacity of the organ to select certain substances from the blood and, after various modifications, to store them in its cells, to return them to the blood or to eliminate them with the bile. In this discussion of the pathologic physiology of the liver it seems desirable that special attention be drawn to the ability of the liver to select from the blood stream and fix within itself various substances that are foreign to the normal metabolism of the body.

It is well known that the liver removes certain substances from the blood with such accuracy that impaired elimination of them may serve as an index of hepatic injury. The experiments of Whipple, Peighthal and Clark [1] showed that the dye phenoltetrachlorphthalein may be used as a test of the efficiency of liver function. Rowntree, Hurwitz and Bloomfield [2] point out the relatively slight change in chemical constitution which determines the mode of elimination of three closely related substances. Phenolphthalein is excreted both in the urine and in the bile. Phenolsulphonephthalein, in which the CO group of the former substance is replaced by the SO_2 group, is excreted chiefly by the kidneys. Phenoltetrachlorphthalein, in which hydrogen atoms of the phthalein radical are substituted by chlorin, is specifically excreted by the liver.

After laboriously testing a large number of chemically related dyes in white rats and in dogs, Delprat [3] found one, namely, rose bengal, which is eliminated in both of these animals only by the bile and may be used like phenoltetrachlorphthalein as an index of disturbed liver function. In the present connection the attempt to enumerate all the substances that are known to be excreted in part or wholly by the bile would not be profitable. Copper salts, hexamethylenamin, methylene blue and amyl alcohol, are substances which in this relation have for one reason or another attracted attention. The ability of the organ to select and eliminate these substances is doubtless incidental to some phase of normal metabolism.

SOLUBLE TOXIC SUBSTANCES

From the standpoint of pathology it is especially noteworthy that certain toxic substances introduced into the body have a selective destructive action on the liver. Although phosphorus produces widespread fatty degeneration, its effect on the liver is especially conspicuous. Chloroform introduced into the body by inhalation or by other means brings about a necrosis of cells almost wholly limited to the liver, and when the quantity of the anesthetic is sufficient a very large part of the organ may be destroyed. Graham [4] found that a similar necrosis is produced by iodoform and bromoform, by dichlormethane and tetrachlormethane, and by monochlorethane, monobromethane and mono-iodoethane; that is, by a variety of hydrocarbon derivatives in which halogen atoms are combined with carbon. Why substances of this chemical constitution find lodgment in the liver and cause necrosis is not evident.

There is a large amount of evidence, much of doubtful value, to prove that the liver is capable of destroying certain toxic substances. The subject has been reviewed recently by Gunn.[5] It has been shown by Buys [6] that emulsions made with the liver of the frog and of the rabbit destroy hyoscyamin when incubated with it, whereas the liver of the dog, which is more susceptible to the drug, fails to destroy it. This observation, according to Gunn, has been the starting point of many experiments to determine the power of liver and other tissues to destroy alkaloids. Schirn [6] found that a certain dose of atropin introduced into the peripheral circulation was as effective as twenty times this dose injected into the mesenteric vein. Cloetta and Schirn [6] have obtained evidence that tolerance to atropin acquired by continued administration of the drug to rabbits is accompanied by increased ability of liver tissue to destroy it in vitro. Gunn finds this conclusion in accord with present knowledge, but finds no convincing evidence that congenital or acquired tolerance to alcohol or to morphin is referable to destruction of these substances by the liver. The action of the organ on various toxic substances still excites widespread interest among pharmacologists.

PARTICULATE MATTER

The foregoing brief references show that the liver can remove from the blood certain substances that are soluble in the plasma. It is difficult to determine how this selection is brought about. Anatomists are familiar with the intimate relation of the wide capillaries or sinusoids of the liver to the hepatic cells. The lining endothelium is so delicate that injections made into the vessels readily penetrate between and perhaps into liver cells. A significant peculiarity of some of the cells which line the sinusoids of the liver is their ability to fix and engulf minute particles of varied composition which have found their way into the circulating blood.

[6] Cited by Gunn (Footnote 5).

The stellate cells of Kupffer are especially active as phagocytes. They are regarded as endothelial cells because they form part of the vascular lining and at the same time they are in immediate contact with the liver cells. They have an important part in the fixation of inorganic particles, bacteria, colloid material and perhaps of substances dissolved within the plasma. We are not at present concerned with their relation to other mononuclear cells or to a hypothetic reticulo-endothelial system. It is noteworthy that similar if not identical cells within the spleen ingest all the substances that are taken up by the stellate cells of the liver, but these changes in the spleen occur on a smaller scale and are in some instances at least contributory to those which occur in the liver.

It has long been known that particles of insoluble substances so finely divided that they can pass through the lumina of capillaries are fixed within the liver by phagocytic cells. Carbon particles which have entered the blood stream are held within the liver, and in the advanced pulmonary anthracosis of miners, anthracotic pigmentation of the liver may occur. In unusual instances, anthracotic pigmentation of the liver, as Professor Welch[7] has shown, may cause cirrhosis.

An accurate method for studying the deposition of particulate matter has been devised by Drinker and Shaw,[8] and their studies demonstrate that the liver is the organ chiefly concerned in removing insoluble particles from the blood. The particles which they have selected for investigation approximate in size many of the bacteria that invade the blood stream, and their experiments, which throw much light on the fate of bacteria within the blood, will be considered in some detail.

Manganese dioxid in the form of particles not greater than 1 micron in diameter suspended in acacia solution was injected by Drinker and Shaw into the venous system of cats. If from 1 to 2 mg. of manganese dioxid per kilogram of body weight was injected, manganese in most instances had disappeared from the circulating blood after eighteen minutes. Quantitative determination of the manganese deposited in various tissues after from one to one and a half hours showed that 90 per cent. was recoverable from the liver, lung and spleen, the averages of several experiments for these organs being 38.3, 47 and 4.3 per cent., respectively, whereas the manganese content of kidney, stomach, small intestine, colon, brain, spinal cord and muscle was little if at all increased.

Further study[9] showed that the manganese present in the lungs of the cat rapidly diminished during the first twelve hours following intravenous injection. Simultaneously, manganese in the liver gradually increased and after eighteen hours exceeded that in the lungs. There is evidently a gradual transfer of manganese from the lungs to the liver. Later the quantity of manganese in the liver diminishes gradually, and after a week manganese is almost completely eliminated from the body. Excretion occurs in part by way of the bile, and much of that which is thus eliminated is in the form of undissolved particles precipitable by centrifugalization.

From these experiments it appears that the liver is the ultimate site of deposition of most of the manganese dioxid introduced into the venous system. The preliminary deposition of a considerable part in the lungs of the cat is exceptional, for in other animals which they have tested Lund, Shaw and Drinker[10] found that the liver was the first and chief site of deposit. In rabbits, dogs, guinea-pigs, rats, chickens and turtles, nearly all the injected manganese (in most instances from 80 to 95 per cent.) was recoverable after one hour from the liver, whereas the amount in the lung was very small (usually from less than 1 to 3 per cent.). Hence in almost all vertebrates the liver removes insoluble foreign particles from the circulating blood within a short time after its injection. It is noteworthy that final elimination of manganese from the body is more rapid in the rabbit than in the cat.

When Drinker and Shaw injected manganese dioxid into the venous system of cats, they found after one hour some particles still free within the capillaries of the liver, but the greater part of the magnesium dioxid was within the Kupffer cells, and these were evidently the most effective agents in removing it from the circulation. A few particles were found on the surface of hepatic cells. The quantitative studies that have been described are in large part an index of the functional activity of the Kupffer cells.

COLLOID SUSPENSIONS

The fate of certain substances introduced in colloid form into the circulating blood is almost identical with that of the finely divided material just considered. Numerous studies, especially those made with silver in colloid suspension, have shown that the liver is the chief site of deposition and the Kupffer cells are primarily concerned in removing the metal from the blood. Voigt,[11] using a concentrated suspension, found that the liver contained a very large part of the recoverable silver. In three rabbits, 38, 89 and 63 per cent. of the injected material was recovered from all tissues, and of these quantities 35, 80.7 and 51.8 per cent., respectively, was found in the liver. This observation is evidently widely applicable to heavy metals in colloidal suspension, for Duhamel[12] has found in the liver by chemical analysis a large part of the colloidal platinum. silenium, mercury, copper and iron introduced into the circulating blood of rabbits. Within fifteen minutes after intravenous injection of colloidal platinum, he found the cells of Kupffer full of gray granules, and by quantitative determination two thirds of the injected platinum was recovered from the liver. The spleen contained only traces of the metal. Almost identical results were obtained with colloidal silenium and mercury, the liver containing two thirds of the dose employed and the spleen and kidneys little if any of the metal. When colloidal copper was employed, slightly less than one half of the injected metal was recovered from the liver, and almost all of the remainder was found still present in the blood. Similar evidence of fixation of colloidal iron within the liver was obtained.

Silica in the colloidal state as a sol in the form of orthosilicic acid kills rabbits when given in large dose, and Gye and Purdy [13] reach the conclusion that it acts primarily on vascular endothelium of the liver and of the renal glomeruli. When given in a small quantity daily, it causes cirrhosis of the liver.

RED BLOOD CORPUSCLES

It is well known that red blood corpuscles that have undergone injury as the result of typhoid fever or other form of intoxication are ingested by mononuclear phagocytes within the spleen, bone marrow, liver and lymph nodes. Whenever the blood of one animal is transfused into another the spleen undergoes enlargement, and the sinuses contain phagocytes distended with erythrocytes. These disintegrate within the phagocyte, and hemosiderin, which gives the characteristic microchemical reactions of iron, is found within the cell as yellowish brown pigment. There is some siderosis of the bone marrow and abdominal lymph nodes, as well, but the liver shows no noteworthy change. Rous and Oliver [14] found that the continued injection of blood into rabbits during two months or more finally brought about an immense deposit of iron containing pigment within the liver. The spleen receives and holds hemosiderin for a time and thus protects the liver, but its capacity to store the iron containing pigment is finally overcome, and iron is deposited in other organs, notably in the liver and kidneys. Masses of pigment enclosed in phagocytic cells are found within the sinusoids of the liver; many Kupffer's cells are filled with pigment; and the liver cells, especially at the periphery of the lobule, contain hemosiderin in great quantity. In the kidney, cells of the cortical tubules take up hemosiderin, and when transfusion has been continued during a long period, the cells of the pancreas and of other organs contain the pigment.

The changes observed closely resemble the remarkable disturbance of iron metabolism named by von Recklinghausen hemochromatosis. In this disease the liver is the seat of an enormous accumulation of iron, which may constitute as much as 7 per cent. of the dried substance of the organ (Anschutz [15]; Hess and Zurhelle [16]).

Another important contribution to our knowledge of this disease both of iron metabolism and of the liver has been made by Mallory, Parker and Nye.[17] They found that the administration of small quantities of copper acetate (0.1 gm.) with the food daily during six months or a year caused changes in the liver similar to those of hemochromatosis in man. The deposition of iron containing pigment in immense quantity in the liver was associated with cirrhosis. Pigment first appeared in the endothelial cells lining the sinusoids and later was deposited in the liver cells. The spleen and bone marrow showed little change, and there was no anemia. Disturbance of iron metabolism was doubtless brought about by the strong affinity of copper for hemoglobin, with the resulting formation of cuprohemol. Exactly how this change causes the iron deposit of hemochromatosis is not clear. It is, however, noteworthy that copper is one of the substances that are eliminated from the body in considerable part with the bile.

This accumulation of iron containing pigment in immense quantity within the liver and other tissues represents a deviation from the normal process of pigment formation and destruction and is doubtless in part referable to hepatic functions concerned with the elaboration of bile pigments. It indicates that secretion of bile is intimately associated with the peculiar capacity of the liver, and especially of its endothelial elements, to select and hold certain iron-containing substances which are normally present in the blood stream.

BACTERIA

In the study of infectious disease it is essential to know what changes occur when micro-organisms enter the blood. The first observations on the fate of bacteria introduced in the blood stream are those of Wyssokowitsch,[18] who injected a nonpathogenic microorganism, *Micrococcus tetragenus,* and a pathogenic form, *Bacillus typhosus,* into the veins of rabbits. By cultural methods he found that they were stored in spleen, liver and bone marrow. Werigo [19] injected anthrax bacilli into the vascular system of rabbits, and after a few minutes found them much more numerous in the liver than in the spleen. Bacilli were found in great number in the lung, in which they were ingested by polymorphonuclear leukocytes. Plate cultures made by Arima [20] showed that bacteria injected intravenously into rabbits disappeared from the blood after about one half hour, and were then most abundant in the liver and present in smaller number in the spleen and bone marrow.

Observations of Bartlett and Ozaki [21] indicate that *Staphylococcus aureus* injected into the circulating blood of the dog and rabbit accumulate in great number in the lungs and are ingested by polymorphonuclear leukocytes. At the same time there is abundant deposition of bacteria in the liver and spleen. Leukocytes containing bacteria rapidly disappear from the lung and are apparently carried to the liver and spleen. Bacteria in the liver and spleen are ingested by endothelial and other mononuclear cells (Kupffer cells), but phagocytosis by polymorphonuclear leukocytes is equally active and finally predominant.

Pneumococci and streptococci, like many other bacteria, when injected into the ear vein of a rabbit in doses insufficient to cause death rapidly disappear from the blood after from two to four hours, and the animal remains in good condition. Bull [22] found that if virulent micrococci are injected in quantity sufficient to cause death within from two to four days, they disappear rapidly so that after two or four hours the blood is sterile or contains only a few bacteria. Within five or six hours, bacteria reappear in the blood and steadily increase until the death of the animal. No gross lesions are found in the organs. With less virulent pneumococci or streptococci in the same quantity, a more chronic type of infection follows. Reentrance of bacteria into the blood is delayed and the number present may be small. The animal lives several days, but finally severe septicemia makes its appearance, and, after a period varying from a few hours to two days, death occurs. The animals have become emaciated, and after death local lesions, such as pericarditis, pleurisy and peritonitis, are usually found. Bull thinks that the progress of septicemia is an accurate index of the severity of infection.

The fate of typhoid bacilli injected into the venous system of normal rabbits was next studied by Bull.[23] They disappear from the blood like pneumococci; bacterial counts of plated cultures following injection of one-fortieth of a twenty-four hour agar slant of typhoid bacilli into the ear vein were as follows: after one minute, 10,000,000 per cubic centimeter; after two minutes, 2,500,000; after five minutes, 100,000; after fifteen minutes, 40; after twenty minutes, 1. Further study has shown that agglutination is almost immediate so that clumps of bacilli are found in blood removed from the heart thirty seconds after injection but have disappeared after seven minutes. Tissues of rabbits removed twenty-one minutes after intravenous injection of typhoid bacilli have given colonies per cubic centimeter of crushed pulp as follows: spleen, 2,000,000; liver, 1,600,000; lung, 100,000; mesenteric lymph node, 1,000; skeletal muscle, brain and other tissues, very few. In view of its size, the predominant importance of the liver in removing bacteria is evident. The fate of bacteria fixed in the liver has been studied. A rabbit received in the ear vein one thirty-fifth of an agar slant culture of typhoid bacilli; pieces of liver were removed at intervals and the number of bacteria determined by plate cultures. After three minutes, 1 c.c. of crushed liver pulp contained 12,000,000 bacilli; after fourteen minutes, 6,000,000; after one hour, 700,000; after two hours, 80,000, and after three hours, 1,000. Films prepared from liver, spleen and lungs showed that bacilli were in large part agglutinated into clumps which were surrounded by polymorphonuclear leukocytes. The largest number of leukocytes enclosing clumps of bacilli was found in the organs of animals removed from thirty to ninety minutes after inoculation. After three hours, bacteria within leukocytes had undergone disintegration into granules or had lost completely the power of staining, but even after three hours some unagglutinated bacilli with staining properties unimpaired were found outside of cells.

Fine particles of inorganic material injected into the circulating blood, as the foregoing discussion has shown, tend to accumulate in the liver; but, according to Drinker, Shaw and Drinker, the cat is an exception to this statement, for its lungs in the period immediately after injection contain more manganese than the liver or spleen, but later give it up. Hopkins and Parker[24] made somewhat similar observations when they injected hemolytic streptococci into cats and rabbits. In cats, immediately after injection, bacteria were more numerous in a given weight (0.1 gm.) of lung than of liver or spleen, but in rabbits streptococci were much more numerous in liver and in spleen. Incubated lung and liver exerted a bactericidal effect on the streptococci that they contained, whereas spleen exhibited less bactericidal activity, but in other tissues multiplication of streptococci proceeded uninterruptedly.

There are a number of observations which show that immunization modifies profoundly the ability of tissues to fix bacteria. Since the liver is predominantly concerned in the removal of bacteria from the circulating blood, it is desirable to consider the effect of immunization on this function of the organ. Experiments have shown that certain antibodies act more effectively within the liver than in other tissues.

When rabbits received into the ear vein a large fatal dose of pneumococci, Bull[25] found that the resulting bacteremia persisted until death; but if antipneumococcus serum was injected, bacteria disappeared from the blood within fifteen minutes. Stained preparations made with blood removed from the heart before injection of the serum showed that the micro-organisms were discretely scattered in the film, whereas one minute after injection they were collected into clumps. These clumps were evidently removed by the liver, spleen and lungs, for clumps of diplococci were found in these organs. Little if any phagocytosis occurred within the circulating blood, but leukocytes in considerable number accumulated about the clumps held within the organs named.

Agglutination, however, is not essential to the fixation of bacteria by tissues of the immunized animal, according to Kitawaga.[26] He injected highly virulent pneumococci practically inagglutinable in the serum of an immunized rabbit and inagglutinable in the blood stream as well. These pneumococci injected into the venous system of normal rabbits persisted undiminished, but disappeared promptly when serum from an immunized rabbit was injected intravenously. He reaches the conclusion that some factor other than agglutination is responsible for the disappearance of these virulent pneumococci.

Ingenious experiments of Manwaring and Coe[27] have demonstrated that opsonins or bacteriotropic substances aid phagocytosis of bacteria by fixed cells of the liver. They washed all blood from the portal and hepatic veins by means of Ringer's solution, and then perfused the organ with pneumococci suspended in the same solution. Plate cultures showed that these bacteria passed through the organ undiminished, and addition of normal blood to the suspension caused no change; but the presence of a small amount of immune serum (1:1,000) caused complete retention of pneumococci. Addition of immune serum caused no removal of bacteria when suspensions were similarly passed through intestine, kidney, lungs or isolated hindquarters of the rabbit.

A measure of the capacity of different tissues to take up bacteria has been furnished by Manwaring and Fritschen.[28] They perfused organs of a dog with bacteria suspended in Ringer's solution, and determined by counting of colonies the number of bacteria removed from the suspension after it had been passed through an organ five times. What they call the microbic affinity of different tissues varies widely. Perfusion of a suspension of *Staphylococcus aureus* through the brain and meninges removed only 0.5 per cent. of the suspended bacteria; the intestine removed 4 per cent., and the isolated lung 6 per cent. The spleen, however, removed 60 per cent., and the liver, 80 per cent. The liver, on account of its large size and abundant blood supply, these observers believe, is the dominant factor in the removal of bacteria from the circulation. Its ability to fix different bacteria varies; it has a high affinity for *B. coli* (40 per cent. fixed after five passages) and for *Staphylococcus aureus* (80 per cent.), a low affinity for *B. bisepticus* (15 per cent.) and for

B. anthracis (25 per cent.), and is almost complete in ability to fix certain micro-organisms such as *B. lactis-aerogenes.* When blood serum from an immunized animal is added to a suspension of the corresponding bacterium, the ability of the liver to fix bacteria is greatly increased, so that micro-organisms which are fixed with difficulty, for example, *B. anthracis* or *B. lactis-aerogenes,* are now removed from the perfused suspension as readily as *B. coli* or *Staphylococcus aureus.* The amount of specific endothelial opsonin in the circulating blood determines the ability of the liver and to a less extent of the spleen to fix bacteria, but does not increase the affinity of other tissues for bacteria.

The foregoing observations have shown that the liver exerts the important function of removing bacteria from the blood stream. The organ is so situated in relation to the portal circulation that it can take up bacteria which under normal or pathologic conditions have penetrated the intestinal wall and thus prevent their entrance into the systemic circulation. It is significant that the activity of this function increases with immunization. The greater selective capacity of the liver tends to make it the final repository of micro-organisms that have temporarily lodged within vessels of the lungs or of other organs.

FOREIGN PROTEIN

The manifold capacity of the liver to remove injurious material from the circulating blood requires the consideration of its relation to foreign protein. Here again it doubtless serves as a buffer to protect the body from material that may find entrance by way of the gastro-intestinal tract.

There are observations which indicate that the liver modifies foreign protein introduced into the body and assists in its elimination. Chiray [29] found that egg white injected into the veins of rabbits appears in the urine after one-half hour, whereas its appearance is much later after injection into the mesenteric vein. In the dog, Langer,[30] found that egg white injected into a vein was demonstrable in the bile by means of the precipitin test after from one-half to one hour, and was still present twenty-four hours later.

In sensitized animals, the liver may modify the effect of the protein used to produce sensitization and may inhibit its toxic action. Falls [31] found that from 0.3 to 0.5 c.c. injected into the jugular vein of sensitized guinea-pigs caused death within from two to five minutes, whereas from 0.8 to 1.5 c.c. was required to produce death within from twenty to thirty minutes when injection was made into the mesenteric vein. Experiments of Manwaring and Crowe [32] indicate that the liver of a sensitized animal can destroy the toxicity of foreign protein. When a mixture of foreign protein used for the sensitization of guinea-pigs together with blood of a sensitized animal was transfused through the normal liver, the mixture retained its ability to produce an anaphylactic reaction; but when the same mixture was passed through the liver of a sensitized animal its power to cause anaphylaxis was lost.

These experiments suggest that the action of the liver on foreign protein is analogous to its action on bacteria, for in both instances the organ diminishes the injurious effect of the foreign substance, and in both instances their protective action is increased as the result of immunization. It is not improbable that the liver acts similarly on many injurious bacterial products which, like foreign protein, act as antigens and induce immunity.

CONCLUSIONS

The foregoing survey of the relation of the liver to intoxication and infection suggests the following statements:

The liver by means of the peculiar endothelium of its sinusoids fixes insoluble inorganic particles, many kinds of organic particles, such as bacteria and substances in colloid suspension, and perhaps by the same means many substances dissolved in the plasma.

With immunization, the liver shows increased ability to fix bacteria and foreign proteins and to render them harmless.

The liver removes from the portal blood many injurious agents which enter from the gastro-intestinal tract, and prevents their entrance into the systemic circulation.

Fixation of injurious substances may cause destructive changes in the liver and permanent lesions of the organ.

THE EVALUATION AND TREATMENT OF DISTURBED LIVER FUNCTION *

C. W. McCLURE, M.D.
W. L. MENDENHALL, M.D.
AND
MILDRED E. HUNTSINGER, B Sc.
BOSTON

In the present communication we outline some of the principal results of correlated studies on the functional state of the liver of the lower animals and of man. The studies include both means for ascertaining the state of liver function and means for influencing that state. In man the state of liver function was determined by estimating the concentrations of cholesterol, "bile acids." "total pigments" and "bilirubin" of duodenal contents. These contents were obtained both from normal controls and from patients with various diseases including lesions of the liver or its ducts. The studies on animals will be reported in detail at a later date.

It is well established that the liver performs a number of functions of foremost importance to the economy of the organism. It converts protein products absorbed from the intestines into urea. It detoxifies poisons that come to it from a variety of sources. It excretes cholesterol, calcium, pigments and other substances comprising the bile. It plays an important rôle in the metabolism of bile salts and bile pigments. As strange as it is true, little definite knowledge is available as to the state of the functions of the liver in even the most common pathologic conditions which affect that organ. Indeed, there is a paucity of methods which will give an adequate conception of the functional state of the liver of patients except at a time when that state is most seriously deranged. The development of more delicate methods would aid in explaining symptoms occurring during the course of diseases affecting the liver, and also might afford a means for detecting disturbances of the liver in their incipence. For these reasons we undertook the development of such methods.

---

* Contribution from Evans Memorial.

* From the Evans Memorial Hospital and Department of Pharmacology of Boston University School of Medicine.

* Read before the joint meeting of the Section on Pathology and Physiology and the Section on Gastric-Enterology and Proctology at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., May, 1925.

One of the most promising means for obtaining information concerning an organ's functional condition is the study of that organ's secretions or excretions. An excretion of the liver, the bile, is poured into the intestines and may be obtained for study by means of the duodenal tube. However, the theoretical objection to such a study is that bile derived from the intestines may have lost its original character through possible action of the gallbladder. But this objection merely adds another phase to the investigation of duodenal bile. In making investigations on man it was found that the experiments could not always be sufficiently controlled to form a suitable basis for arriving at definite explanations for the phenomena observed. For this reason animal experimentation was entered on. The correlated results of these experiments with those on man have explained many of the indefinitely understood phenomena observed in man.

The study of the bile fraction of the duodenal contents of man may be divided into the following five stages:

1. The development of clinically applicable methods for examination of the bile fraction of duodenal contents.
2. Procedures for obtaining duodenal contents; this entails the development of means for stimulating uniformly the flow of bile in normal persons.
3. The establishment of the character of bile found in duodenal contents of normal persons.
4. Ascertaining the immediate source of bile found in duodenal contents.
5. Determining whether, regardless of the immediate source of the bile, the findings in the bile of duodenal contents of normal persons differ essentially from those of persons whose livers were demonstrably affected by disease.

The methods that have been devised represent procedures for estimating in conventional terms the concentrations of various constituents in the bile moiety of duodenal contents. To the present, methods have been developed that will determine the concentrations of cholesterol, bile acids, combined pigments and bilirubin of this bile fraction. All the methods are colorimetric. The cholesterol method [1] depends on the characteristic color developed by a chloroform solution of cholesterol when added to sulphuric acid and acetic anhydrid. The bile acid method [2] depends on the color produced by them in the presence of furfurol and sulphuric acid. A commercial preparation of glycocholic acid is used as a standard. The pigment concentration method [3] is the most simple of all. It consists of mixing duodenal contents with sodium sulphite and acetic acid, filtering and reading against a standard of a solution of chromates, expressing relative concentrations in conventional terms. The bilirubin method [2] is a modification of Ehrlich's diazoreaction, using a commercial preparation of bilirubin as a standard. The indexes of concentration of bilirubin and cholesterol are expressed in milligrams per hundred cubic centimeters of duodenal contents. Pigment and bile acid concentrations are expressed in percentage of arbitrary standard found to approximate the normal. Whether the methods proposed determine only the substances named is open to grave doubt. This is because the chemistry of these substances is highly complex and but little understood. But the methods do permit the determination of four substances persistently present in normal bile and with uniformly reliable results. The methods, therefore, afford a means of ascertaining the normal concentrations of these various constituents. They further give means for determining the influence on such concentrations of diseases affecting the liver; and by comparing the latter with the normal criteria, the functional condition of that organ can be estimated.

The method for stimulating the flow of bile is of foremost importance to the success of liver functional studies as reported here. Obviously, a substance must be used that will invariably stimulate the liver of normal persons to excrete bile. If the substance does not always stimulate the liver, it will be difficult to differentiate between the nonstimulation due to disease and that due to the failure of the substance employed. The pioneer studies [3] of the investigation reported here were carried out on duodenal contents obtained after the introduction of magnesium sulphate solution into the intestines. The use of this drug indicated the results which this method for establishing the functional state of the liver could give. However, it was found that magnesium sulphate [3] and other inorganic salts do not invariably stimulate the flow of bile in normal persons. The variability of the stimulating effect of magnesium sulphate may be explained on the basis of the results of animal experimentation. These results show that by varying the size of the dosage of magnesium sulphate, introduced either into the duodenum or into the blood stream, the excretion of bile by the liver may be increased or decreased; i. e., the biliary function of the liver may be stimulated or depressed. These findings indicate that the biliary function of the liver presumably was depressed in those normal persons in whom the use of magnesium sulphate failed to produce a flow of bile.

The occasional unsatisfactory effect of magnesium sulphate led to the use of various foodstuffs or their digestion products as stimulants to the flow of bile; and it was found that in proper amounts these would always produce stimulation of the biliary function of the liver of normal persons. Oleic acid was selected for use in the present investigation because it invariably produces a flow of concentrated bile in animals and normal persons; it is, also, nontoxic and cheap, and a good preparation is easily obtainable on the market. Furthermore, experimental work on animals shows that oleic acid is a very powerful stimulant to the biliary function of the liver. Large amounts of oleic acid do not depress the activity of this function, while other food products may cause depression. When oleic acid is used, the procedure for collecting duodenal contents from the human subject is as follows: The duodenal tube is swallowed before breakfast on an empty stomach; the metal tip is allowed to pass into the second portion, as determined by fluoroscopy. The subject then reclines on the right side and a mixture of 5 c.c. of oleic acid and 45 c.c. of tap water is introduced into the duodenum through the tube. After about fifteen minutes has elapsed, collection of duodenal contents is commenced by siphonage. As soon as bile appears, the collecting flask is changed and collection carried out for a period of thirty minutes, provided there is no gross change in the color of the bile; as for instance, from pale yellow to dark brown or deep green. If a marked change in color does occur, the collecting flask is again renewed and the duodenal contents collected over a period of the ensuing thirty minutes.

---

[1] McClure, C. W., and Vance, E: Boston M. & S. J. **191**: 765 (Oct. 23) 1924

[2] Unpublished observations

[3] McClure, C. W.; Vance, E, and Green, M. C.: Boston M. & S. J. **192**: 431 (March 5) 1925. McClure, C. W., and Vance, E.: Ibid. **192**: 433 (March 5) 1925

Observations on normal subjects and patients without demonstrable hepatic lesions showed that introducing oleic acid into the duodenum always gave rise to a flow of definitely brown bile. The minimum and maximum concentrations of the four constituents of this bile, as determined by the methods outlined, are as follows:

Cholesterol concentration from 30 to 213 mg.
Pigment concentration from 100 to 500 per cent.
Bile acid concentration from 80 to 212 per cent.
Bilirubin concentration from 6.7 to 23.5 mg.

These figures are fully comparable to those obtained in the duodenal contents of normal subjects in whom magnesium sulphate stimulated a flow of bile.[4] On a basis of these observations it is considered that the figures given for the four biliary constituents establish the limits of their normal variation.

During studies on normal and pathologic duodenal contents of man, data have been obtained which throw light on the immediate source of the bile fraction. It is important to know whether the bile to be examined has come directly from the liver; as bile which has passed through the gallbladder may be greatly modified from that derived directly from the liver. For this reason, the immediate origin of duodenal bile will be discussed.

It is well established that, in the presence of chronic cholecystitis, the bile of duodenal contents is often pale yellow. This color has been commonly regarded as indicative of the presence of bile that has come from the liver directly, and without having been subject to the modifying influences of the gallbladder, its presence leads to the assumption that the cystic duct is occluded and that the gallbladder does not function. Our studies show that by certain therapeutic measures the pale yellow bile may eventually be changed to a dark brownish color. One of the measures used to develop this change was duodenal lavage with magnesium sulphate solution. It does not seem probable that this would open the occluded cystic duct, especially if the occlusion were a stone. After repeated lavages, one or more of the solid constituents of the bile, which were normally low at first, often increased to normal amounts before the change from yellow to brown occurred. The same phenomenon was observed in the duodenal contents of patients whose gallbladders had been removed. Furthermore, in a certain stage of convalescence from catarrhal (infectious) jaundice, and during the same period of collection, duodenal contents may change from a golden yellow to deep grass green, and vice versa several times. Deep sage green bile of duodenal contents was obtained from a patient with a marked degree of pigmentation due to chronic hemolytic jaundice, and brick red bile from another such patient.

There is no known basis for explaining these color variations as the result of changing conditions in either the gallbladder or the duodenum, while it is well established that the liver can secrete biles of different colors. Furthermore, deep grass green duodenal contents have been obtained repeatedly from patients whose gallbladders have been removed. On the other hand, it may be maintained that the color variations noted were the result of exposing bile to the air. If this were true, then, the bile pigment present reacted entirely differently from that of normal persons. Color changes in the duodenal contents of normal persons occurred, if at all, only after a number of hours, when the specimens were not exposed to bright light or to bacterial action. Bile of normal character, as determined by the tests employed, has been obtained from patients whose gallbladders were completely excised. The most plausible explanation for these findings is obviously that the bile of duodenal contents comes directly from the liver under the conditions of experiment. For this reason, duodenal contents offer a direct means of examining secretions from the liver. This conclusion is supported by animal experimentation. In animals it has been found that oleic acid and the proper amount of magnesium sulphate solution introduced into the portal circulation actively stimulate the flow of bile even after ligation of the cystic duct.[2] Furthermore, Crohn[5] showed that an animal's gallbladder during digestion does not alternately empty and refill, and that when emptied, the gallbladder refills only very slowly and at irregular intervals.

Table 1.—*Character and Analyses of the Biles of Duodenal Contents Obtained from Normal Persons and Patients*

Case	Cholesterol, Mg. per 100 C.c. of Duodenal Contents	Pigment Concentration, per Cent.	Bile Acid Concentration, per Cent.	Bilirubin, Mg. per 100 C.c. of Duodenal Contents	Color	Diagnosis
	30	100	80	6.7	Brown	Normal minimum limits
1	16	43	42	0.0	Pale yellow	Cirrhosis of liver; no jaundice *

* Diagnosis confirmed on laparotomy.

The first clinical studies by the methods mentioned were carried out on patients with cirrhosis of the liver, in whom the condition varied from that which was well marked to that of apparently mild degree. The great majority of these patients were not jaundiced. The biliary fraction of duodenal contents from these patients was found to vary widely from that obtained from normal persons, which is illustrated by the findings in Case 2 of Table 1. These findings were accepted as fully demonstrating that the procedures used would show disturbances in hepatic function; regardless of whether the bile examined had or had not been modified by action of the gallbladder. Since the procedures showed disturbances in the mild grades of cirrhosis, it was considered that they furnished fairly delicate tests for determining the state of hepatic function. The status of the procedures having been established, they were next applied to the study of the liver functional condition of patients with various diseases. As a result, it was found that disturbances in the functional state of the liver accompanied lesions affecting its parenchyma, such as cancer, and derangements of its circulation, such as passive congestion. It was also found that acute and chronic cholecystitis were accompanied by disturbed liver function. In addition, disturbances in hepatic function have been found in patients presenting gastro-intestinal symptoms and in whom there are few or no signs of organic disease of either the liver, its duct, or the gallbladder. Some of these patients had been subjected to exploratory laparotomy and no intra-abdominal lesions were demonstrated. The symptomatology of these patients will be made the subject of a future communication.

The establishment of procedures for ascertaining the state of hepatic function afforded an objective means for ascertaining whether or not this state could be influenced by therapeutic measures. One of the measures studied was the introduction of magnesium sulphate solution into the duodenum in the manner proposed by Lyon.[6] For the purposes of this study, patients with cirrhosis of the liver or with gallbladder disease were given duodenal lavage with magnesium sulphate solution once or twice a week, while coincidently the state of hepatic function and the patient's clinical condition were also determined. It was found that this method of treatment was accompanied by decidedly favorable changes in the functional state of the liver in more than half the patients. Coincident with these changes, improvement in the patient's clinical condition occurred. Such findings are well illustrated in the protocol of a representative case outlined in Table 2. The patient was given duodenal lavage with magnesium sulphate solution once a week.

4/ 4	25	110	62	7.2	Brown	No symptoms
5/20	No symptoms up to date. Has gained from 125 to 142 pounds (from 56 to 64 kg.). Is back to full time work.					

* The patient, a man, aged 70, had had the gallbladder, with stones, excised three years before examination. Two years before he had had an attack of severe epigastric pain with chills, fever and sweats. For the past eighteen months he had had chills and fever, at first every few months, and for the past few months every week and later nearly every day, but no pain. Persistent dyspepsia was marked.

At the beginning of treatment of the patient represented in Table 2, the state of liver function was much disturbed, and clinical symptoms were marked. It will be observed that liver function ultimately became greatly improved and that the patient returned to a normal state of well-being. This coincidence of improvement in liver function and in clinical symptoms can be obtained in a fair percentage of patients. Such results indicate very strongly that magnesium can influence the functional state of the liver. The findings indicate also that improvement in hepatic function is the cause of clinical improvement. These conclusions find some support in the fact that animal experimentation shows definitely that magnesium can stimulate the liver to functional activity.

In contradistinction to the favorable findings discussed above, it was observed that in some patients liver function was apparently depressed by the introduction of magnesium sulphate solution into the duodenum. Such observations were not properly interpreted until experimental work on animals showed that improper amounts of magnesium sulphate will markedly depress the functional activity of the liver. On the basis of these observations, the depression of liver function in certain of the patients would seem to have been the result of improper dosage with magnesium sulphate. In some of these patients, changing the dosage was accompanied by improvement in the function state of the liver. These findings suggest that magnesium sulphate should be used with some degree of caution. However, at present the proper dosage can be determined by observing the effects of the drug on the functional state of the liver. Unfortunately, this tends to limit the usefulness of an apparently efficient therapeutic measure to those physicians who possess the special equipment necessary to determine the functional activity of the liver.

SUMMARY

Procedures have been devised for estimating the functional condition of the liver. These procedures consist of stimulating the liver with oleic acid and then obtaining the resultant bile from the duodenum by means of a tube. This bile is inspected for its color and analyzed for the concentrations of four of its constituents, which for purposes of description are called bilirubin, total pigments, bile acids and cholesterol. Neither the indefiniteness of the chemistry of these constituents nor the immediate origin of duodenal bile is of great moment as regards the clinical value of the findings. However, results obtained show that duodenal bile has suffered little, if any, modification by action of the gallbladder, and that the analytic methods are uniformly reliable.

The results obtained show definitely that magnesium sulphate has a pronounced effect on the functional activity of the liver in man and animals. This drug will either increase or depress that activity, depending on the amount reaching the liver. Further, the results indicate that the drug can modify favorably a functional state of the liver which has been deranged by disease, and that the favorable modification produces amelioration of clinical symptoms. For this reason, its use under properly controlled conditions is considered to be an efficient therapeutic measure. Unfortunately, the use of the procedures either for determining the state of liver function or for the therapeutic use of magnesium sulphate requires a considerable amount of experience in order to obtain good results.

THE THERAPEUTIC VALUE OF NON-SURGICAL DRAINAGE OF THE BILIARY TRACT *

B. B. VINCENT LYON, M.D.
AND
WILLIAM A. SWALM, M.D.
Chief, Gastro-Intestinal Clinic, Samaritan Hospital
PHILADELPHIA

During the past decade, a number of noteworthy contributions have furthered the earlier recognition and more rational treatment of certain diseases involving the liver, gallbladder, gall ducts, pancreas and duodenum. Our knowledge of the physiology of the liver, gallbladder and pancreas is becoming more exact, although much remains mazed in speculation.

In this paper we aim to emphasize the fact that disease of the gall tract is a manifold and composite disease in which many organs are intimately or remotely involved. For many years, too great emphasis has been laid on the gallbladder as the chief offender. Until recently, we have not clearly enough recognized the concurrent infection and degenerative changes in the liver, bile ducts, pancreas and intestines which often play a prominent rôle in gall tract disease and produce a widely varying digestive complex.

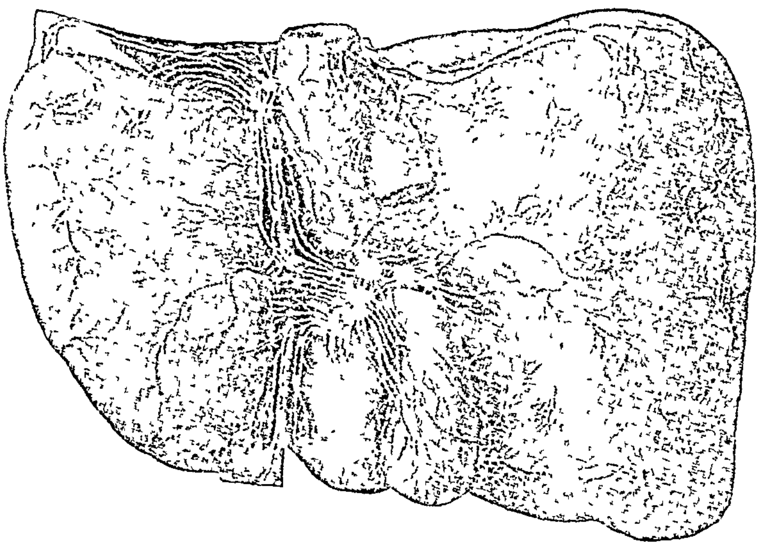

Fig 1.—Lymphatics of the liver and gallbladder, posterior view; first vicious circle in gall tract disease.

To understand the protean nature of gall tract disease, it is important not only to recognize the close anatomic contacts that exist between the stomach, duodenum, pancreas, liver, gallbladder, gall ducts and certain portions of the colon, but also to realize the intimate interrelationship for producing or transplanting disease that exists between these organs because of their blood, lymph and nerve supply. The spleen, likewise, must be considered in connection with the portal system.

Careful students of this subject will do well to follow closely the recent contributions of Graham, Heyd, Rous and McMaster, Mann, Rosenow, Whipple, Boyd, Aschoff, Westphal, Pribram, Chiray, Matsuo and others.

Eight years ago, the procedure now known as nonsurgical drainage of the biliary tract was introduced. It was found that a more careful plan of examination of the mixture of fluids recovered (liver, pancreatic and gastroduodenal juices) by gross inspection, but more importantly by proper microscopic, chemical and bacteriologic study, supplied evidence, which, when added to the usual fundamental methods of diagnosis, served often to clarify an obscure diagnostic problem. When the previously recommended technic [1] is carefully and intelligently carried out, it is of great diagnostic value, and will disclose during the second and third decades, many cases of early gall tract disease which ordinarily do not progress to the more definite clinical picture common to the fourth and following decades.

Van den Bergh's,[2] Fouchet's,[3] Meulengracht's [4] or Bernheim's [5] determination of bile pigment in the blood, and Rosenthal's [6] test for liver function are of differential diagnostic value in gall tract disease.

The roentgen ray, in expert hands, can furnish diagnostic evidence of great value, but when positive usually represents late pathologic changes.

Graham's [7] recently introduced method of cholecystography is a distinct advance in roentgen-ray diagnosis but it, too, gives far more definite evidence of an established pathologic condition of the gallbladder than it can furnish in the earlier breeding period of the disease; nor does it greatly inform us regarding disease of the ducts, and less of the liver.

This method, moreover, has some disadvantages still to be overcome. In addition to the sometimes severe reactions that followed intravenous use of sodium or calcium phenoltetrabromphthalein, now lessened by using the iodin halogen,[8] recently appearing experimental studies [9] have indicated a potential or actual damage to liver cells and tissue in addition to a local phlebitis, which has followed the intravenous use of various dyes.[10]

DIFFICULTIES IN DIAGNOSIS

Acute intra-abdominal disease, although often requiring astute differential diagnosis, in no sense offers the diagnostic problem common to chronic gastro-intestinal disease. In acute disease the intra-abdominal crisis often concerns predominantly one organ; in chronic gastro-intestinal disease there is rarely ever a distinct clinical symptomatology involving one organ alone.

[10] *Through the courtesy of Dr. H. R. Hartman* of the Mayo Clinic, we have learned that the oral administration of tetrabromphenolphthalein gives as satisfactory shadows of the gallbladder with negligible reactions. He believes that the dosage used, from 5 to 7 gm. in formaldehyd hardened capsules, is far in excess of the amount required.

A careful diagnostic survey will usually disclose multiple and interlocking disease of mouth and appendages, stomach, duodenum, gall tract, pancreas and intestine. Often disease or disorder of the nervous system, or of the cardiovascular-splenic-renal systems, or a disturbance in metabolism or endocrines will play a part either as contributing factors to or sequelae of chronic gastro-intestinal disease. Focal infection in tonsils, teeth, sinuses, lungs or bronchi, gallbladder, appendix, colon, prostate and pelvic organs, less frequently acute infectious disease flooding the circulation with bacteria, often initiate such chronic disease.

TOTAL DIAGNOSIS

Therefore, total diagnosis of chronic gall tract and associated disease, especially during the breeding period, is based on complete and methodical history and physical examination. This, when properly carried out and competently analyzed, furnishes a provisional diagnosis based on previous experience in clinical medicine. Sometimes, however, this is unreliable, and always incomplete.

Final diagnosis must be developed and proved by: (*a*) fractional gastroduodenal study; (*b*) biliary-pancreatic tract drainage study; (*c*) cardiac, hepatic, pancreatic, renal function tests; (*d*) intestinal motor function test to carmin, or to barium progress meal; (*e*) routine but complete study of feces, urine, blood, and less often sputum and saliva; (*f*) blood chemistry and serology; (*g*) general bacteriology, less frequently transplanted through animals; (*h*) expert roentgen-ray study; (*i*) various special tests; (*j*) in the very occasional case, operative exploration, which may become necessary to establish final accuracy of diagnosis.

DIAGNOSTIC BILIARY DRAINAGE

Nonsurgical biliary drainage, in its diagnostic conception, was based on Meltzer's "law of contrary innervation."[11] As applied to the biliary tract, this law of Meltzer's has been repeatedly challenged because many experimental physiologists cannot demonstrate its validity or even agree in their findings. We have elsewhere pointed out certain sources of error that must be overcome.

We believe that this law is fundamentally correct because of the accumulated clinical and laboratory evidence from more than 14,000 drainages. Furthermore, we have the testimony of Sachs[12] of Nebraska, Pribram[13] of Austria and Matsuo[14] of Japan that they have visualized the gallbladder expelling its contents as a result of intraduodenal stimulation with magnesium sulphate and peptone. And again, we have proof of the gallbladder emptying tetrabromphenolphthalein, using Graham's method, coupled with intraduodenal magnesium sulphate, as shown by D. N. Silverman,[15] C. R. Comstock,[16] H. M. Eberhard[16] and others.

TRANSITION FROM DIAGNOSTIC TO THERAPEUTIC PROCEDURE

Following the performance of repeated diagnostic drainages on the first groups of patients we studied, we were impressed by the striking clinical improvement, both subjective and objective, that often took place. This gave rise to the hope that in properly selected cases of gall tract disease, something definite might be accomplished therapeutically if a systematic course of frequent drainages could be given.

Experience proved that the response of many patients was most gratifying to drainage alone, although critics queerly asserted that much of this was due to a psychic reaction, ignoring the significance of the positive objective findings drained out in the bile and the various laboratory control checks. Gradually a more common sense combination of many nonsurgical measures was added with increasing success. Reports of series of such cases so treated have been published.[17]

The successful crux of the therapeutic problem lies in the proper selection (after thorough study) of patients in various stages of gall tract and associated disease, for whom appropriate surgical, nonsurgical or combination methods are adapted.

Upper right quadrant surgery is the most difficult abdominal zone to work in and requires experience, expert technic and sound surgical judgment.

Recent attention was directed to this aspect of the subject in a review[18] of a series of our cases in which operations were performed by first class surgeons in which the immediate mortality was 10 per cent. and there were serious hospital complications in 33 per cent. Even cursory examination of many protocols of multiple or even primary operations vividly shows that it is not merely a surgical "feather in the cap" whether or not the patient escapes a hospital death. Rather, does he recover a reasonably normal state of health? End-results and not surgical technic should be the criterion.

THREE VICIOUS CIRCLES IN CHRONIC GALL TRACT DISEASE

A close study of the factors concerned in the continued or relapsing ill health of the victim of chronic gall tract disease will show that there are three vicious circles at work.

The first is concerned with the lymphatic drainage between the gallbladder, liver and pancreas. If there exists a mural or interstitial cholecystitis of bacterial nature, the gallbladder becomes a genuine focus of infection and the lymphatic distribution reroutes the infection to the liver and pancreas and back again to the gallbladder. Such gallbladders will fail to be relieved permanently by nonsurgical drainage, and tend to relapse. The only way to break this first vicious circle definitely is to remove the gallbladder (Fig. 1).

Occasionally the focal mural infection may die out or become attenuated after connective tissue overgrowth has become excessive; but by this time the function of the gallbladder has usually been destroyed, and the end-result is much the same and warrants cholecystectomy.

From 70 to 85 per cent. of such gallbladders when removed early, without injury to ducts or without peritoneal soiling, will insure satisfactory recoveries which redound to the credit of surgery—the percentage of restoration to health being in direct ratio to the skill and technic of the surgeon who pays attention to reducing surgical trauma to liver, intestine, and the blood and nerve supply.

Am. **8**: 803 (Nov.) 1924; Therap. Gaz., November-December, 1924; Non-Surgical Drainage of the Gall Tract, Philadelphia, Lea & Febiger, 1923.

[18] Lyon, B. B. V.: Therap. Gaz., November-December, 1924.

Still too high a percentage of all cases relapse, most frequently when surgery is poor, but not infrequently despite the most skilful surgery. Seeking a reason for this, the commonest cause lies in a preexistent hepatitis which often creates a residual infection and catarrh in extrahepatic ducts (if not already infected), as pointed out particularly by Graham [19] and by Heyd,[20] and produces a relapsing cholangeitis heretofore often requiring secondary surgery.

In such cases, the liver, ducts and intestinal tract become the chief focal points of infection, and in them the second and third vicious circles become predominant.

The liver or ducts, or more commonly both, continue to carry the infected and poisoned bile into the duodenum and down through the intestine to exit in the feces. This disseminates the infection throughout the intestines until they, in turn, often develop mural as well as mucosal disease.

This second vicious circle, therefore, consists in reabsorption of bacteria or toxic substances in the bile by way of mesenteric veins, emptying into the portal vein, thence back to and through the liver, part of the toxic dose being shunted by the hepatic veins through the inferior vena cava into the right heart, but the larger part again reexcreted by the liver bile to be again reabsorbed in the intestine (Fig. 2).

The third vicious circle is similar, but represents that toxic portion of the bile picked up by the mesenteric lacteals, emptied into the receptaculum chyli, thence by way of the thoracic duct into the left innominate or left subclavian vein, finally to reach the heart. Once again this poisoned or impoverished blood is pumped out into the arterial circulation to exert a harmful effect on all tissues (Fig. 3).

Particularly important is that portion of total blood carried by the abdominal aorta to nourish the intra-abdominal viscera. After supplying the spleen, stomach, pancreas and intestines, the waste materials from such sources are in part again carried through their veins into the portal system and back to the overworked and functionally enfeebled liver cell to be reexcreted, and the vicious circle is renewed.

No wonder that the cardiac, renal, blood-vascular, neural and intestinal systems, in varying degrees in different cases, begin to groan with a wide variety of symptoms. The effect of the second and third vicious circles, especially in the visceroptotic patient, is clearly evident.

It is generally conceded that the liver has a wide margin of reserve, with great power of recuperation from direct and indirect insults. Nevertheless, the continued absorption of toxins devitalizes liver cells and in time seriously impairs or destroys their function and encourages degenerative tissue changes.

BREAKING THE VICIOUS CIRCLES

How, then, can the second and third vicious circles be broken? Obviously, each is beyond the scope of judicious surgery, which cannot remove the liver or ducts and have the patient survive, certainly not for long, as witness the recent experimental work of Mann.[21]

Herein lies the greatest value of nonsurgical drainage of the biliary system as a therapeutic agent. Previous surgical experience has shown that by removing from the body the quotient of recoverable toxic factors in the bile, the muscular irregularity of the heart disappeared, evidence of toxic irritation of the kidneys subsided, neural irritation (neuritis) quieted down and digestive function improved. In short, general symptomatic improvement was usually secured, but its duration was too often limited to the surgical drainage period; and relapse often occurred after sinus drainage was terminated, and the poisoned bile was again passed through the usual intestinal channels. Therefore, it appeared that simple removal of the bile from the body, plus the lesser element of bed rest, regulation of diet, etc, was the cause of much clinical improvement.

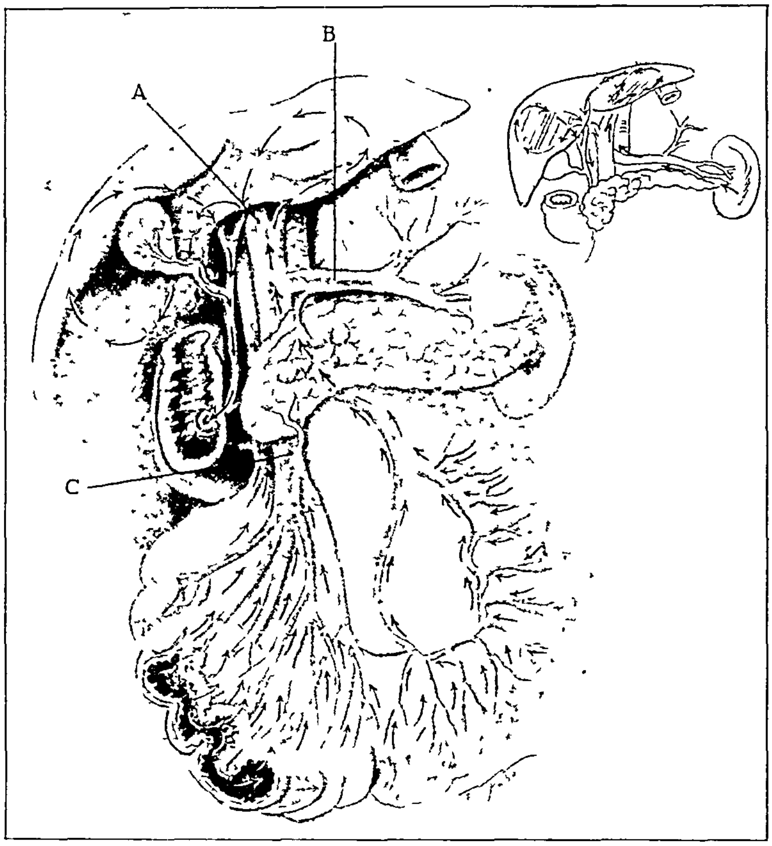

Fig 2.—Second vicious circle (blood) in advanced gall tract disease. *A*, portal vein; *B*, splenic vein, *C*, mesenteric vein

As knowledge of the first vicious circle became more widely appreciated the era of cholecystectomies

began, with increased success in the hands of first class surgeons. Nevertheless, relapses still occurred, as a result of the activity of the second and third vicious circles, factors in chronic gall tract disease not clearly enough appreciated.

Our experience indicates that the evil effects of this can be controlled and often eradicated by nonsurgical drainage, vaccine therapy and total management by methods already reported.

Maximum drainage of the liver and ducts can be secured by the duodenal tube. A study of many bedside notes and surgical reports of the amount of bile drainage recovered by glass or rubber intubation of common or hepatic ducts averaged not quite 500 c.c. in twenty-four hours (except in jaundiced cases due to common duct obstruction), whereas an average of 1,500 c.c. bile drainage in twenty-four hours can be secured by the duodenal tube.

INTERMITTENT DRAINAGE VERSUS CONTINUOUS DRAINAGE

Until about three years ago, nonsurgical therapeutic drainage was confined to the use of the intermittent method. By that, we mean a four to eight hour daytime drainage repeated at daily, semiweekly or weekly intervals. This amount of drainage was often sufficient to clear up the mildly catarrhal or infected gall tract systems, but was not adequate in securing permanent improvement in the more severe grades of hepatitis, cirrhosis, cholangeitis and pancreatitis.

A four hour morning drainage will recover, on an average, 300 c.c. of mixed bile of which three quarters approximately will be "AC" (duct-liver) fraction. An eight hour day drainage will average about 600 c.c. of which five sixths represents "AC" fraction. If such intermittent drainages are carried out once a week for two months the amount of bile recovered will average either 2,400 or 4,800 c.c. removed from the body during that period of time.

Each drainage removes from the body much inflammatory débris and myriads of bacteria, as is evidenced by microscopic and cultural examination. The transduodenal lavage flushes out the intestinal tract and helps to detoxicate, but despite eight weekly drainages, the catarrhal gall tract fills up for fifty-two out of sixty days. Therefore, it became apparent that in the more severe cases, the treatment should be intensified, and by degrees the present method of more continuous drainage was instituted, and found to be a practical procedure contributing to final success. Continuous drainage will recover and remove from the body an average of from 3½ to 4 gallons (from 13,248 to 15,140 c.c.) of bile in three weeks' treatment. This thoroughly drains the liver, revitalizes its cells, flushes ducts, prevents clogging with mucus, inflammatory or infected débris, avoids secondary stasis and minimizes the possibility of secondary calculi. It likewise drains the pancreas, lightens its labors and lessens chemical and bacterial insults to duodenal mucosa.

CONTINUOUS DRAINAGE SCHEDULE

8 a. m.	The mouth and stomach are prepared by thorough gargling and lavage.
8:30 to 12 m.	Duodenal drainage, stimulating with magnesium sulphate, peptone, olive oil, dilute hydrochloric acid, physiologic sodium chlorid solution or hot water (depending on whether the gallbladder has been removed or on the individual drainage response to any of these solutions).
12 noon	The tube is passed to a point 95 cm. from the teeth and the following duodenal feeding given:

		Calories
Milk (whole)	120 c.c. (4 oz.)	80
Cream	15 c.c. (½ oz.)	30
Yolk	1 egg	50
Lactose	15 gm. (4 tsp.)	60
Salt	1 pinch	..
		220

	The food is predigested for ten minutes with peptonizing powder, put in a vacuum bottle at 105 F. and introduced slowly by the rectal drip method, not less than thirty minutes being taken for its introduction. If nausea is present the egg yolk is omitted, the rate of inflow slowed, or both.
	The tube is clamped off for an additional half hour to permit this feeding to pass into the jejunum.
1 to 4 p m.	The tube is drawn up to 75 cm., marked and drained.
4 to 5 p. m.	The duodenal feeding is repeated.
5 to 8 p. m.	Bile drainage is resumed.
8 to 9 p. m.	Duodenal feeding.
9 p. m.	The tube is pulled up to 75 cm., marked and unclamped, and bile is drained into a gallon bottle throughout the night.
8 to 12 m.	The following day, the patient is restimulated with magnesium sulphate, peptone solution, olive oil, hot water or physiologic sodium chlorid solution and biliary drainage is continued until noon. A transduodenal lavaging enema of 250 c.c. of Ringer's solution is given, or suitable disinfectants—silvol, neutral acriflavine, mercurochrome-220 soluble, etc.—are substituted, as previously recommended. The tube is removed.
12:30 p. m.	A lunch of cereal, soft egg, toast, fruit juices or fruit.
3 p. m	Milk or crackers.
6:30 p m.	Dinner tray, either well balanced or low in animal protein and fat and high in carbohydrate, sugar, starch, as indicated by knowledge of the patient's gastric, duodenal, pancreatic and blood chemistry.
9:30 p. m.	Milk and crackers.

That night, the patient sleeps without the tube, and the following morning the foregoing schedule is repeated and so on over a period of from two to four weeks, until from 3 to 6 gallons (from 11,355 to 22,710 c.c.) of bile mixture has been recovered, provided the daily microscopic and biweekly cultural objective evidence parallels clinical improvement.

During this period of intensive treatment, the patient should be suitably controlled by additional laboratory observations (blood counts, blood chemistry, urinalysis, quantitative urine output, etc.) and the usual careful bedside notes carried out by a nurse trained in the technic of this management.

SELECTION OF CASES FOR TREATMENT

Biliary tract drainage, when properly carried out, will be found to have great therapeutic value in the following groups:

1. Relapsing cholangeitis (particularly after a cholecystectomy has failed to relieve) can often be cured without resorting to secondary operations, provided there is no evidence of residual stone in the common or hepatic ducts.

2. In many cases of obstructive jaundice due to impacted or ball-valve common duct stone the foregoing plan, aided by morphin, has lessened inflammatory

edema and sphincter spasm and permitted the stone to bob back into the dilated common duct. Occasionally, it has been passed and recovered in the sieved stool. After drainage has been established, the jaundice rapidly clears and toxic myocarditis and nephritis subside, and thus safer surgery is permitted at an earlier period than under the older form of management.

3. When proper judgment is used in the selection of patients, many persons with quiescent cholelithiasis may be restored to satisfactory health. Some patients with restless cholelithiasis with inflamed mucous membrane of gallbladder and gall ducts may be relieved of their colics and brought to a state of quiescence, and necessary surgery can be carried out at the most suitable interval period, as in appendicitis, when the risk is less.

4. In many cases of gall tract disease, including quiescent cholelithiasis, in which, for some reason (particularly in those of advanced years) surgery cannot be undertaken, we have seen nonsurgical drainage substituted for surgery with most satisfactory results. When there are serious surgical contraindications in gallbladder disease requiring cholecystectomy, a week or two weeks of preoperative drainage, when practicable, serves to detoxicate the patient more rapidly, and permits earlier surgery with increased safety.

5. Postoperative persistent hiccup, and vomiting may be brilliantly checked sometimes after the first few hours of drainage, certainly after a day or two. A number of cases of epidemic hiccup have been promptly aborted. In most of these cases, a streptococcus has been isolated from the bile.

Postoperative adynamic ileus has been successfully combated by biliary drainage and duodenal lavage.

6. Some persistent biliary fistulas have been successfully closed by this form of drainage, with the aid of vaccines. Jaundice following arsphenamin treatment can be aborted.[22]

7. Simple catarrhal jaundice usually clears promptly in from two to seven days after the obstructive plugs of mucus are removed. This spares the liver and pancreatic cells many days of pressure damage.

8. Early gallbladder and gall duct catarrhs, with subinfection, and especially cystic duct obstruction due to catarrh, diagnosable only by medical drainage study, can often be permanently cleared up and later more serious pathologic conditions prevented Cholecystitis as a complication of acute infectious fevers will often respond favorably. The objective drainage findings in many infectious fevers give evidence of the early mucosal damage to gallbladder and ducts, microscopically showing pronounced exfoliation of tall and short columnar gall tract epithelium.

9. This continuous method of drainage, modified slightly in diet, has been found an excellent plan of treatment for gall tract disease associated with duodenitis or the medical form of duodenal ulcer.

10. There is a large group of patients with hepatic-intestinal toxemia who give vague histories of atypical digestive symptoms, "dyspepsia," "nervous indigestion," and "biliousness," with anorexia, constipation, headache, nausea, belching, flatulence, dizziness or vertigo, and various skin changes—swarthiness, petechiae, "liver spots" or telangiectases—suggesting biliary or portal cirrhosis, but no definite evidence in physical examination, roentgen-ray studies or drainage findings to condemn the gallbladder or appendix. In many patients of this group, the gallbladder and appendix have already been removed. Medical biliary drainage and colonic irrigation will secure much better results than calomel or other drugs.

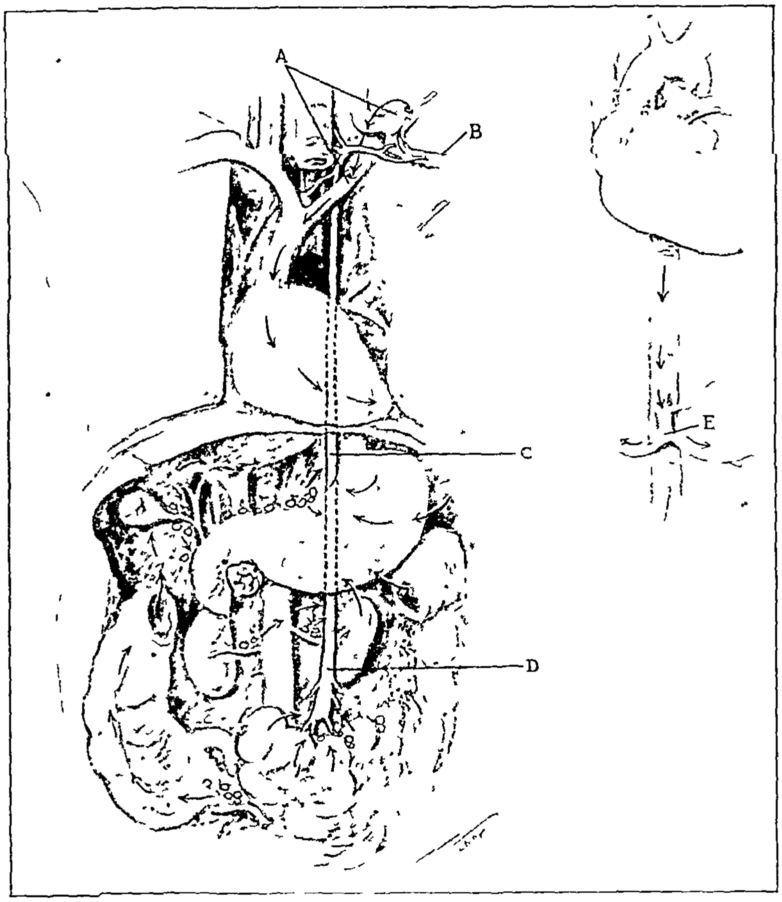

Fig 3.—Third vicious circle (lymph) in advanced gall tract disease: *A*, innominate vein; *B*, subclavian vein, *C*, thoracic duct, *D*, receptaculum chyli, *E*, celiac axis.

11. Another large group suffers with severe sick headaches, often cyclic, suggesting biliary migraine. Many such patients can be completely relieved. It is important to exclude headaches due to eye strain, sinusitis, nephritis, arteriosclerosis, ovarian dysfunction and intracranial conditions which require different treatment. The use of erysipelas and prodigiosus toxins (Coley's serum) has been worth while in some unusually stubborn cases not responding to other measures.

12. Certain forms of asthma which do not type properly to allergy tests seem to be due to some toxic factor within the gastro-intestinal tract which responds favorably to this form of treatment.

13. In association with other measures, some cases of chronic neuritis and arthritis have been greatly improved, particularly joint cases in which there is

[22] Wilhelm, L F X: Duodenal Lavage in Treatment of Jaundice Complicating the Treatment for Syphilis, Arch Dermat. & Syph. **10**: 499 (Oct) 1924

infection within the liver or intestine. All recognizable extra-abdominal foci should be removed, if possible.

14. In a group embracing typhoid carriers, flagellate or other parasitic infections involving biliary tract and upper intestines, this treatment will be found helpful. Giardiasis is especially stubborn and, in its tendency to relapse, suggests invasion of the gallbladder.[23]

15. Finally, there is a group embracing various problem diseases for some of which cases very distinct improvement has been secured. In cirrhosis of the liver, when detected in an early stage, often accidentally at the time of gall tract surgery, this treatment, when added to the orthodox plan of management offers some promise of forstalling the later more serious aspects of the disease.

Among others benefited may be mentioned a patient with hemolytic jaundice with splenomegaly, several with pernicious or grave secondary anemias (due to circulating liver toxins?), chronic pancreatitis or subfunction. Some patients with diabetes have been distinctly aided.

A case of erythema nodosum and a case of purpura hemorrhagica, both in association with manifest gall tract disease, cleared up satisfactorily, after diet and chemotherapy alone had previously failed.

We have had several cases of a nontraumatic form of epilepsy, especially in young adults, but in two cases of chronic epilepsy of many years' standing, the seizures were greatly lessened in frequency and severity, after phenobarbital and other drugs had failed to relieve. One man, aged 49, who had weekly convulsive attacks, has gone without an attack for more than a year since drainage and colonic irrigation were discontinued. There is clinical evidence to suggest that there may be circulating toxins from liver or intestines, the removal of which by drainage and irrigation prevents or ameliorates the attack. The foregoing group embraces our personal experience.

LIMITATIONS OF NONSURGICAL DRAINAGE

We have heretofore called attention to the limitations of this method. Our views have been aptly summed up by Niles,[24] after an experience of more than 3,000 drainages. He says:

> In order to properly evaluate any procedure, the therapeutic use of such a procedure should presuppose: First, that the proper cases should be selected, and secondly, that the procedure should be carried out in a thorough and skilful manner. . . . The assumption that this method will remove gallstones, will break up adhesions, will cure appendicitis, or cancer of the liver, or remove deep seated organic pathology of the gallbladder and duct, is ridiculous, and the patients should be plainly so informed. . . . Furthermore, no physician should use this method unless he goes into it wholeheartedly, performing it in a technically correct manner, and is willing to persevere in his efforts, regardless of either active opposition from many of his confrères, whose approbation he desires, or those who would "damn it with faint praise."
>
> While neither the principle nor practice of nonsurgical gall tract drainage is accepted by a multitude of conscientious physicians, on the other hand, a multitude who are employing it are getting satisfactory results.
>
> The writer wishes to express an earnest belief that this procedure will continue to enjoy a wider acceptance among the medical profession, as its real value is better understood, and its limitations more definitely fixed; and that it will eventually reach a proper and accepted place as a recognized therapeutic procedure.

This summarizes the position which we have constantly maintained.

THE NECESSITY OF TOTAL MANAGEMENT IN GALL TRACT DISEASE

In association with the use of nonsurgical drainage as a preoperative and postoperative measure, total management of chronic gall tract disease should embrace a dietetic regimen of frequent small feedings with reduced fat and animal protein content, colonic irrigations when indicated and vaccine therapy. Chemical therapy by mouth should be prescribed only to correct known factors of abnormal gastroduodenal, pancreatic and biliary tract chemistry. Common sense efforts should be directed to restoration of normal bowel function, breaking the laxative habit—constipation vicious circle—and, finally, education of the patient to adjust his life so as to place the least strain on damaged organs.

HOW MUCH BILE DOES THE LIVER SECRETE?

During our experience with continuous therapeutic drainage, we were struck by the very large quantities of bile that can be recovered by duodenal tube. In many instances, from 3 to 6 gallons (from 11,355 to 22,710 c.c.) could be removed from the body in from three to four weeks' time. Depending on its viscosity and admixture with other fluids, such as gastric, duodenal and pancreatic juice, a gallon averages 7 or 8 pounds (3.2 or 3.6 kg.) in weight. From 35 to 40 pounds (from 16 to 18 kg.) of fluid weight have been extracted with inconspicuous loss of body weight. Indeed, certain patients show a gain in weight despite the diminished caloric intake.

In some cases, it would appear that the larger amount of bile secreted by the liver was removed since the stools were brought to an acholic state. In others, the color of the stools and the tests for the bile content indicated that, despite the withdrawal of these large amounts, it did not represent the recovery of the total bile secreted.

We question whether this large withdrawal of bile from utilization for digestive function could be practiced without unfavorable results in persons with normal digestion and no intra-abdominal disease. However, in the sick, especially those suffering from hepatic intestinal toxemia or advanced gall tract disease, the beneficial effect of such treatment is very striking.

Should we not recast some of our former views expressed in current textbooks in regard to how much bile the liver secretes? It has been generally stated to range between 1,000 and 1,500 c.c. in twenty-four hours. Our experience leads us to believe that these figures are much too low. Perhaps they could even safely be doubled. Admitting the fact that the fluids recovered from the duodenum represent a mixture of secretions from liver, pancreas, stomach and duodenum, which cannot be readily separated for individual analysis or weighing experiments, it would appear that by far the largest part represents liver secretion.

Case 1.—From a man with chronic cholecystodochitis and catarrhal cystic duct obstruction (but without jaundice), severe pain, depression and erythema nodosum, 16,960 c.c. (4½ gallons [17,033 c.c.] of bile mixture) weighing 35 pounds (16 kg.) was recovered in twenty days. The actual number of drainage hours was 147, representing 113 c.c. an hour, or 2,764 c.c. in twenty-four hours. The patient's weight on admission was 207 pounds (94 kg.), on discharge, 201 (91.2 kg.). There was entire symptomatic recovery over a period of one year.

---

[23] Giardiasis, Frequency, Recognition, Treatment and Certain Clinical Factors, to be published.

[24] Niles, G. M.: J. M. A. Georgia **13**: 165 (April) 1924.

Case 2.—From a man, aged 32, with cirrhosis of the liver with subjaundice, two years after a cholecystectomy, 19,760 c.c. (5 gallons) of bile mixture weighing 40 pounds (18 kg.) was recovered in 133 drainage hours, over an eighteen day period, or at the rate of 141 c.c. an hour, or 3,384 c.c. for each twenty-four hours. His weight on admission was 121 pounds (54.9 kg.), on discharge, 123 (56 kg.). One year later, this patient remained greatly improved, was no longer jaundiced, and had gained 30 pounds (13.6 kg.).

In states of frank jaundice, the amount of bile recovery is much larger but this does not indicate increased secretion, as shown by Case 3.

Case 3.—From a man, aged 50, with postoperative obstructive cholangeitis, 3,600 c.c. of bile was recovered in eighteen hours, or at the rate of 200 c.c. an hour, or 4,700 c.c. for each twenty-four hours.

Case 4.—A man, aged 50, had had previous operations; a pyloroplasty, a cholecystostomy and an appendectomy in 1916, and, following a relapse, a cholecystectomy and a choledochostomy in 1917. Three weeks' surgical drainage recovered 1¾ gallons (6,624 c.c.) of bile. He was referred in 1922, seriously ill with relapsing cholangeitis with jaundice, Grade 4, pain, fever, sweats, leukocytosis and myocarditis. Continuous drainage for five days recovered 2½ gallons (9,463 c.c.) of bile. Microscopy revealed acute catarrhal inflammation and *Staphylococcus aureus* infection. Vaccine was given. Improvement followed. A lesser relapse occurred four months later, with jaundice and pain. Eighteen hours' duodenal drainage recovered 3,600 c.c. of bile. There was prompt improvement. Intermittent drainage was carried out for a year. No further relapses occurred, and in 1925 this patient remains in much better health.

We have noted that a proportionately larger amount of bile is often recovered during the night drainage hours, during the interdigestive phase, when the liver is not being stimulated by ingestion of food. Frequently, amounts ranging between 800 and 1,800 c.c. of bile mixture have been recovered from 9 p. m. until 9 a. m. An increased rate of liver secretion can be noted in certain cases following the introduction of a duodenal feeding, whereas in others this effect is not so marked.

Clinical observations on different patients, indicate that there is a distinct variability in the rate of bile secretion in individual livers. In some, it appears greatly accelerated; in others, definitely retarded. Most of our experimental observation has concerned persons who were sick. Not enough opportunity has developed for controls with so-called normals, because of the difficulty in securing normal persons who will undergo this form of clinical experimentation.

ILLUSTRATIVE CASE

The beneficial effect of biliary drainage on a laboring cardiorenal system clinically noted can often be substantiated by laboratory findings.

Case 5.—A man, aged 52, had relapsing cholangeitis after a cholecystectomy for gallstones performed one year earlier. Pure cultures of *Bacillus typhosus* of the "carrier" type were revealed twenty-seven years after the primary infection. This patient, with damaged cardiovascular and renal systems, was seriously ill, jaundiced and in severe upper abdominal pain. Intermittent drainage, followed by continuous drainage, recovered 14,440 c.c. (3⅝ gallons) of very viscid liver bile, weighing 31½ pounds (14.3 kg.) after 124 drainage hours, with definite clinical improvement. The laboratory control is illustrated by the accompanying table.

* Albumin, glucose and ketones negative throughout. Bile positive from February 24 to March 3. Discharged April 14.

The improvement in blood chemistry findings was conspicuous in regard to urea and nitrogen retention, and suggests that by withdrawal of these elements in the bile, a load is lifted from laboring kidneys, permitting better function. This is in keeping with the latest experimental work of Mann,[25] indicating that the liver is the chief organ concerned with the formation of urea.

SUMMARY OF THERAPEUTIC RESULTS SECURED

In a recent study of 376 cases, 318 were treated by nonsurgical measures alone, in which duodenal drainage was featured. Some patients had incipient disease, some late pathologic changes with complications, and many were seriously ill. Thirty per cent. remained "cured;" i. e., symptom free for from one to four years; and objective findings became normal.

---

[25] Bollman, J. L.; Mann, F. C., and Magath, T. B.: Am. J. Physiol. 69: 371 (July) 1924. Mann, F. C.; Bollman, J. L., and Magath, T. B.: Ibid. 69: 393 (July) 1924.

Fifty-two per cent. were so much improved as to resume former occupation, discard further active treatment and remain in good health for periods longer than one year.

Nine per cent., in a group representing chronic illness of many years' duration, were considerably improved.

Two per cent. were entirely unimproved. Only one patient (0.2 per cent.) died.

Of this series of 376 patients, fifty-two had gall tract surgery practiced without relief, averaged two abdominal operations per patient and were badly incapacitated. This result was partly due to persistent postoperative complications and partly to bad choice of original operation, or incomplete exploration and failure to recognize a multiple lesion. Many were found to have residual pus or bacterial foci in tonsils, teeth, etc., which accounted for relapses or unfavorable end-results.

Twenty-seven of these fifty-two patients were treated entirely by various nonsurgical procedures, including biliary drainage and vaccines with marked improvement; nineteen patients required further gall tract surgery, preceded and followed by nonsurgical drainage, before health was restored.

Our five years' experience has shown that excellent end-results have been secured in three out of four gall tract patients by the use of nonsurgical measures alone. It is impossible to evaluate end-results in any comparative series of gall tract cases in which operations were or were not performed and draw reliable conclusions. Individual cases vary too greatly. But analysis of the details of this study will show that the results speak for themselves.[18]

We believe that many gall tract operations now being done (often because of errors in diagnosis) might be avoided if expert nonsurgical management is available; but, we also believe that in conditions of chronic gall tract disease, the indications for cholecystectomies may even be increased.

This seeming paradox is explained by the fact that diagnostic biliary drainage, when intelligently performed, will detect larger numbers of nonfunctioning gallbladders due to obstructed cystic ducts, with associated evidence of hepatitis or cholangeitis. This will demand a larger number of cholecystectomies to break the lymphatic vicious circle between liver and pancreas, that only surgery can accomplish. Thus, only the functionless gallbladder will be removed, to the benefit of the patient. We believe that there will be a smaller number of postoperative relapses if cases treated by surgery are given preoperative and postoperative nonsurgical drainage.

All cases of advanced gall tract disease theoretically require surgery; but cholecystectomy removes only one end-product of gall tract disease, and not the disease itself. Practically, surgery might better be confined to removal of pathologic conditions (gallbladder, stones, cancer, adhesions, stricture, etc.) or to short-circuiting operations for nonremovable obstructive lesions (cholecystoduodenostomy, etc.) and then drainage established in nonobstructive lesions by duodenal tube methods. This will prove to be the better, if not the only, way of breaking the second and third vicious circles in chronic .ll tract disease.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. CARLSON; MANN; GREENE; OPIE; MCCLURE, MENDENHALL AND HUNTSINGER, AND LYON AND SWALM

Dr. L. G. Rowntree, Rochester, Minn.:. Dr. Carlson's statements fairly present our present knowledge of the physiology of liver function. Dr. Whipple calls attention to another important matter, and I hope that we shall follow up his suggestive leads in regard to possibilities of better dietetics in the treatment of anemia. Dr. Mann's work will go down into medical history, along with Claude Bernard's work on the glycogen function of the liver. By means of hepatectomy he has been able to gage the function of the liver. His findings are of tremendous significance to biology, physiology and medicine. Unfortunately, the results of his work are not all generally applicable in the clinic. His uric acid work, however, contains another fertile suggestion, and it should be worth while to follow this up in the clinic. Dr. Opie has touched a most important need in medicine: the correlation of function and morphology in the study of diseases of the liver. There is no field of differential diagnosis at the present time more unsatisfactory than that of the liver, especially in the field of jaundice. A knowledge of such matters as Dr. Opie has discussed is essential to diagnosis. Furthermore, we need more information on the funcion of the liver in experimentally induced diseases of the liver. Dr. McClure has brought out new methods of approach. It seems a field well worth while cultivating. I myself do not believe we are justified in drawing definite, clean-cut conclusions, relating to liver function, on the quantitative side, from the data based on the examination of mixed juices found in the duodenum. The question of interpretation of the findings is difficult. We must go slowly in accepting these results as quantitative for the liver, until they are proved to be so. I am particularly interested that Dr. McClure is following function from the standpoint of treatment, for, after all, it is of great significance to ascertain whether the measures employed in liver diseases are effective from the standpoint of benefit to the patient. We have found that circulatory disturbance is a great factor in some conditions, particularly in cirrhosis of the liver. In some instances, the liver function has improved as the ascites of cirrhosis has been cleared up under the use of novasurol. Dr. Lyon's work is familiar to us all. In Rochester, we rarely use and rarely obtain information of value from transduodenal drainage from the standpoint of diagnosis. Also, we are using it less frequently than formerly in treatment, though we do get favorable results from it at times. However, in fairness, I should admit, that, so far as I know, we have had no experience with the long-continued drainage to which he has referred. I concur in Dr. Greene's conclusions most heartily. The cases that constituted the basis of his report are proved cases. In the field of function study there exist many striking analogies in regard to the liver and kidney. At present, we consider the phenoltetrachlorphthalein test the most valuable single test. I wish to pay tribute to Dr. Rosenthal, who has done much to popularize this test.

Dr. Franklin W. White, Boston: The most serious difficulty in liver function tests is the tremendous compensatory power of the liver, the large margin of safety, which is a fine thing for the individual, but hard for the test. The older tests for sugar tolerance, and nitrogen in the blood and urine have been disappointing in diagnosis. They have been rather characteristic of disease groups, as Dr. Greene has said, not diagnostic in individual cases. Dr. Greene has been wise in laying stress on two tests, on the excretion of certain dyes and the detection of serum bilirubin. The excretion of tetrachlorphthalein seems to be one of our best methods of diagnosis at present. We get marked retention in serious diseases, such as cancer, cirrhosis and syphilis of the liver, and we also get retention in less serious cases, such as infectious jaundice and toxic conditions (after arsphenamin), and by using this test we can follow the condition of the liver. With regard to the serum bilirubin test, there is no question that bile in the blood precedes and is more important than bile in the tissues, and it seems reasonable to use this as a liver function test, and at the present time it is proving valuable in detecting liver injury. The value of this test may lead to some unreasonable expectations. I will cite a single instance: Jaundice is an important sign of gallbladder disease; we expect some hepatitis. Will the test for latent jaundice help us to pick up more latent gallbladder cases? It would seem not. We get hepatitis, but Dr. Greene found little change in liver function. This is a minor point. I was interested in the close parallelism in the two tests, namely, the retention of dye and the blood bilirubin, and it seems possible at that time we might use the simpler test to represent the whole situation, instead of carrying out both, which means more work. The tests for bile solids which Dr. McClure has presented seem perfectly logical and reasonable; we do not expect a diseased liver to pour out normal bile. There are, however, some drawbacks. The chemical methods for the detection of bile solids are at present dubious, and also the duodenal contents have many variables. We have some stomach contents, some duodenal secretion, some pancreatic secretion as well as a variable mixture of gallbladder and liver bile, and it seems to me remarkable that in the presence of so many variables Dr. McClure's quantitative results have been so consistent. Nonsurgical biliary drainage has seemed to me, from the purely clinical side, to have real value as a method of treatment in a limited group of cases, not so much in emptying the gallbladder as in draining the general liver passages and getting rid of infected bile. Dr. McClure's studies have shown that the duodenal contents are completely changed in character in chronic gallbladder cases after repeated drainage with magnesium sulphate. This perhaps is an indication of real value in this method in certain cases.

Dr. Martin J. Synnott, Montclair, N. J.: My experience with nonsurgical duodenobiliary drainage began about five years ago, and during this time we have done the procedure approximately 3,000 times. We follow the Lyon technic, except that we now rarely wash the stomach, unless there is a definite indication for so doing, as we have found that the metal tip of the tube passes more readily into the duodenum if the stomach washing is omitted. We believe that the stomachs of certain hypersensitive patients are irritated by lavage to a state of very active peristalsis, which accounts for our failures in intubing the duodenum, causing the tube to coil up in the stomach, and in a few instances actually tying knots in the tube. Our procedure now is to pour through the tube into the stomach, after the tube has been swallowed to the 55 cm. mark, 100 c.c. of water; then we have the patient lie down on the right side, and swallow very slowly, taking twenty minutes to do so, to the 75 cm. mark, at the end of which time the tip is almost invariably found to be in the duodenum. Dr. Lyon has referred to the value of nonsurgical drainage of the biliary tract in diabetes. I should like to elaborate a little on this subject. In the fall of 1921, a series of experiments was conducted at the Physiatric Institute in Morristown at my suggestion and under my direction, and the report of the work was published by my co-workers, Dr. J. J. Selman and Dr. H. S. Martland and myself in the *Journal of Metabolic Research*, March, 1922. We did duodenobiliary drainage in fifty-three diabetic cases. Twenty, or 37 per cent., of these cases gave a definite history of jaundice or affections referable to the upper right abdominal quadrant. Six cases, or 11 per cent., showed positive and conclusive evidence of existing biliary infection. This led us to conclude that, in an appreciable percentage of diabetic cases, ascending duct infections, or gallbladder infections extending into the pancreas, either directly or through the lymph channels, played an important part in the etiology of the disease. We believe that every case of diabetes should be carefully examined and studied according to the Lyon method because it is the most practical, the most available, and in certain early cases the only method of determining whether or not the biliary system is infected. Where such infection is found to exist, it is most important to give therapeutic drainages in order to eliminate one of the main factors contributing toward downward progress. Since this article was published, I have had a chance to observe the results of duodenobiliary drainage in numerous cases of chronic diabetes in the middle aged, where I have reason to believe gallbladder and duct infections have been the main etiologic factors in causing the pancreatic disease, and where continued therapeutic drainage according to the Lyon technic has not only cleansed up the biliary infection but has relieved the clinical symptoms of the diabetes and increased the carbohydrate tolerance of the patients, without insulin or rigid dietary regulation.

Dr. J. Quincy Thomas, Morristown, Pa.: I am convinced that biliary drainage as a therapeutic measure is no longer a theory; it is a fact. Proved theories are facts. We all accept new theories with more or less mental reservation, but after they have become proved we should be broad minded enough to accept them as facts and I have accepted biliary drainage as a therapeutic and diagnostic measure because we are dealing with facts. Prior to the publishing of the technic which has been so carefully worked out by Dr. Lyon, what method did we have of treating these cases outside of surgery? Nothing but the common methods which some of us are still sticking to. Biliary drainage today as carried out by the Lyon method, and not any short-cut method, will give wonderful results in the properly selected cases. Following cholecystectomies, what methods did we have prior to the biliary drainage method? Again, we had nothing of any account. We gave calomel and magnesium sulphate, sent our patients to resorts and what not, and when they returned we had to resubmit them to the surgeon. Today we have a very simple method which will give complete relief to our patients, and we can promise much in these cases if it is carried out according to the method as subscribed by the author. I want to make the plea to stick to this method; I am sure the results will be surprising. The three vicious circles of which Dr. Lyon spoke in which he plainly admits that the first cycle can be cured only by surgery is exactly right. The two other cycles will respond to proper biliary drainage. The Lyon method includes not only passing the duodenal tube into the duodenum and draining off a few cubic centimeters of bile and trying to arrive at a diagnosis, but also a very careful study of the patient as a unit, and we sometimes get overscientific.

Dr. S. M. Rosenthal, Montreal: In an attempt to find out the mechanism by which certain dyestuffs and bilirubin are excreted by the liver, I have studied their behavior from a physicochemical standpoint. By ultrafiltration experiments I have found that they circulate in the blood firmly bound to the serum proteins. This prevents their elimination by the kidneys. Bile salts, by virtue of their effect on surface tension, are able to liberate bilirubin and these dyestuffs from their adsorption compound with the proteins, so that they can be further excreted by the liver. This is of interest because it indicates a physiologic rôle for the bile salts in washing away, from the blood proteins, substances that are excreted in the bile, and because it is an approach to the explanation of certain phases of the mechanism of hepatic secretion. The objection is frequently raised that dyestuffs are unsuitable to test the functional ability of an organ because they are unphysiologic. This can hardly be upheld if we do not even know what physiologic means, and my studies indicate a similar mode of excretion for the dyes and for bilirubin. Bromsulphalein, a new dye worked out by Dr. White and me, has proved the most satisfactory in the clinic as a test for hepatic function because of its simplicity of technic and its freedom from untoward reactions. Normally it is excreted in the bile more rapidly than any other substance I know, and in liver disease its retention in the blood is the most striking. In acute liver disease there is a tendency for the various function tests to give parallel results, although differences occur which have not been fully explained. In chronic liver disease, information may be obtained from the dye test which can be obtained in no other way.

Dr. Robert H. Rose, New York: Nonsurgical gallbladder drainage, in my experience, has benefited patients who could not have been helped with other methods. The first case was migraine headache, occurring twice a week. I had dieted this patient according to my former information and had produced some benefit, but the headaches were recurring, not quite so severe, but as often, and the nonsurgical gallbladder drainage stopped the headaches. I have seen the same thing happen in other cases. There is no question about it. I have used silver nitrate, 1:6,000, in conjunction with Epsom salt, and found that it does not interfere in any way with the use of Epsom salt. One can inject Epsom salt and follow almost immediately with silver nitrate, and it does not interfere. I believe that silver nitrate is of benefit in many instances, and helps in these cases as well. It will aid in drainage when there is a great deal of mucus; it cuts mucus and permits the solution to come through the small tube.

Dr. L. R. Whitaker, Boston: With regard to the question of nonsurgical biliary drainage, a discovery has been made which seems to be of considerable importance. In 1922, Dr. Edward A. Boyden of the Medical School of Harvard University found that by feeding cats a mixture of egg yolks and cream the gallbladder could be made to empty in from three to six hours. We have found independently by the use of cholecystography at the Peter Bent Brigham Hospital that after the patient had been given food containing fat, the gallbladder shadow would exhibit a marked shrinking within a period of from half an hour to two hours. Following this we tried several substances, among which was magnesium sulphate, which had been previously observed by Silverman and Menville to produce a reduction in size of the gallbladder shadow when given by the duodenal tube. The mixture of egg yolks and cream produced in one subject a much more striking reduction after a period of one and one-half hours than was exhibited in another subject after the intraduodenal injection of magnesium sulphate over a longer period than that. This is a finding which I believe has a great deal of bearing on nonsurgical drainage and would seem to offer an entirely new view.

Dr. William Henry Kraemer, Wilmington, Del.: I consider myself an embryo in duodenal drainage. I am still working on my first hundred cases. There were just one or two points that were not brought out and I want to ask largely for information. The first was that Dr. McClure, who spoke before Dr. Lyon, mentioned the variation in dose of magnesium sulphate in those cases in which he failed in the usual prescribed amount. The second was the striking experience I had in finding the short chain streptococci in gallbladder cases, which also was revealed in the focal infection of tonsillar abscesses and in teeth. The other point I wanted to make was that I usually follow up my gallbladder drains with sodium phosphate to stimulate still further the function of the liver. What I principally wish to ask is, What are the variations in magnesium sulphate doses from the usual ones described by Dr. Lyon?

Dr. Daniel N. Silverman, New Orleans: The original studies on the effect of magnesium sulphate administration on the visualized gallbladder have been made by Dr. Menville and myself. The introduction into the duodenum of a singular dose of magnesium sulphate solution produces an apparent modification in the size of the gallbladder shadow. Our later experiments have proved that repeated injections of magnesia produce a greater reduction of the gallbladder shadow. The employment of magnesium sulphate for gallbladder drainage by the Meltzer-Lyon method is obviously advantageous, since it allows for a microscopic study of the bile return.

A. J. Carlson, Chicago: One of the men discussing these papers said he was convinced that what Dr. Lyon said regarding biliary drainage, diagnosis and treatment was true. He said he was convinced of its truth. I can only say I wish it were true. I did not have time to develop the physiology of the gallbladder and the possible reflex relations to the duodenum. I have tried my best to understand the physiologic mechanisms of the results reported on gallbladder drainage by Lyon's technic. Textbooks usually state that bile does not enter the intestine between meals. That is wrong. If there is no mechanical obstruction, bile enters the intestine practically all the time, even during fasts of from fifteen to thirty days in man, and of sixty days in dogs. Show me the data proving that magnesium sulphate in the duodenum drains the bile tract any more completely than does food. I do not understand Dr. Lyon when he says that he "disinfects the duodenum." What is meant by "poisoned bile"? One of the men reported hookworms in the contents returned from the duodenum. How many hookworms would he have secured with a dose of salts by mouth followed by examination of the stools? The removal from the body of the amount of bile reported cannot have much significance either for the gallbladder or for the intestine, unless there is an unusual permeability or irritability of the intestine. Pus in the bile may be significant, but what symptom is induced by this pus acting in the intestine? We are swallowing bacteria every day. There are a few bacteria that are specifically toxic in the intestine. There are a few toxins poisonous by mouth, but, so far as I know, we could eat pus, ordinary pus, and not be influenced, excepting esthetically. It is not clear, therefore, that finding bacteria or pus in the duodenal content means injurious effects from the bacteria or bile lower down. The vicious circles that Dr. Lyon describes are largely theoretical, except the first one, in which there is mechanical obstruction. I have tried to understand the duodenal drainage therapy on its physiologic basis. I do not understand how the effects reported can possibly be due to drainage of a patent bile system with the additional removal of some of this bile from the duodenum. In saying this I may merely be exposing my ignorance. But I feel that in the cases in which Lyon's duodenal drainage is followed by improvement we must search for additional factors. Koch's postulates are still good science and good medicine. Has Lyon or Smithies reproduced the disease by putting the duodenal return into the duodenum of well persons or dogs? Dr. Rowntree said I was a harsh critic. I try to be fair in my destructive and helpful in my constructive comments.

Dr. George H. Whipple, Rochester, N. Y.: I am a little bit skeptical about some of the things Dr. McClure said. I was not aware that there were accurate tests for bile salts in the presence of duodenal secretion. I should like to be pleasantly surprised. Therefore I do not know just what Dr. McClure was measuring, but I don't believe he was measuring bile acid. I know a little about the dye test in the clinic from my association with Dr. Rowntree some time ago. I believe that in the literature too much emphasis has been placed on these dye elimination tests when jaundice and obstruction are present in the biliary passages. I don't believe this dye test is of any value whatever when there is obstruction of the bile passages. With no abnormality of the bile passages, dye elimination has definite value; but how often can the clinician be sure that the passages are normal? I feel that the interpretation of the dye test in many clinics has not been rigidly enough controlled. I may say that Dr. Greene and Dr. Rowntree have been very careful in their interpretation.

Dr. F. C. Mann, Rochester, Minn.: It is rather gratifying to me after working several years on the physiology of the liver to have this free discussion. It has brought out the great importance of the liver not only physiologically but also clinically. I think that in future years we are going to see the liver occupy a more important position physiologically, pathologically and clinically. Let us go a little slow in some respects until we know more about the function of the liver. For example, the levulose test was mentioned as a method of determining liver function. In some recent experiments we have found that the body can seemingly utilize levulose without the liver. How could it be a liver function test when the body can utilize it without the liver? This is true also of many other of the liver functions. In many of the physiologic processes in which the liver is involved, other organs or tissues also play an important part. A good example of this is the relation of the liver to the blood sugar level. The liver regulates the concentration of glucose in the blood, but the pancreas and other tissues have to do with its utilization. The difficulty of establishing a glucose tolerance test for liver function is readily seen.

Dr. Carl H. Greene, Rochester, Minn.: Dr. White raised the question of the use of the dye test in cases of jaundice. As I tried to make clear, jaundice completely dominates both the clinical and the laboratory findings. Under these conditions the dye test and the serum bilirubin are of value not so much in establishing the presence of jaundice as in furnishing a quantitative means of following the progress of the jaundice. Serum bilirubin will show the presence of latent jaundice, and in the absence of that dye, reaction will be of value. The dye test particularly will show diffuse injury to the liver, as a whole, much more readily than a localized lesion. Prolonged chloroform anesthesia will produce diffuse necrosis throughout the whole liver, and the dye test will show marked retention. Chloroform injected into the portal vein will produce areas of local necrosis, but the remaining liver tissue is undamaged. Under these conditions the dye test will not show changes because the uninjured normal portion of the liver is sufficiently active to give a normal test. The same thing is true in clinical experience. A patient with multiple metastasis with nodules in the liver may have sufficient undamaged liver tissue to result in a normal test. I saw one patient with a hydatid cyst giving a normal test because the left lobe of the liver was in normal condition, and 10 or 15 per cent. of liver may be sufficient to carry a patient through. Positive tests are of particular value in extending and increasing the knowledge that we obtain from clinical means. The question of latent jaundice in cholecystitis came up. The clinical picture of cholecystitis with stones is recognized by repeated attacks of colic and jaundice. Clinically recognizable jaundice does not always follow such colics. The finding of a bilirubinemia or latent jaundice in such a case has the same significance as jaundice. Medical literature has long been filled with references to biliousness, torpid liver, and so forth. An attempt has been made to interpret these in terms of actual insufficiency of the liver. Many different physiologic factors may enter to explain that condition. At present, our tests will not give positive objective evidence of actual disturbance in the liver in many cases of that type. It is all part of the larger field of the disease of the liver, and I don't want to be misunderstood in that relation because these tests are only one point in the question of diagnosis. The final test will depend on the correlation of the studies, not only of the physiologist, but of the chemist, the pathologist, the clinician, the internist and the surgeon as well.

Dr. Eugene L. Opie, Philadelphia: Dr. Lyon has suggested that toxic products from the liver return to the liver in vicious circle. It is important to realize that the liver has considerable capacity to overcome infection. The bacterial content of the blood might suggest that the liver has failed to control bacteria brought to it, but we have no index of its relation to toxic products of bacteria.

Dr. B. B. Vincent Lyon, Philadelphia: Dr. Carlson has challenged me to defend my position. The experimental physiologist who lives each day among his laboratory animals sometimes knows very little about the sick human animal as seen in general practice. Our problems are therefore different. Dr. Carlson asks me how much of my belief is based on proved facts and how much on theory. The laboratory problem can often be proved with mathematical exactness. Few clinical experimental problems can be proved except by deductive reasoning, and rarely in their entirety. The results of our methods of diagnosis and treatment of gall tract diseases speak for themselves. Our diagnostic platform utilizes all the agents spoken of today, but in addition we gain a further impression of the total clinical picture by a properly conducted study of duodenal aspirates. If a given sick man's gallbladder is surgically removed or its contents are drained and the patient regains health, no particular criticism is directed against surgical methods or the question raised as to why that patient improved. We accept that as a clinical fact. But if the sick man does not improve or becomes worse and goes through repeated operations and still continues to relapse, as a result of the vicious circles I have described, no matter how hypothetic Dr. Carlson chooses to call them, and, if under our methods of nonsurgical drainage plus total management the patient regains health and remains well under close observation, I submit that this should establish reasonable clinical proof of the value of such methods, even though we cannot explain the exact why of it to the scientist's satisfaction. Dr. Carlson asks me just what poisons we drain out of the liver. I wish I knew. I wish the physiologists or the physiologic chemists could tell us. We have listened to a symposium on the detoxicating and bactericidal powers of the liver and its other functions, and still we don't know. There is a great difference between what the healthy liver cell can detoxicate or destroy or manufacture, and what the diseased liver, working with damaged heart, kidneys, spleen or intestines, can do. Our removal of bile from such patients improves them. Hence, we argue that the bile is poisoned. Dr. McClure's methods should be commended. They are a step in the right direction and furnish help not yet secured from the pure scientist. We need more such work on the human animal. Such clinical studies will in the end contribute much to the progress of medicine that will be of profit to the patient.

Dr. F. C. Mann, Rochester, Minn.: In order that we might not go with too many definite, clean-cut things, I want to state that the pictures showing differences in sizes of gallbladder do not necessarily mean that the gallbladder emptied by forcing contents through the cystic duct. If these substances open the sphincter, the gallbladder would not fill and in the time available between pictures the size of the viscus could be diminished as much as shown by concentration. I don't know what did happen.

THYMUS AND THE TREATMENT OF ITS HYPERFUNCTION

CLINICAL AND ROENTGENOLOGIC CONSIDERATIONS *

LAWRENCE R. DE BUYS, M.D.
ERNEST C. SAMUEL, M.D.
AND
ELEAZAR R. BOWIE, M.D.
NEW ORLEANS

The study of the thymic shadow shown on the roentgenogram was undertaken in the Newly Born Service of Touro Infirmary about three years ago with the idea of arriving at some definite conclusions as to the size, shape and position of the thymus. Examinations were made, beginning during the first twenty-four hours of birth, up to the present time, and an endeavor was made to show what type was causing the peculiar syndrome that we see in children.

The first authentic description of this clinical picture was in Rokitansky's textbook, which appeared in 1861. He described a general hyperplasia of all the lymphatic structure, with an especial reference to the increase in the size of the thymus. Arnold Platauf, in an article published in 1889, still adhered to Rokitansky's theory of a specific constitutional anomaly. Sheila, in 1876, showed that the specific thymic extract, when injected, produced a long train of clinical symptoms. This extract is never present in the human embryo, but forms after birth. (It is probably a hyperthymization in the gland that is hypertrophied which causes the symptoms seen.) Bartel, as the result of more than a hundred necropsies on children, interpreted status thymus lymphaticus as being a part of a general glandular hypertrophy. This hypothesis we have been unable to prove or disprove, as we have had only one death that came to necropsy.

We will not repeat the statistics of others, as this is purely a clinical paper, but we will try to give our experiences together with the method of roentgenography and the means of radiotherapy.

---

* From the Department of Pediatrics and the Department of Roentgenology, Touro Infirmary.

* Read before the [illegible] the Section on Miscellaneous Topics at the [illegible] Session of the American Medical Association, At[illegible] 1925.

The child is brought to the roentgen-ray department within the first twenty-four hours of birth; a roentgenogram of the thymic area is made, double intensifying screens being used; one tenth second; 80 milliamperes at from 85 to 90 kilovolts; and distance of tube from plate, 36 inches. It is quite essential that the child be held still, and this is best done by one assistant holding the child's arms and head, another the legs, and both making slight traction. The examination is repeated in three, six, nine and twelve months, then again in the second year, and we now have a few cases going into the third year period.

Up to the present, we have been unable to arrive at a definite standard as to the size, shape and position of the gland causing symptoms, some patients having all the effects of a hyperfunctioning thymus, and on examination showing only a very slight enlargement, while other cases in the series, with marked enlargement of the gland, show no clinical manifestations. We have seen patients in whom we reported an enlargement at birth show the same proportionate increase in the gland throughout the entire series. The heart shows no relationship in size to the thymus, although we rarely see a marked thymic enlargement that is causing symptoms without an increase in the size of the right side of the heart.

In a large percentage of these cases, the shadow of the thymus is seen to the right and left, with the large finger-like projection overlying the right side of the heart. Holmes states that the diagnosis of enlarged thymus is difficult, and when no shadow is seen, especially in patients before operation, a false sense of security is given. This has not been our experience, as we have had a considerable number of cases in which operation was performed, especially for tonsils and adenoids. These patients have had enlarged thymuses and were treated by us, and films made the day before operation and a control made in a few days failed to show any recurrence of the condition or evidence of any ill effects from the anesthetic. We agree with Holmes in regard to the importance of the clinical symptoms, as we always review these cases before a final diagnosis is made; but we both feel that the roentgen-ray findings are of paramount importance. We are not satisfied with negative findings in some of the patients, and in a few cases have made semilateral roentgenograms of the chest to bring out the enlarged gland that merges with the shadow of the aorta. This, however, is not possible in all cases, because of the movement of the child.

It is amazing what some of the films will show in the first twenty-four or forty-eight hours. We are yet to see a patient without enlarged mediastinal glands and with very definite lung markings suggesting some fibrosis, and as these cases are observed, the glands become larger and the markings more pronounced. We think, as time goes on, that this sort of study will bring us to change our ideas of lung pathology from the roentgen-ray point of view. We think that the diagnosis congenital heart disease should not be made too readily without considering the thymus as a causative factor. We do not wish to suggest in this paper that all pathologic conditions within a child's chest are due to an enlarged thymus, but on the contrary, we only desire that the roentgenographic findings be considered most carefully.

Finally, as a matter of technical detail, we are now working on a plan to make exposures during both systole and diastole of the heart for the sake of comparison. We have noted an apparent enlargement during diastole that disappears during systole as the result of a marked engorgement of the gland with blood during one period of the cycle. This presents a great deal of technical detail in regard to apparatus and will have to be done eventually with some type of electrical timing device. Report on this phase of the problem will be made later.

Treatment, after the diagnosis of the enlargement is established, is done under the supervision of one of us (E. R. B.). Our choice must be made whether the irradiation shall be done with roentgen or radium rays. In the application of the rays to children, theoretically the use of radium is preferable, as it can be fixed firmly in the desired location and, no matter how restless the child, the rays are constantly directed to the region of the gland. In using radium, our method has been to use 100 mg. of radium element in 2 mm. of brass filter, separated from the skin by a distance of 5 cm., firmly fixed in place by adhesive plaster reinforced by a binder. The duration of the exposure has varied from eight to twelve hours, depending on the urgency of the case and the size of the thymus, as well as the age and size of the child. Anterior applications have been the rule, although in giving a series of three radium exposures we have usually applied the first dose anteriorly and the second dose posteriorly, and lastly we have come back to the anterior chest wall. The interval between applications has usually been from ten days to two weeks, unless the condition of the child is grave. Three applications, with no improvement, has been our limit of radium dosage, as we feel that if we have accomplished nothing by this, the case is not amenable to irradiation. Our success, however, has been quite uniform, and rarely have more than three or four applications been required. Here, as with roentgen irradiation, we have observed no ill effects.

Our roentgen-ray dosage, our method of choice in thymus irradiation, will possibly seem rather mild, but we feel that our best reply to any question of its adequacy is to refer our critics to our results. We have yet to encounter a case of thymic enlargement that has not been controlled with the ray. We have tried various technics of treatment—from 1 to 3 mm. of aluminum filtration; from 5 to 7 inch spark gap; 5 milliamperes, 10 inches distance, from one to three minutes' time—and we have finally settled on uniform exposures of one minute, 7 inches gap, 5 milliamperes 1 mm. of aluminum filter, 10 inches distance, this giving approximately one tenth of a skin unit. The number of treatments required is determined primarily by the clinical symptoms, and to a distinctly secondary degree, by the size of the thymus as shown in the roentgenogram, for we have frequently found the absorption of the gland following very slowly after a complete and permanent disappearance of the clinical picture. No bad effects have been observed following the treatments. The only difficulty attendant on roentgen irradiation of the thymus has been the restlessness of the patient, but it has always been possible in some way to hold the child still for the length of the treatment. The average number of exposures required is between four and five.

Out of a total of 623 cases of children irradiated at various ages from birth to 39 months, 125 cases of thymic enlargement have been observed, or approximately 20 per cent. The length of time these cases have been under observation has varied greatly, owing to the difficulty of retaining clinic patients under observation.

These cases of thymic enlargement have had varying numbers of control examinations, roughly averaging three. The necessity for control of these cases has in only about one third of the cases extended longer than a period of six months.

ABSTRACT OF DISCUSSION

Dr. I. S. Trostler, Chicago: A little trick that I employ in diagnosis is to get the baby to crying and make the exposure while the child is crying. I have another little stunt for holding the baby during the treatment. I place a folded sheet under the child, bringing it up to the axilla; I put the arms through the openings and pull the sheet tight, and the baby cannot move the arms. Another sheet fastened firmly over the legs holds the baby motionless.

Dr. Preston M. Hickey, Ann Arbor, Mich.: Do you make the exposures in an anteroposterior or postero-anterior direction?

Dr. C. E. Piersall, Reno, Nev.: What was the dose of radium?

Dr. Maurice Lenz, New York: How soon do you repeat the second dose? In some experimental work that I did, the young rabbits had the thymus completely regenerated within three weeks, after one twelfth of an erythema dose.

Dr. Samuels: Roentgen ray or radium?

Dr. Lenz: Roentgen ray.

Dr. C. D. Chappell, Flint, Mich.: I have treated several cases of enlarged thymus. One baby, with a diagnosis of congenital heart lesion, died three or four days afterward from pneumonia. At the necropsy, we found a thymus which was so large that it obliterated the heart. Two children, whom I was unable to treat, died on the way home from my office. The treatment that I use is essentially the same as that of Dr. Samuels, but the exposure is longer because I increase the distance.

Dr. Henry K. Pancoast, Philadelphia: We have treated a large number of cases of suspected enlarged thymus in children and also a group of adult patients with persistant thymus who were going to be operated on for goiter. I cannot make a roentgen-ray diagnosis of enlarged thymus in children in many instances, because it is very difficult to say whether the thymus is too large for the age of the child or not. Often the thymus seems to be about the normal width and density for the age of the child, and yet there are very definite clinical signs of obstruction. I believe that these cases need treatment, and I rely entirely on the clinical diagnosis as an indication for treatment. We administer a little less than half an erythema dose with the low voltage machine, delivering about 130,000 or 135,000 volts. This seems to suffice in most instances. Sometimes we have to repeat the treatment in ten days or two weeks. We rarely have to give more than two doses.. When children are obviously thymic cases, and when during the roentgenologic examination we are very much alarmed at their condition for fear they may die on the table, we do not treat them with the roentgen ray. I would hesitate to tie such a child on a table and to put a roentgen-ray tube over it. We refer such cases to a nearby institution to be treated by a radium pack. If we wait until the child gets perfectly quiet, lying down, the pack can be adjusted and a part of the dose given without danger. This should be a fairly good part of the dose, however, to get the effect. Later the remainder of the dose can be given. This is a much safer procedure than attempting to use the roentgen ray. Several clinicians in Philadelphia have been much alarmed by having had a thymic death or two in their practice, and as a result they are taking no chances with children under suspicion. If they suspect that a child is likely to have an enlarged thymus, a single treatment can be easily given and does no harm.

Dr. A. L. Gray, Richmond, Va.: I agree with Dr. Pancoast. We must not be governed altogether by the size of a thymus as it appears on the roentgenogram. I have seen a perfectly normal child, so far as could be determined by physical examination or clinical evidence, with a thymus so large that if we had observed anything like it in size in a supposed thymus case, we would not hesitate to say it was pathologic. My experience has been altogether with roentgen-ray treatment. My technic is approximately one-half an erythema dose, but I usually irradiate two areas in a series, one on the front and one on the back.

Dr. Ernest C. Samuels, New Orleans: The roentgenograms are made in the anteroposterior position. The radium dosage usually is 100 with 3 mm. of brass filter, at a distance of 5 cm. from the skin. We repeat this dose in seven or eight days and make a control roentgenogram before the treatment is given. In answer to Dr. Pancoast, I think that our statistics stand for what they are. We have not had one single death on the table, and we have had these children in all stages of the thymic syndrome. We have been worried sometimes. The one death we had was not a thymus death. It was due to pneumonia, apparently an aspiration pneumonia. It was one of the first twenty-four cases in which we saw the enlarged thymus that had had only one exposure. We have used radium quite extensively in a large number of cases. We shall adhere to our roentgen-ray dosage, because we find absolutely no reason to change over to radium when we have had uniformly good results in these cases. Dr. Pancoast spoke about depending more on the clinical diagnosis in the amount of therapy to be given. All of our work is done in collaboration with the department of pediatrics. It is not purely a roentgen-ray diagnosis, but is done in conjunction with the clinician.

THE SIGNIFICANCE OF EDEMA OF THE FACE IN MYOCARDIAL INSUFFICIENCY *

WILLIAM H. RESNIK, M.D.
AND
CHESTER S. KEEFER, M.D.
BALTIMORE

The edema that occurs in patients suffering from myocardial failure is characteristically of the dependent type; that is to say, it is almost always most prominent in the lower extremities or across the sacrum, depending on whether the patient has been on his feet or has remained in bed. In the more severe grades of heart failure, edema may involve the subcutaneous tissues of the entire trunk, and free fluid may appear in the abdominal and pleural cavities. The type of edema that we wish to discuss is that which involves chiefly the eyelids and occasionally the entire face of patients with myocardial insufficiency, excluding those who have organic renal disease or obstruction of the veins of the head and upper extremities. In these patients, edema of the face is almost always associated with edema of the usual type, and frequently swelling of the upper extremities is present as well. In other words, the distribution of edema in these cases resembles very closely the edema that is commonly seen in patients suffering from renal disease.

Little reference is made to edema of the face in most of the books on heart disease that we have consulted. Mackenzie[1] says: "If the patient leans more to one side than the other, *in extreme cases* (italics ours), the arm and cheek of that side may become greatly swollen." Miller[2] has observed that children with very severe and acute rheumatic heart disease frequently have puffy eyelids. Crummer[3] has also called attention to edema of the face in myocardial failure, stating that when it occurs, it is usually indicative of some lung or mediastinal condition complicating the original heart disease. In several textbooks, there has been no statement concerning the occurrence of edema of the face.

3. Crummer, L.: Clinical Features of Heart Disease, New York, Paul B. Hoeber, Inc., 1924, p. 24.

We have been impressed by the severity of the degree of myocardial failure in patients in whom edema of the face or of the arms occurs. Indeed, practically all such patients that we have seen have died within a relatively short time. We have had the opportunity of observing a number of patients with myocardial failure who, after repeated entries into the hospital, on each of these occasions showing the usual type of "cardiac" edema, have finally been seen with the "renal" type as well. Almost invariably, death has resulted within a few weeks.

The following cases are more or less typical of the others.

REPORT OF CASES

CASE 1.—*Chronic rheumatic endocarditis, mitral stenosis, auricular fibrillation, myocardial insufficiency, infarct of lung.* E. S., a man, aged 41, was first admitted to the hospital in 1899, when he was 15 years old, for acute rheumatic fever and rheumatic heart disease. From this time to June, 1923, he was admitted on six different occasions for acute rheumatic fever or for myocardial insufficiency, or both. In June, 1923, as on other occasions, the symptoms and signs of myocardial failure were typical, the edema being confined to the lower extremities; the blood nonprotein nitrogen was 32.2 mg. per hundred cubic centimeters.

In April, 1925, he entered the hospital for the eighth time. The degree of myocardial failure was extreme; edema was extensive in the lower extremities and trunk, and was present in the face and arms also. The blood nonprotein nitrogen was 68.2 mg. per hundred cubic centimeters. For a short time, there was moderate improvement. May 1, however, following the development of pulmonary infarction, his condition rapidly grew worse; the edema of the face became striking. May 4, the blood nonprotein nitrogen was 86 mg. per hundred cubic centimeters; May 6, it was 77.5 mg.; May 13, it was 92 mg. and May 15, the day of his death, it was 80 mg.

At necropsy, the kidneys were normal except for the presence of chronic passive congestion.

CASE 2.—*Chronic myocarditis (syphilitic); myocardial insufficiency; terminal bronchopneumonia.* J. J., a man, aged 34, in 1917, had a chancre. From March, 1922, to August, 1924, he was a patient in the hospital on four separate admissions. On each of these occasions, he had the usual signs of myocardial failure, without evidence of valvular defects; the blood Wassermann reaction was positive. Edema, when it was present, was always confined to the dependent portions of the body. During two of the admissions, the blood nonprotein nitrogen was 33.5 and 42.8 mg. per hundred cubic centimeters.

On the fifth admission, in October, 1924, there was slight puffiness of the eyelids, in addition to moderate edema of the lower extremities and across the sacrum; the blood nonprotein nitrogen was 38 mg. per hundred cubic centimeters. He became progressively worse. December 8, the blood nonprotein nitrogen was 55.8 mg. per hundred cubic centimeters; at this time edema of the face was striking. He continued his progressively downward course and died, Jan. 29, 1925.

At necropsy, the kidneys showed only chronic passive congestion.

CASE 3.—*Acute rheumatic myocarditis, chronic rheumatic endocarditis, aortic insufficiency, mitral stenosis, myocardial insufficiency, transient auricular fibrillation and heart block.* E. K., a youth, aged 16, at the age of 5, had "rheumatism" in one knee. Following an attack of chorea, at the age of 12, he developed typical cardiac symptoms. These symptoms increased, and were quite severe during the last year.

He presented evidences of myocardial failure, without any edema, in addition to manifestations of acute rheumatic fever. Shortly after his admission, his blood nonprotein nitrogen was 48.6 mg. per hundred cubic centimeters. During the next few weeks, his condition became gradually worse.

May 4, the patient was very ill; it was noted that there was conspicuous puffiness of his hands and face. There was a slight amount of fluid in the abdominal cavity, but no edema elsewhere. On the following day, the blood nonprotein nitrogen was 74 mg. per hundred cubic centimeters. The edema of the face and hands, as well as the other symptoms, increased rapidly, and he died, May 6.

At necropsy, the kidneys were normal except for the presence of chronic passive congestion.

COMMENT

Since the edema that we have observed in these and other patients resembles so closely that which develops in many patients with organic renal disease, it seemed probable that when this symptom appears, it is an indication of disturbed renal function due to the severity of the myocardial failure. We have attempted to gain some confirmation of this view by comparing the renal function of patients with different degrees of myocardial insufficiency. As the criterion of renal function we have taken the amount of nonprotein nitrogen of the blood. In view of the fact that phenolsulphonephthalein excretion may be considerably depressed relatively early in myocardial failure, we have not used this test as a basis for comparison. We have taken the histories of eighty consecutive patients who were admitted to this hospital for myocardial insufficency, and who fulfilled certain requirements. They were all 45 years of age or under, in order to avoid patients who might have significant renal lesions incident to old age; none of them were suffering from hypertension or generalized arteriosclerosis, or gave other evidence that organic renal disease was present. Almost all these patients were subjects of either rheumatic or syphilitic heart disease; a very small number had myocardial failure due to hyperthyroidism.

For the sake of simplicity we have divided the patients into those who died and those who left the hospital improved to a greater or lesser extent. We have subdivided these groups into those in whom the nonprotein nitrogen content of the blood was 50 mg. per hundred cubic centimeters or higher, and those in whom it was less than 50 mg. per hundred cubic centimeters. The data are shown in the accompanying table.

Nonprotein Nitrogen Content of Blood in Patients with Myocardial Insufficiency

	Total Number of Cases	Cases in Which Blood N. P. N. Was Less Than 50 Mg. per 100 C.c.		Cases in Which Blood N. P. N. Was 50 Mg. per 100 C.c. or More	
		Number	Per Cent.	Number	Per Cent.
Died	28	16	57	12	43
Lived	52	49	94	3	6

Without laying too great emphasis on percentage figures, it is apparent from the table that there is a definite relationship between the severity of impairment of the renal function, as judged by the nonprotein nitrogen content of the blood, and the prognosis in myocardial insufficiency. Actually, the figures minimize the importance of the increase in blood nonprotein nitrogen as an indication of the degree of myocardial insufficiency. Of the sixteen patients who died with blood nonprotein nitrogen contents of less than 50 mg. per hundred cubic centimeters, only seven died of progressive heart failure. Of the other nine, four had acute rheumatic myocarditis; one with complete heart block died of prolonged ventricular asystole; two had multiple pulmonary embolisms and infarctions; one had a ball thrombus of the mitral valve; one had subacute bacterial endocarditis; and four, with syphilitic aortitis and aortic insufficiency, died suddenly, the cause of the sudden death being undetermined. In other words, death in each of these nine cases was due in part at least, to causes other than progressive myocardial insufficiency.

In many of the patients who eventually left the hospital as improved, there was a slight elevation of the blood nonprotein nitrogen, usually not above 45 mg. per hundred cubic centimeters. In general, these figures are substantially in agreement with those which have been obtained by others, including Klein,[4] who has studied the nonprotein nitrogen content of the blood in myocardial insufficiency. We have found, as he has, that although the blood nonprotein nitrogen runs fairly parallel with the severity of myocardial failure, there are a few cases in which this is not true. In a small number of cases, the blood nonprotein nitrogen may be considerably elevated in patients who, though quite ill, later improve; and there are a few patients who die without ever showing a distinct rise in blood nonprotein nitrogen. Klein has attributed these exceptional findings to factors other than renal functional impairment, chiefly the rate at which the edema fluid and tissues absorb and give up the nonprotein nitrogen of the blood during various stages of myocardial failure. That is to say, even though functional impairment of the kidneys may tend to cause the blood nonprotein nitrogen to rise, the nonprotein nitrogen may diffuse from the blood into the edema fluid and tissues at a greater rate, so that the blood nonprotein nitrogen may remain at a relatively low level. Conversely, during periods of improvement, the blood nonprotein nitrogen may rise, because of the fact that the nonprotein nitrogen of the edema fluid and tissues diffuses into the blood at a greater rate than it is excreted by the kidneys. In any case, the level of the nonprotein nitrogen of the blood depends on a balance of these two factors.

We have presented these figures of the blood nonprotein nitrogen in patients with myocardial failure in order to show that it is likely that the renal type of edema which is seen in patients with severe myocardial failure is due to functional impairment of the kidneys. Unfortunately, we do not have figures for the blood nonprotein nitrogen of all the patients who have had edema of the face. In all but one of the patients whose blood nonprotein nitrogen figures are available, there was a definite increase. In view of Klein's studies, it is not to be expected that every patient with functional impairment of the kidneys, even though severe, will show an elevation of the blood nonprotein nitrogen.

We do not mean to imply that the severity of myocardial failure is to be judged by the nonprotein nitrogen content of the blood. The clinical symptoms and signs are usually clear enough. Our purpose is to offer an explanation for the type of edema that we have described, the distribution of which is unusual in patients with heart failure. We wish to point out also that when there is distinct depression of renal function, even when there has been no previous structural change in the kidneys, myocardial failure has advanced to such a stage that it is usually incompatible with life.

SUMMARY

In cases of advanced myocardial insufficiency, occasionally edema of the "renal" type may appear, involving the face and often the upper extremities. It is probably due to impaired renal function, and when it appears it is usually indicative of a grave prognosis.

CONVALESCENT SERUM IN PREPARALYTIC CASES OF POLIOMYELITIS

RESULTS OF INTRAMUSCULAR ADMINISTRATION *

E. B. SHAW, M.D.; H. E. THELANDER, M.D.
AND
E. C. FLEISCHNER, M.D.
SAN FRANCISCO

The brilliant observations of Levaditi and Landsteiner, Römer and Joseph, Flexner and Lewis, and Anderson and Frost that immunity or neutralizing substances to the poliomyelitis virus are present in the blood serum of recovered monkeys and human beings were followed fairly promptly by the reports of Netter and his associates in France and later by Amos and his co-workers in this country on the use of convalescent serum in the treatment of the disease. The French investigators used the subdural method of injection and believed that they had unquestionably proved the procedure to be of value. They stressed the time element particularly and urged that the injections be given in the earliest stages of the disease. The American observers employed the intraspinal and intravenous routes either directly into the blood vessels or indirectly by way of the subcutaneous tissues, and their results certainly justified their conclusions, that the earlier in the course of the disease the serum is employed in suitable doses, the more promise there is of benefit, and that the action of the serum appears to be more precise and definite in arresting paralysis than in rapidly bringing about its retrogression.

The adoption of the intramuscular method of administration of the convalescent serum in the treatment of poliomyelitis was determined on only after careful consideration of several cardinal facts associated with the disease. Poliomyelitis must be classed, at least in its early stages, as a general infection. Both the symptomatology and the consistent involvement of organs other than the nervous system, notably the liver, spleen and lymph nodes, bear irrefutable proof of this fact. Furthermore, the pathology of the disease with its striking perivascular infiltration in all the viscera supports the view that the blood and the blood vessels are intimately associated with the action of the virus on the parenchymatous tissues. Peabody, Draper and Dochez, in their encyclopedic monograph on poliomyelitis, call attention to the striking changes in the liver, characterized by areas of necrosis closely associated with the blood vessels, chiefly the portal vein, but also with the central or sublobular vessels. Under these circumstances, it can hardly be questioned that the virus is carried very largely by the blood stream.

The exact method whereby natural immunity is developed in this disease has not been determined, but whether it is a function of the tissue cells, as is more likely, or a property inherent in the blood makes no difference as far as the significant presence of immune substances in the blood stream of convalescent patients is concerned. When recovery occurs without treatment, it must be accomplished by means of the immune substances in the blood, and it seems logical to assume that, in furnishing these immune bodies artificially to an individual suffering from the disease, the closest adherence to the natural processes should be carried out. Poliomyelitis is therefore a disease in which the virus

---

* From the Department of Pediatrics, University of California Medical School, and the Children's Hospital, San Francisco.

is transported very largely by the blood vessels, in which the effects of the virus manifest themselves by marked pathologic changes around these blood vessels and in which recovery is associated with the presence of immune substances in the blood. It seems reasonable therefore to assume that, in the treatment of the condition, a mode of injection should be chosen whereby the antisubstances are made available to the tissue cells at the earliest possible moment, particularly when one considers the tremendous importance of the time element in determining the question of successful treatment. Under ideal conditions, therefore, there is no doubt that the intravenous method of injection is desirable. From a practical standpoint, it is impossible. The difficulties incidental to procuring convalescent serum in sufficient amount and the time lost in carrying out those laboratory procedures necessary to make the intravenous injection of human serum a safe practice are disadvantages so great as virtually to preclude intravenous therapy as a common practice. On the other hand, the subcutaneous method of injection is definitely contraindicated if one is justified in drawing conclusions from analogous experiments with antitoxin in horse serum when the antitoxin is made available to the tissues two and one-half times as rapidly by the intramuscular as by the subcutaneous route. Even without experimental proof, it is certainly likely that absorption will take place more quickly in the depths of the muscles than from the subcutaneous tissues.

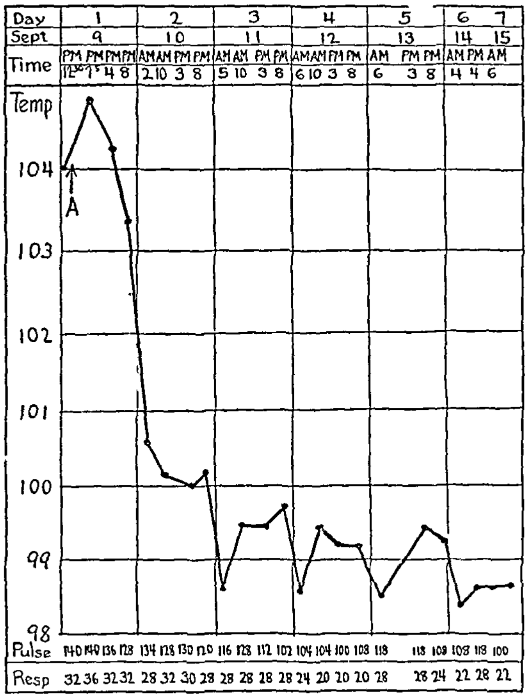

Chart 1.—Course in Case 2: A, 45 c.c. of convalescent serum.

Summarizing, one may state that the intramuscular injection of convalescent serum is at least theoretically a means whereby passive immunity may be achieved in a manner similar to that observed in the development of active immunity; namely, through the blood. For practical purposes it is the most logical method of administration.

REPORT OF CASES

Case 1.—A girl, aged 3½ years, at 5 p. m., Aug. 20, 1925, complained of pain in the neck, head and left arm. She slept two hours and awakened complaining of pain in the head; she had a slight fever. August 21, she was brought to the outpatient department and examination showed that she had marked tremor, loss of grasping power in the left hand, slight rigidity of the neck and positive Kernig sign on both sides. The abdominal reflexes were present, but not active. The temperature was 100.4; the pulse, 140. Lumbar puncture was not done, on account of evident diagnosis. The child was admitted to the hospital at 2:30 p. m., and 50 c.c. of convalescent serum was given intramuscularly, twenty-two and one-half hours after the onset of the illness. August 22, eighteen and one-half hours after the administration of the serum, the temperature was normal, tremor and weakness of left hand were still present, rigidity of neck and Kernig's sign were less pronounced, and movements of the lower extremities were normal.' August 23, the temperature was normal; there was some resistance in flexion of the neck and a suggestion of Kernig's sign on the right side. Tremor of left hand was very slight. The child made an uninterrupted recovery, without paralysis.

Case 2.—A girl, aged 7, was taken ill at 6 p. m., Sept. 8, 1925, with vomiting, headache and fever. She complained during the night of pain in the abdomen and legs, and she was actively delirious. At 10 o'clock the next morning, her temperature was 104, the delirium pronounced, there was marked tremor of the left hand and incontinence of feces and urine. The abdominal reflexes were not obtainable. The knee jerks were diminished, and there was marked rigidity of the neck and profound toxemia. She was admitted to the hospital at 12:30 p. m., eighteen and one-half hours after the onset of her illness. Lumbar puncture was not done, on account of the evident diagnosis. The patient was given 45 c.c. of convalescent serum intramuscularly. At 8 p. m., seven and one-half hours later, the temperature was 102.4. September 10, ten hours after administration of the serum, the temperature was 100 rectally, the patient was conscious and rational, there was slight rigidity of the neck and the tremor had disappeared. The knee jerks and Achilles jerks were diminished. September 11, the temperature was normal and the pulse rapid. It was difficult to elicit the knee jerks. The examination was otherwise negative. September 14, a neurologic examination revealed a normal child.

Case 3.—A boy, aged 5¼ years, Sept. 11, 1925, at 4 p. m., four hours before being seen, complained of being chilly, developed looseness of the bowels, described a sensation in the lower part of the back as if needles were sticking into the skin, and complained of headache, particularly when the top of his head was touched. The temperature was 101.8, which rose in three hours to 103.8. The boy looked ill; he was conscious and reacted promptly to external stimuli. There was no rigidity of the neck. The tongue protruded slightly to the left. Only a left upper abdominal reflex could be obtained on first examination; subsequently all reflexes were absent. The knee jerks were active. The patient had frequent diarrheal stools and complained of severe abdominal pain. There was an absolutely definite history of exposure for a period of two hours to a frank case of poliomyelitis, four days previously. Lumbar puncture was not done. September 12, at 2 a. m., 40 c.c. of fresh convalescent serum was injected intramuscularly, ten hours after onset. Ten hours

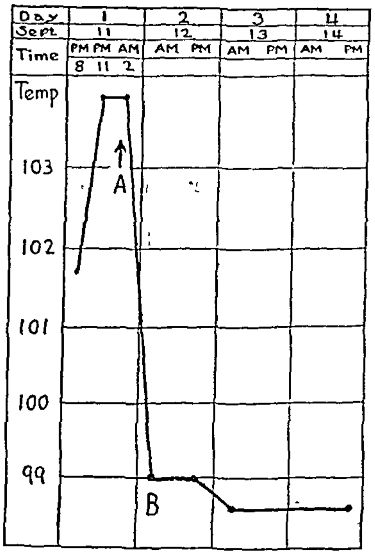

Chart 2.—Course in Case 3: A, 40 c.c. of convalescent serum; B, pulse, 120; respiration, 30.

after the administration of the serum, the temperature was normal and remained normal, although the pulse and respirations continued rapid for forty-eight hours and the bowel movements frequent for about seventy-two hours. September 15, four days after onset, the abdominal reflexes were still absent, but the child was otherwise normal. September 28, the left upper abdominal reflex returned; the others are still absent.

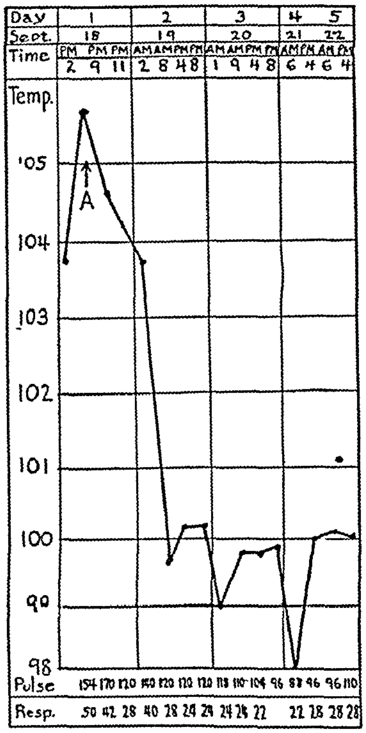

Chart 3.—Course in Case 4; *A*, 92 c.c. of convalescent blood.

CASE 4.—A boy, aged 5 years, Sept. 18, 1925, at 7 a. m., complained of severe headache, chilliness, and pain in the right lumbar region and in the left arm and the right leg. A severe diarrhea developed during the day, and the child vomited five times. Examination at 2 p. m., seven hours after the onset, showed a temperature of 103.8, knee jerks absent on both sides, slight rigidity of the neck, marked tremor of all the extremities, and profound delirium. Lumbar puncture showed 62 cells, mostly mononuclears. A diagnosis of fulminating poliomyelitis was made. The child was admitted to the hospital at 9 p. m., fourteen hours after onset. The temperature was 105.6; pulse, 154, and respiration, 50. The patient was extremely toxic, and a jerking tremor, particularly of the hands and arms, was discernible in all the voluntary muscles, including those of the eyelids, mouth, abdomen and lower extremities. He was semiconscious and did not cooperate, although he made a weak attempt at gripping hands. The pupils were sluggish to light. The abdominal reflexes were not elicited; there was a bilateral Kernig's sign, neck rigidity, and a positive Brudzinsky sign. The patient's general appearance suggested the most fulminating type of poliomyelitis, with death almost a certainty. Convalescent serum was not available. At 9 p. m., about fifteen hours after the onset, 92 c.c. of convalescent citrated blood was injected into the buttocks, in order to avoid delay incidental to procuring the serum. While this was being given, the extreme intoxication was manifested by repeated involuntary defecation and urination. At 10:45 p. m., one and three-fourths hours after injection, the temperature was 104.6; pulse, 160; respiration, 42. September 19, at 2 a. m., five hours after injection, the temperature was 103.6; pulse, 170; respiration, 42. Nine hours after injection, the temperature was 101; pulse, 140; respiration, 40; eleven hours after injection, the temperature was 99.8; pulse, 120; respiration, 28. The temperature remained normal throughout the day and never rose afterward above 100 rectally. The patient had twelve stools during the twenty-four hours and vomited five times; otherwise he was perfectly rational and feeling comfortable in every way. On examination, the child seemed very quiet, was not toxic looking, was rational, and cooperated. The knee jerks were present, but diminished. The abdominal reflexes were elicited. Nuchal rigidity was still quite marked. There were slight Kernig's signs on both sides. September 20, at 10 a. m., the patient complained of severe abdominal pain; he had two loose bowel movements during the day, but there was no vomiting. He seemed more listless and knee jerks were present, but diminished, and equal on the two sides. There was no paralysis. The following day he complained of some pain in the lower extremities; his neck was slightly rigid and tender, and the knee jerks were active. September 22, the patient was bright and conversative; he complained of some pain in the lower extremities. Reflexes were active, and tenderness in the nuchal region was much less marked. September 25, the patient was practically normal, on neurologic examination.

CASE 5.—A girl, aged 19, at 6 p. m., Sept. 24, 1925, had a large watery evacuation of the bowels. The next day the bowel movements had become very frequent, contained blood and mucus, and were associated with marked abdominal pain. She complained of profound dizziness, severe headache and pain in the back. At 7 p. m., the patient's temperature was 102.5; pulse, 80, and respiration, 20. She was acutely ill and toxic looking, and had a violent chill lasting two hours. The patient also complained of severe abdominal colic and pain in the head, shooting down into the back and thighs. There was general cutaneous hyperesthesia, no weakness or rigidity of the extremities, and a slight suggestion of a bilateral Kernig's sign. The reflexes all were hyperactive, except the radials and biceps, which were sluggish. The neck was not rigid. At 8 p. m., the temperature was 102.8 and the pulse 124. The patient was quite delirious at times, although rational at intervals. By 9 p. m., the reflexes were hyperactive, and there was a definite bilateral Kernig's sign and a slight neck rigidity. At 10 p. m. there was an increasing headache, very severe pain in the back and thighs, occasional spasmodic contraction of the muscles of the back and slight opisthotonos, numbness of both hands, a feeling as if the left hand were paralyzed, occasional fine tremor of the hand, and definite extensor weakness of the left wrist. At 10:30, there was a suggestion of muscle weakness in the right eye, the reflexes were profoundly exaggerated, and there was a Kernig's sign on both sides. The temperature was 104, and the patient was actively delirious. Lumbar puncture showed 25 cells, 88 per cent. lymphocytes, and 12 polymorphonuclears. At 11 p. m., five hours after the onset of symptoms, the patient was given 50 c.c. of convalescent serum intramuscularly. September 26, at 3 a. m., the temperature was 103.4 and the pulse 92. At 8 a. m. the temperature was 100.2 and the pulse 88. Severe headache persisted, but the patient was quite rational and comfortable. There were no more bowel movements, and

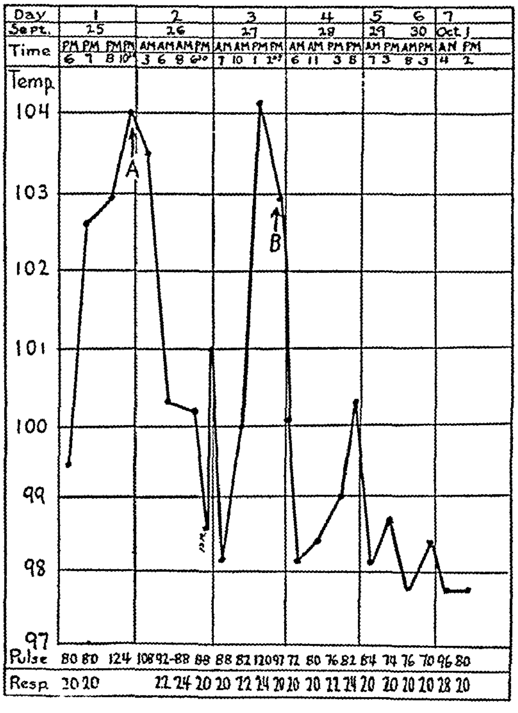

Chart 4.—Course in Case 5; *A*, 50 c.c. of convalescent serum; *B*, 70 c.c. of convalescent serum.

Kernig's sign was less marked. At 8:30 a. m., about nine and one-half hours after the administration of the serum, the temperature was 99. The patient was comfortable all day, with only a slight headache and backache. There was no repetition of the frequent bowel movements, but the temperature rose to 101 at 6:30 p. m. On the morning of September 27, the temperature was normal. Pain in the abdomen became suddenly severe, with three very loose bowel movements. The patient vomited twice and complained that headache and backache had again become very pronounced. She was very toxic looking, and there was a marked tenderness in the nuchal region, with slight rigidity on extreme flexion. The patient complained of pain in the lower extremities, when endeavoring to elicit the Kernig phenomenon, although the reaction was not distinctly positive. At 1 p. m., she had a slight chill followed by a rise in temperature to 104.2; the pulse was 120; the respiration, 24. At 4:30, 70 c.c. of convalescent serum was given intramuscularly, and at 6 the temperature was 101.8; pulse 96 and respiration, 20. At 11:30 p. m., the temperature was 100.2; the pulse, 90, and respiration, 20. September 28, at 8 a. m., fifteen and a half hours after administration of the serum, the temperature was 98.2. It remained normal all day. Headache, backache and numbness in the extremities practically disappeared; abdominal pain was not present, and diarrhea had ceased. The next day the patient was apparently normal, and October 1, no abnormal signs or symptoms were present. The patient is making an uninterrupted recovery.

COMMENT

Lumbar punctures were not done in Cases 1, 2 and 3, because the diagnosis seemed perfectly evident at the time of examination, and intrathecal therapy was not under consideration. It is perhaps lamentable, in view of the results, that the spinal fluid findings are not available, although it is not credible that the diagnosis in these patients can be questioned when one considers the histories, physical findings and prevailing epidemic. The symptoms were identical with those observed in other untreated cases in which typical paralyses occurred. Puncture was done in Cases 4 and 5 when it was realized that the results of treatment were striking and that publication of the data necessitated full confirmation of the diagnosis as far as this was possible, by a study of the spinal fluid. A typical increase in the cell count was noted in both of these instances.

The number of cases treated is not large, but the results are so consistent and so impressive, even in those patients who presented classical clinical pictures of the fulminating type of poliomyelitis, that it seemed advisable to publish the data in view of the prevailing epidemic, in the hope that use might be made of the method described for purposes of confirmation. It is scarcely necessary to enter more fully into the individual results beyond brief mention of Case 4. This patient was treated with whole blood, as his extreme condition did not seem to justify the delay entailed in separating the serum. In Case 5, a second dose of serum was necessary at the end of forty-eight hours, on account of a relapse probably associated with too small a primary dosage on account of lack of available serum.

Further comment is not essential because a consideration of the case histories and a study of the charts reveal in a lucid manner the character of the material and the effect of treatment. Realizing the danger and difficulty of drawing radical conclusions from so small a material, it seems sufficiently conservative and justifiable to conclude that the evidence indicates that preparalytic cases of poliomyelitis, even when presumably of the malignant or fulminating type, can be cured by intramuscular injections of fresh convalescent serum, if it is administered in adequately large doses at a sufficiently early period of the disease.

384 Post Street.

THE FEMALE SEX HORMONE

II. AN ANALYSIS OF FACTORS PRODUCING PUBERTY [*]

ROBERT T. FRANK, M.D.
NEW YORK
H. M. KINGERY, PH.D.
AND
R. G. GUSTAVSON, PH.D.
DENVER

Why, in a given species, puberty sets in at a fairly fixed period of time has always remained a mystery. In recent years various glands of internal secretion have, without real evidence, been credited with a restraining or accelerating influence. Clinical record of premature puberty has accumulated and has shown that pineal, suprarenal or ovarian neoplasms are most often causative, although cases in which no abnormality other than the precocious puberty is discoverable are also not unusual (Lenz;[1] Reuben and Manning[2]).

Premature puberty can be experimentally induced by the injection of lipoid extracts of corpus luteum, placenta or follicle fluid. Such experiments have been performed since 1913 on rabbits, guinea-pigs and albino rats (Aschner;[3] Fellner;[4] Frank and Rosenbloom;[5] Frank;[6] Allen and Doisy;[7] Frank and Gustavson[8]). The effect shows itself in a marked hyperplasia of the female genital tubular system (vulva, vagina, uterus) and mammae.

Long and Evans[9] demonstrated that the ovaries of immature white rats when successfully transplanted into adult rats at once began to function (ovulation). This behavior would indicate the absence of some factor necessary for the development of puberty or the presence in the immature of some restraining factor.

Allen and Doisy,[7] employing follicle fluid or lipoid extracts of it, in the course of three days induced pubertas praecox in immature albino rats. This species is especially suitable as, at the age of puberty, the closed and solid lower third of the vaginal tract opens by canalization, and the vaginal smear, at the time of each estrus, consists exclusively of squamous epithelial cells.

The present investigation was undertaken to determine, on the one hand, whether restraining influences were at work, or, on the other, whether absence of the female sex hormone[8] was at fault.

As by previous investigation[6] we had convinced ourselves that follicular, corpus luteum and placental lipoids are physiologically identical, we used the female sex hormone obtained from human placenta exclusively. Young, immature rats from the same litter were employed. After from three to five days of injection, the vaginal canal opened and the vaginal smear proved characteristic of estrus. The smear could be kept positive for from eight to nine days at least, by continuing the injections.

At the time at which artificial premature puberty is reached, the ovaries of the experimental animals do not differ in any way from those of the untreated controls. The ovaries show no fully maturing follicles, but only follicles undergoing atresia before full maturation is reached. The puberty effect induced is therefore entirely due to the exhibited extracts.

If, however, after artificial premature puberty has been attained, these rats are watched further, it will be noted that, after a latent period of from five to seven days (at least from two to three weeks before the control sisters show this change), spontaneous ovulation may occur and recurring cycles appear every four to six days, as in the adults. The ovaries of these animals contain corpora lutea, thus demonstrating that the ovaries have begun to function.

These experiments not only indicate that puberty can be accelerated artificially by injection of the female sex hormone, as has been known, but also that as soon as the threshold is once passed, the ovaries, which appear to respond more slowly than the tubular system to the female sex hormone (after a short latent period) can function just as in the adult. No evidence of stimulation of ovogenesis and the new formation of ova could be obtained, even after continued injection of the hormone (up to twelve days).

SUMMARY

1. Injection of the female sex hormone into immature female white rats in from three to five days causes opening of the canal and estrual phenomena (pubertas praecox), without the occurrence of ovulation.

2. After a further interval of from five to seven days, the artificially produced puberty may be followed by spontaneous, regular cyclical phenomena consequent to follicle ripening and ovulation.

3. If the threshold of puberty is once crossed, sexual maturity may be maintained spontaneously in immature rats.

4. These findings indicate that puberty results from the elaboration, in sufficient amount, of the female sex hormone, and that the advent of puberty is not due to the removal of an inhibitory influence, such as might be exerted by one or more of the glands of internal secretion, such as the thymus or the pineal.

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION. W. A. PUCKNER, SECRETARY.

PARA-THOR-MONE-LILLY. — Parathyroid Extract-Collip —A stable, aqueous solution containing the active principle or principles of the parathyroid gland of cattle and having the property of relieving the symptoms of parathyroid tetany and of increasing the calcium content of blood serum. It is standardized by its capacity to increase the blood serum calcium in normal dogs: one unit being defined as one one-hundredth of the amount of solution required to cause an increase of 0 005 Gm of calcium (Ca) in the blood serum of a twenty kilogram dog, the increase in calcium being determined fifteen hours following the injection of the solution

Actions and Uses—Para-Thor-Mone-Lilly relieves the tetany of parathyroidectomized dogs and by its continued daily administration in small doses further attacks can be prevented. Experiments with animals show, however, that frequently repeated small doses are cumulative and may raise the blood serum calcium to dangerous levels. It must be recognized that para-thor-mone-Lilly is a most potent therapeutic agent and that its use may be attended with great danger unless due precautions are taken to avoid overdosage and the consequent development of hypercalcemia.

Para-Thor-Mone-Lilly is claimed to be a specific in tetania parathyreopriva and to have relieved acute and chronic tetany following thyroidectomy, so-called idiopathic tetany, and infantile tetany The experimental clinical use of para-thor-mone-Lilly in conditions believed to be due to a low calcium content of the blood serum must be carried out with extreme caution

Dosage—In cases of true tetany where all the classical symptoms are fully developed, twenty to thirty units of para-thor-mone-Lilly may be administered. In severe cases, if necessary, this dose may be repeated two or three times within the first twenty-four hours, and the dosage then diminished as indicated by the condition of the patient. Doses ranging from ten to twenty-five units daily have been found sufficient to prevent the recurrence of tetany in chronic cases.

Para-Thor-Mone-Lilly may be administered subcutaneously, intramuscularly or intravenously.

Manufactured by Eli Lilly & Co, Indianapolis, under license from the University of Alberta. Patent and trademark applied for.

- *Para Thor Mone Lilly, P 20, 5 Cc* Each Cc contains 20 units

Fresh parathyroid glands of animals from which fat and connective tissue have been removed are ground and extracted with a hot acidified solution After maceration for five hours, the glands are separated and again extracted with a hot acidified solution The united extractions are cooled and the separated fat is removed Alkali is added to neutralize the liquid, and the precipitate which forms at the neutral point is removed by filtration and dissolved in acidified water (p_H 2 5). The hydrogen ion concentration of the solution is then adjusted to approximately p_H 7 and the precipitate is again formed. This precipitate is dissolved in slightly acidified water, diluted approximately to the desired potency, filtered through a Berkefeld filter and submitted to standardization and sterility tests

To determine blood serum calcium 10 Cc glass syringes are cleaned in a hot solution of potassium dichromate and sulphuric acid (800 Cc of concentrated sulphuric acid to 200 Cc of a saturated solution of potassium dichromate in distilled water) Then after repeated rinsings in distilled water, the syringes are placed in the hot air oven until thoroughly dry. The needles are cleaned in dilute sulphuric acid, washed with distilled water and dried in the oven Before bleeding, all syringes are examined carefully to ascertain that no moisture remains As blood containers, 15 Cc graduated Pyrex centrifuge tubes are used These are cleaned in the same manner as the syringes in the dichromate cleaning mixture These also must be thoroughly dry About 10 Cc of blood is drawn and is transferred to one of the clean, dry centrifuge tubes The tube of blood is centrifuged at once Two Cc of the clear serum are added to 2 Cc of distilled water in one of the 15 Cc centrifuge tubes This is shaken until the serum and water are well mixed, then 1 Cc of a saturated solution of ammonium oxalate is added, and the whole again well mixed After standing exactly 30 minutes, the tube is centrifuged at about 2,000 revolutions per minute for 10 minutes Then the supernatant fluid is poured off The rim of the tube is wiped dry, and inverted on a filter paper. It should drain in this manner for at least five minutes, and the mouth of the tube again dried Three Cc of ammonia water (2 Cc. of stronger ammonia water made up to 100 Cc with distilled water) are directed upon the precipitate by a fine spray from a wash bottle so as to loosen the precipitate The tube is now centrifuged and drained as before To the precipitate of calcium oxalate are now added 2 Cc. of normal sulphuric acid, and the tube heated in boiling water until the precipitate is dissolved The oxalic acid liberated is now titrated with freshly standardized one hundredth *normal* potassium permanganate.

SATURDAY, NOVEMBER 14, 1925

VACCINATION FACTS

The propaganda for the public health cannot afford to overlook any evidence of the success of preventive medicine. The cultists that profit by opposing preventive medicine and the misguided sentimentalists of the antivaccinationist and antivivisectionist types are constantly alert to attack present-day practical hygiene. So long as published statements are accepted uncritically at face value, regardless of their authorship, by a large part of the public, it becomes important that the facts of modern medicine be circulated as freely and widely as are the pronouncements of the nonmedical healing cults. In the battle for what is best, the most effective weapon usually is the dissemination of truth.

The value of vaccination as a preventive of smallpox is so firmly established that it should not require mention, let alone defense. The physician and the public health official are not infrequently called on, however, to act as protagonists in the promotion of vaccination. New and telling facts are available in recently published statistics from California. According to the university physician,[1] there has been no case of smallpox among the students of the University of California at Berkeley since 1907, when the regents adopted the rule that all entrants must possess satisfactory evidence of immunity to smallpox before they could be admitted. This is the record of perfection in a state in which more than 9,000 cases of smallpox were reported in 1924, making a case rate of 2.41 per thousand of population. Calculated on the student population at the university, twenty-four cases were to have been expected, if vaccination had not been enforced. There were, in fact, cases of smallpox among unvaccinated employees, while all students were absolutely protected during a local epidemic in 1913.

Legge[1] notes that the colleges of Massachusetts and New York have no record of smallpox. Both of these states have laws providing for the vaccination of school children, which again demonstrates the protection afforded by this public health measure. With this, we may contrast the situation in Utah, where health and school authorities are prohibited from excluding unvaccinated pupils from school or from requiring the vaccination of any person in the community. The University of Utah had a serious smallpox epidemic in 1922.

Eternal vigilance seems to be the price of many valued possessions. The unimpeachable good record of the policy of vaccination must be safeguarded against error. The United States Public Health Service[2] has reported eleven recent cases of postvaccinal tetanus, not due to any contamination of the vaccine but to the use of bunion pads as a vaccination dressing. In view of the fact that 25 per cent. of one lot of these glue-coated felt rings showed the presence of tetanus organisms, the menace of the undesirable practice is obvious.

Physicians who value the blessing of smallpox vaccination should make every effort to prevent the use of improper methods of dressing.

ALCOHOL—PURE AND IMPURE

The surreptitious production and distribution of alcoholic beverages have brought about the possibility of the consumption of improperly refined distillates obtained from crude sorts of fermentations. The drinking of "bootleg" liquor may lead to the ingestion of substances of unknown chemical composition and physiologic action, in addition to the inevitable ethyl alcohol. The "alcohol question" of today has thus become, from a medical standpoint, even more complex than it was in the preprohibition period.

In the discussions of the pathology of alcoholism, some of the organs of the body seem to have received comparatively little attention. The well known British report[3] of the Advisory Committee of the Central Control Board points out that the way in which alcohol acts in chronic alcoholism is complex. According to these foreign authorities, its injurious effects are only partially the direct result of the drug entering the system; they are largely brought about through its detrimental action on the lining membrane of the stomach and bowel, causing chronic inflammation and failure in the action of the digestive juices, and so promoting the absorption from the alimentary canal of poisonous matters (digestive and microbial toxins, as they are termed), which, in healthy conditions of the mucous membrane would be formed in lesser amount, if at all, and would certainly not be allowed to pass so freely into the system. According to the British report, it is indeed a question whether many of the morbid changes that occur in other organs in the course of chronic alcoholism may not really be secondary to these local disorders in the gastro-intestinal tract.

[3] Alcohol: Its Action on the Human Organism, London, H. M. Stationery Office, *1918*.

Studies that MacNider[4] has completed at the University of North Carolina indicate that ethyl alcohol in the doses administered by him over a period of weeks to animals is only slightly nephrotoxic. Naturally nephropathic animals are more susceptible to the toxic effect of the same amount of alcohol than are normal individuals of the same species. However, when the latter are given, instead of pure alcohol, an alcoholic distillate obtained without refining from a fermented mixture of cereal products, there develops evidence of its nephrotoxic action, which is shown functionally by a pronounced albuminuria. In nephropathic animals, the effect is even more pronounced. Associated with a reduction in urine formation occurs a decrease in the elimination of phenolsulphonephthalein, a retention of nonprotein nitrogen in the blood and a reduction of its alkali reserve. Fatty changes arise in the glomerular vessels, and the tubular epithelium also may show evidence of injury. The toxicity of the unrefined "distillates" from fermented mixtures is not primarily due to their content of ethyl alcohol but to some undetermined substance. Ethyl alcohol is assuredly not entirely guiltless of pronounced potencies, when its dosage exceeds a debated minimum in the body. It may even be debated whether there is any "minimum" that represents a zone of safety for the consumer. Whatever the answer may be, purified ethyl alcohol should not be held responsible for the insidious harm that even small quantities of undesired accompaniments in crude distillates may bring about.

VIEWS IN THE STUDY OF CANCER

Cancer has been described as one of the strangest and apparently most lawless of vital phenomena. Considerations of this sort help to explain why the study of its problems has attracted so many investigators throughout the world, regardless of the practical aspects of the subject. On the other hand, the picture of "helpless beings harboring unwillingly a rapacious object, which eats its way through tissues and saps vitality until death brings the inevitable end," has doubtless been the foremost reason for the flow of liberal financial aid into the coffers of cancer research in many lands. During the past summer there has been a recrudescence of popular enthusiasm and an awakening of hopes by the widely acclaimed "discovery" of the cause of cancer. The prominent features of this investigation, which doubtless suffered some undeserved distortion by an inadvisable publicity, have already been discussed in The Journal.[1] The theory advanced included two items that were of themselves likely to win immediate favor: there was the prospect of a culpable micro-organism, always a "popular" hypothesis in the etiology of disease in the past generation; and this was supplemented by the cooperation of an unidentified chemical substance—a reminder of vague biologic potencies such as have been expressed by the terms *hormone*, *vitamin*, enzymes and trephones.

Outbursts of enthusiasm for new findings in science are the excusable reactions of ardent investigators. They give zest to the search for truth; they help to sustain the energy of the worker. To the latter little harm is likely to result from the optimistic outlook of a colleague, for he has presumably learned to inspect new data with judgment and to use caution in interpreting them. It is rather the untutored person who does not know how to evaluate new announcements; consequently, he may experience an awakening of false hopes. And it is the quack who quickly attempts to profit by the promise of new attacks on disease; for he is prone to capitalize misfortune.

One of the means of cultivating a sane outlook on the debated fields of medicine is to secure clear points of view in many directions; to survey the possibilities with an adequate appreciation of the varied avenues of approach. This is particularly true in cancer research, in which there are many facts and many conflicts. If one group of observers points vigorously to the environment of the aberrant cells as the cause of their disorderly behavior, whether it be a micro-organism, a chemical substance, or a deficiency that constitutes its abnormality, one should recall that others have regarded the cancer cell as primarily present in the body and inherently parasitic—a differentiated cell bound on a work of destruction if by any chance it is released from its normal inhibitions. It is corrective to appreciate that malignant tumors may or may not contain micro-organisms; and that the development of neoplasms has been initiated by such varied agencies as tar, radium, the roentgen rays and animal parasites. A realization of this seeming diversity of etiologic sequences exerts a sobering influence.

As cancer is a manifestation of growing cells, it may be helpful to consider critically the ordinary biologic experiences of the body's smallest structural units. When the organism becomes well developed it largely ceases to acquire new tissue. As Lee has expressed it, the period of active cell growth and division has nearly come to an end; the existing cells have learned what they are to do, and the real business of one's physical life proceeds according to law and system. Presently cell division and growth may start anew; "it is unbridled, rapid, often tumultuous, and it rudely interrupts the orderly processes of life."

[1] The Cause of Cancer, London Letter, J. A. M. A. **85**: 368 (Aug. 1) 1925; The Latest Cancer Parasite, editorial, ibid. **85**: 438 (Aug. 8) 1925.

As one of the many contributions to the understanding of the genesis of tumors, Burrows[2] and his co-workers at St. Louis have pictured the change as a disturbance in the balance between growth and function in the body units. As they point out, the organism is a mass of cells. It has come about through a definitely regulated growth of the egg cell and the formation of the different types of cells. It matures and functions through a gradual change in the cells, so that they use their energy for function rather than for growth. This organism maintains itself for a given period of time in that enough energy is used for growth to take care of the destruction suffered by the cells in their function. According to Burrows and Johnston, however, there has never been any evidence that the functioning body cells may not under the proper conditions utilize their entire energy for growth. *It is evident that in such a colony* of cells as the body of man, in which these units as a mass are using their energy for function, if one cell breaks away from the conditions that force it to function and acquires the property of independent growth, it must soon destroy its neighbors weakened by their functional burdens.

The foregoing is, of course, merely a restatement of the view of one school of cancer research which holds that the irrepressible growing cell is derivable from any tissue cell, rather than the sudden development of some repressed embryonic rest. The cancer cell is thus not primarily different from the normal cell. The problem is to explain the active independent growth of body cells. Burrows believes that it depends on a crowding of the cells together in a stagnant area or an area having a relatively poor blood supply. Foreign agents, including bacteria that induce cancer, act by promoting the formation of dense cellular masses.

The special claim of the hypothesis advanced by Burrows is that the factors of stagnation and cell crowding become important for growth because the growth of body cells depends on a certain concentration of a primary product of the oxidation of the cells, the "archusia," or driving substance of the cell. Ordinarily this is withdrawn into the blood. When it accumulates, cells begin to grow. Function, as Burrows expresses it, is something that exists only in an environment that inhibits an independent growth. It occurs only in a richly vascularized tissue. Any tissue, he adds, may be made cancerous by anything that frees the cells of the effect of their intercellular substances and an active circulation of blood. These are, let it be clearly emphasized, only views, but they enable one to envisage many aspects of the problem and unite them into one of many synthetic pictures.

Current Comment

HEATING AND RESPIRATORY DISEASE

Among the various panaceas that have been proposed for prevention of respiratory disease are nasal operations, tonsillectomy, radical tooth extraction, vaccines, sprays, gargles and, during epidemics, the wearing of masks. Ventilation and heating have demanded their share of interest, and two recent writers emphasize this phase of the problem. From a dependable source in Boston comes the assertion that the maintenance of a normal respiratory mucous membrane in the hot dry air customary to our houses and offices is impossible. "It would do no harm," says the author, "to remind parents that their children's tonsils would give no more trouble in winter than in summer, and might not have to be ripped out, if the child were given air fit to breathe." Just as American heating has been condemned, English heating methods—or the lack of them—have been praised. This is, *in part, the view* taken by Hubbard.[1] If the average temperature of American houses is too high, their humidity too low, and Americans unhealthy as a consequence, it is argued, obviously Englishmen, whose houses are not overheated and the air in them not dried out, should show a better health record. Strictly speaking, facts on which to determine this point are unavailable, for respiratory diseases in their milder forms are not reportable. Deaths, however, are recorded, and the inferences drawn from comparative mortality statistics for 1921 are rather unexpected. In 1921 the combined death rate per hundred thousand from whooping cough, diphtheria, *influenza, pneumonia and an unclassified* group of other respiratory diseases (tuberculosis excepted), was: United States, 136.4; England and Wales, 155.09. If tuberculosis of the respiratory system and bronchitis are included, the result is: United States, 231.4; England and Wales, 332.4. Authors who stress the importance of correct temperature and humidity in relation to the prevention of respiratory disease are no doubt warranted in their assertions, but it would seem to be unwise, in the light of our present knowledge, to attach too much importance to any single etiologic factor.

HUMAN TEARS

Man is unique in more ways than one. The poet has referred to the significance of our "footprints on the sands of time." Less idealistic laymen occasionally observe the thumb-prints of their fellow men; and surprising are the identifications and discoveries that have been made thereby. Our blood carries within its chemical self the proof of its species identity, and it may betray even closer human relationships. In lesser degree the evidence of such identity is present in other body fluids, in milk and in muscle. Our "flesh and blood" thus literally bear the stamp of a common, yet independent, origin. And now we are assured that even the tears tell a similar story. At any rate, it has been demonstrated[1] that in the human lacrimal secretion there is a protein which, when tested by immunologic methods, seems to be common to all samples of human tears, but is different from that of the tears of other animals. It also appears to be different immunologically from the human blood proteins and those of other secretions and tissues. Our tears may be more than the expression of joy or sorrow; for with them goes forth the special chemical imprint of their human origin.

HEART DISEASE

Dyspnea, edema and sleeplessness, with a hopeless attitude on the part of the patient, his family and his physician, make up the picture of advanced heart disease. Fully as distressing, in a slightly different way, are the conditions surrounding cardiac decompensation in nearly any stage. Fifty per cent. of the cases occur in persons who should be in the prime of life,[2] with earning capacity and family expenses both at their highest. As a result of heart disease, all of those afflicted are partially or wholly disabled, and the families of a third of them are partially or wholly dependent on charity. McLean[3] suggests, in the first number of the new periodical devoted to diseases of the heart, "Let us learn the lesson taught by the tuberculosis campaign, that we have not materially lessened the number of tubercle bacilli, but have lessened the fields on which they could grow." He would prevent heart disease through increasing resistance to communicable illnesses—the frequent precursors of cardiac disease. School children would be the beneficiaries of his campaign by yearly examination of all pupils between the ages of 6 and 12, first, to discover defects; secondly, to note the results of efforts at correction. "The tuberculosis campaign took twenty years," he says, and he prophesies optimistically that "the heart disease campaign will probably not take quite so long."

RICKETTSIASIS

The rôle of insects as vectors of disease for both man and animals has been clearly established, although practically nothing was known about it forty years ago. The arthropods act not only as mechanical carriers of disease germs but also as intermediate hosts. Mites, ticks, lice, bugs, mosquitoes, flies, fleas and their ilk have been incriminated at one time or another. Since Manson, in 1879, proved that insects, in the case of *Filaria* and the mosquito, are the immediate hosts of human parasites, many important diseases have been shown not only to be transmitted by arthropods but to be exclusively transmitted by certain species. The names of the maladies have become increasingly numerous; and the general mode of transmission of the infections has in many cases been definitely ascertained before the etiologic micro-organism was definitely established. Of late, considerable attention has been focused on certain organisms of minute size that have been designated as Rickettsiae. Their relationships are still rather obscure, but they are evidently concerned with Rocky Mountain spotted fever, typhus fever and trench fever. To these the studies of Cowdry[1] in South Africa have added heartwater, a specific febrile disease affecting sheep, goats and cattle there. This, as Cowdry points out, will enlarge our conception of the scope of the pathogenicity of these micro-organisms by the inclusion of a disease of domestic animals that never is found in man. The bringing of new diseases under the general heading of "rickettsiosis" suggests to Cowdry the likelihood that the limitations of this group have not yet been established and that other febrile diseases of unknown etiology, which are insect-transmitted, may eventually be found to fall in the same category. How fitting that the general designation should perpetuate the name Ricketts, a martyr to the cause of science in the investigation of insect-borne diseases.

REDUCTION OF TAX ON PHYSICIANS UNDER HARRISON LAW

On November 10, the Ways and Means Committee of the House of Representatives approved a reduction from $3 to $1 of the tax levied on physicians under the Harrison Narcotic Law. When a beneficent government decided to make the medical profession bear a part of the burden of the enforcement of the Harrison Narcotic Act through assessing physicians the sum of $1 in registering them under the act, the burden was assumed without complaint. When legislators who are charged with providing the government with funds sufficient to conduct its activities concluded that two additional dollars might be added as a war measure, the medical profession cheerfully accepted this additional burden. But when the war taxes were otherwise reduced and the tax of $3 was continued, perhaps as a simple method of increasing revenue, our profession revolted. It seemed sufficient for physicians to assume the task of keeping endless personal records without having to pay as well for the keeping of records in Washington. In THE JOURNAL, Feb. 17, 1923, appeared an editorial comment protesting against this additional tax, particularly as it was shown that by the additional assessment the United States actually reaped a profit on the traffic in narcotic drugs. Again in 1924, THE JOURNAL, in its consideration of the recommendations submitted by Secretary Mellon, protested against the lack of any specific provision for a reduction in this indefensible tax Regardless of these protests, the Commissioner of Internal Revenue attempted, on several occasions, to justify this tax In THE JOURNAL, Dec. 10, 1924, it was pointed out that the government had again profited by several hundred thousands of dollars from this tax. The House of Delegates, at the annual session of the American Medical Association held in Atlantic City last May, again urged the Board of Trustees to do all in its power to reduce this tax. Moreover, the issue of the *American Medical Association Bulletin* for June, 1925, presented a statement by Dr. W. C. Woodward, secretary of the bureau, giving the complete facts. Finally, the *American Medical Association Bulletin* for October, 1925, published the statement which the Board of Trustees, acting on instructions from the House of Delegates, had transmitted, to the Secretary of the Treasury, the chairman of the Ways and Means Committee of the House of Representatives, and the chairman of the Finance Committee of the Senate. Here is clear evidence that a united medical profession, arguing a just cause, can secure promptly a satisfactory verdict.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Plague Infected Rats.—In the week ending October 3, three plague infected rats were found at Los Angeles, according to *Public Health Reports*. The number of rats trapped during the week was 2,375; of the squirrels and mice trapped, none were found to be infected. The date of the last human case of plague in Los Angeles was January 15.

Chiropractic College Sues Chiropractic Board.—The Berkeley Chiropractic College has gone to court to restrain the state board of chiropractic examiners from conducting an investigation of that institution. The president of the "college" considers, it is reported, that since no member of the board was a licensed chiropractor for three years prior to his appointment as required by law, such an investigation would be a violation of the school's rights.

Smallpox Control in Richmond.—When smallpox appeared in a public school in Richmond, October 12, the health officer notified the principal of the school that he would be on hand the following morning to exclude from attendance for twelve days every teacher and pupil who had not been successfully vaccinated. Such evidence could not be given by 595, and they were sent home; the next morning 233, who had been vaccinated in the meantime, returned to school and the next morning 160 more newly vaccinated pupils returned; eighty more vaccinated pupils returned on Friday.

New Classification in Telephone Directory.—The Southern California Telephone Company has agreed to insert in its next directory a special list in the classified section entitled "Physicians and Surgeons, Members of the Los Angeles County Medical Association." There will be a brief statement concerning the association at the head of the list, and the name, address, telephone number and specialty of those who desire this service. The council of the Los Angeles County Medical Association authorized the new classification, October 19. The cost to those who desire to have their names inserted will be 50 cents per line, monthly.

Society News.—Col. Robert E. Frith, federal prohibition administrator, Judge William M. Bowen, and Capt. Otis Sayre, head of the permit department, spoke before the Los Angeles County Medical Association, November 5, on "The Relation of the Doctor to the Eighteenth Amendment"; Dr. Steele F. Stewart on "Convalescent Care of Infantile Paralysis"; Dr. Sterling N. Pierce on "Kielland Forceps," and Dr. Meyer H. Newman on "The Maternal Hazard in Parturition."——Dr. Vittorio Putti, director, Rizzoli Institute, Bologna, Italy, will address the society as the guest of the Los Angeles Orthopedic Society during the week of November 16.

Abortionist Wanted for Murder.—A man who calls himself "Dr. W. W. Watkins" is wanted by the police of Los Angeles, according to the *Police Bulletin* of that city for October 13. The *Bulletin* states that warrants are on file for the arrest of this person charged with second degree murder on the accusation of performing a criminal operation on a 17-year-old girl. The *Bulletin* states further that this man uses a physician's certificate formerly belonging to the late Dr. W. W. Watkins. His method is to go to different cities and advertise in the papers as a specialist in women's diseases. The records of the American Medical Association show that Dr. W. W. Watkins, a reputable physician, died in 1901. In 1914 we attempted to learn something of the so-called Watkins Sanitarium at Pasco, Washington. A Pasco physician wrote at that time that the self-styled "W. W. Watkins" had originally been the stable man for the real Dr. Watkins, and that on the death of the latter stole the doctor's diploma and came to Pasco, Wash., where for some time he operated a so-called sanatorium, which was nothing more than an institution for criminal abortions. The doctor added at that time (in 1914) that "W. W. Watkins" was in the Washington state penitentiary.

COLORADO

Personal.—Dr. Frank H. Zimmerman has been appointed medical superintendent of Mount Airy Sanatorium, Denver. ——Dr. Chester H. Elliott has accepted a full-time appointment with the department of pathology of the School of Medicine of the University of Colorado.

Increase in Death Rate.—The death rate for Colorado for 1924, according to the Department of Commerce, was 1,247 per hundred thousand of population, as compared with 1,242 in 1923. The increase is accounted for largely by increases in death rates from measles, pneumonia and nephritis.

FLORIDA

Hospital News.—According to *Hospital Management*, Dr. Maurice H. Tallman, Miami, has purchased land for the erection of a $1,500,000 clinic and sixteen story hospital-hotel on Douglas Road and Coconut Grove Drive, Coral Gables.

Personal.—Dr. James B. Griffin, St. Augustine, has been appointed a member of the Florida State Board of Medical Examiners to succeed Dr. William J. Buck, Jacksonville, resigned.——Dr. Cecil Brannen has been elected city health officer of Coral Gables.

GEORGIA

Personal.—Dr. John D. Jungman, Philadelphia, has been appointed health officer of Columbus to succeed Dr. James A. Thrash, Jr., resigned, effective, November 1.

County Society Clinic.—The president of the Medical Association of Georgia, Dr. Frank K. Boland, writes in the state journal that at the clinic conducted by the Bartow County Medical Society recently at Cartersville, 763 children were examined before entering school, 106 had their tonsils removed, forty-eight had glasses fitted and twelve were found to have hookworm disease, and one tuberculosis and two trachoma. More than 400 children had teeth extracted. The "whole county" cooperated to make the clinic a success. The home of Mr. Dodd Warren was converted into a temporary hospital in which thirty-five beds and four operating tables were set up. The dentists of Bartow County cooperated with the medical society.

ILLINOIS

Smallpox in Bloomington.—An outbreak of smallpox occurred in Bloomington in which on October 29 there were more than fifty cases. The first death occurred, October 30. The city health director ordered that all public gatherings be abandoned until further notice.

Personal.—Dr. Victor H. Bassett, health officer of Savannah, Ga., has not accepted the position of health officer of the Quincy public health district.——Dr. William Jones, Aurora, was adjudged insane by a commission before Judge Hoover, October 29, it is reported, and ordered to the Elgin State Hospital.

Epidemic of Catarrhal Jaundice.—There has been for the last several weeks an "epidemic of catarrhal jaundice" at Batavia. A Fellow of the American Medical Association writes that his associate has seen about forty cases. The jaundice appears after about a week of prodromal symptoms, and in at least two cases in which the blood was examined a spirillum was found. There have been no fatalities.

Psychiatric Community Service.—The psychology department of Northwestern University will supervise a free clinic at Evanston at the old college building, south campus, for the examination of persons mentally deficient and of cases of emotional and behavior disorders, on Thursday afternoons. It will be at the disposal of Evanston's public schools, hospitals, police department and social service agencies. The clinic will be separate from the routine of the university and will be a branch of the clinic in Chicago. Dr. Herman M. Adler, director, Institute of Juvenile Research, will cooperate in providing the service of a psychiatrist.

Chicago

Hospital News.—The North Chicago Hospital, 2551 North Clark Street, is planning a four story addition to its building. ——John E. Ransom has resigned as superintendent of the Michael Reese Dispensary.

Rush Medical Alumni Fund.—As a contribution from Rush Medical College Alumni to the development fund of the University of Chicago, a committee of physicians throughout the country has been organized, under the leadership of Dr. Ralph W. Webster, Chicago, to raise $250,000. Rush Alumni have already contributed $155,000 toward this fund. During Dr. Webster's absence in Japan with the University of Chicago baseball team, Dr. Wilber E. Post, Chicago, is in charge of the campaign.

Society News.—Dr. Edward H. Hatton, professor of pathology, Northwestern University, Dental School, and special research investigator of the American Dental Association, will address the Chicago Ophthalmological Society by invitation, November 16, at the Hotel Sherman, on "The Dental Factor in the Etiology and Treatment of Iritis." Dr. Wendell C. Phillips, New York, President-Elect, and Dr. Charles W. Richardson, Washington, D. C., Trustee, of the American Medical Association, will be guests of honor at the meeting of the Chicago Laryngological and Otological Society, Hotel Sherman, November 19. Dr. George E. Shambaugh will present a statistical study of the 290 children in the Chicago public schools for the deaf and speak on "Congenital and Acquired Deafness—Partial and Total Defects, Vestibular Responses, Consanguinity as a Cause for Deafness."

INDIANA

Outbreak of Infantile Paralysis.—Following a conference of the board of health and school board of New Albany, October 27, the public schools were ordered closed on account of an outbreak of infantile paralysis in a district school near this city. An order was also issued, it is reported, against children attending other public functions in the community. At this time there had been only one case in the public schools.

IOWA

Two Hundred and Fifty Physicians Fail to Reregister.—At present more than 250 physicians in Iowa have not complied with the recent state law which requires physicians to renew their certificates annually and pay a renewal fee of $1 to practice medicine in the state. The state commissioner of health writes that he is continually receiving letters from insurance companies, the federal narcotic bureau and the federal prohibition director wanting his office to certify some physicians as being reregistered, and that this cannot be done unless a physician has paid his renewal fee. It seems possible that some physicians have failed to register on account of not knowing of the new law, although efforts have been made to reach every physician in the state (The Journal, June 27, p. 2009).

KENTUCKY

More Schools Closed on Account of Infantile Paralysis.—The Jefferson County Board of Health ordered the county public schools closed, October 26, on account of the outbreak of infantile paralysis. The Louisville schools were ordered closed several days ago. There had been reported up to October 29, according to the *Jeffersonian*, thirty-nine cases, only two of which were in the county outside of Louisville.

MASSACHUSETTS

Hospital News.—The Free Hospital for Women, Brookline, celebrated its fiftieth anniversary, November 4. Among others, Dr. W. W. Chipman, professor of gynecology and obstetrics, McGill University Faculty of Medicine, Montreal, gave an address.

Society News.—The Middlesex East District Medical Society celebrated its seventy-fifth anniversary at the Winchester Country Club, Winchester, October 21. Among others, Dr. James S. Stone, president of the Massachusetts Medical Society, gave an address.——Dr. Leo M. Davidoff addressed the Harvard Medical Society, Boston, November 10, on "With MacMillan in the Far North."

Personal.—Dr. Winfred Overholser, Boston, has been appointed to the faculty of Boston University School of Medicine to take charge of the work in psychiatry, succeeding Dr. Nathaniel Emmons Paine, who was West Newton professor of psychiatry in this school for many years.——Dr. Eugene A. Darling, after fifteen years' service as president of the Cambridge Anti-Tuberculosis Association, requested at a recent meeting to be relieved, and Dr. H. F. Day was elected to succeed him.

Appointments at Harvard Medical School.—According to the *Boston Medical and Surgical Journal*, the following appointments were made, at the October meeting of the faculty of medicine of Harvard University:

Dr. John Ignatius Bradley, assistant in anatomy.
Dr. Lawrence Wells Sloan, assistant in anatomy
Dr. Fei-fang Tang, research fellow in bacteriology
Dr. James Hitchcock, assistant in medicine.
Dr. Millard Smith, assistant in medicine.
Dr. Henry S. Forbes, research fellow in neuropathology.
Dr. Henry Pinkerton, instructor in pathology.
Dr. Shields Warren, instructor in pathology.
Dr. Wyman Whittemore, instructor in surgery
Dr. William L. McClure, alumni assistant in surgery
Dr. William A. Rogers, assistant in surgery.
Dr. Horace K. Sowles, assistant in surgery.
Dr. Charles E. Teel, assistant in genito-urinary surgery
Dr. Willard O. Thompson, research fellow in medicine
Dr. Tracy J. Putnam, Arthur Tracy Cabot fellow in charge of the laboratory of surgical research.

The following reappointments were made:

Dr. Maurice Fremont-Smith, assistant in medicine.
Dr. Harry C. Solomon, instructor in neuropathology.
Dr. Donald J. MacPherson, assistant in neuropathology.
Dr. Frank Fremont-Smith, assistant in neuropathology
Dr. William G. Lennox, research fellow in neuropathology.
Dr. George H. Binney, assistant in surgery.
Dr. Grantley W. Taylor, assistant in surgery.
Dr. Lester R. Whitaker, Arthur Tracy Cabot fellow in charge of the laboratory of surgical research.
Dr. Albert A. Hornor, assistant in tropical medicine.

MICHIGAN

Ford Hospital Abandons Flat Rate System.—The staff of the Ford Hospital, Detroit, has been officially informed, it is reported, that the flat rate system of charging for treatment has been abandoned and that hereafter charges will be made on an "income basis." Under the new plan the maximum limit on surgical fees will be $1,000, and the maximum limit on medical charges $70 a week. According to *Detroit Saturday Night*, there has been a deficit of $2,400,000 in the period during which Mr. Ford has operated the hospital.

"Minimum Program" for County Societies.—Thirty-four of the county medical societies had adopted the "minimum program" for county medical societies at the time the November *Journal of the Michigan State Medical Society* was published. The county medical society was considered during the year by the council and other officers of the state society and by officers of various county medical societies; from the suggestions offered, a program was developed and approved. There recently has been a series of meetings of the constituent society officers and councilors to take up the adoption of the minimum program, and at each meeting the societies have given unanimous approval. Those societies which have adopted the program have placed themselves on a sound business and educational basis

Personal.—Mr. W. T. Bishop, president of the Lansing Board of Health, has resigned.——Dr. William T. Dodge, Big Rapids, formerly president of the Michigan State Medical Society, has been appointed chief surgeon of the Michigan Soldiers' Home, to succeed Dr. Howard A. Grube.——Dr. Silas B. Frankhauser, Hillsdale, has been reappointed county physician.——Dr. Carl G. Fahndric, Northville, has been appointed medical director of the Calhoun County Hospital located east of Battle Creek.——Dr. George L. LeFevre, and Dr. Guy L. Connor, Detroit, have been elected president and secretary, respectively, of the state board of registration in medicine.——Dr. Leonard F. Thalner, city physician of Jackson, tendered his resignation, to take effect November 1, to engage in private practice; his successor is Dr. Earl B. Ritchie.——The Eugenics Society of the United States has awarded the first trophy prize in the recent fitter families contest, conducted at the Michigan state fair, to Dr. Thomas Reese Foster, Detroit (The Journal, August 29, p. 684).

Dedication of New University Hospital.—The board of regents of the University of Michigan, Ann Arbor, announces the dedication of the New University Hospital, November 19-21. The formal exercises will take place in the Hill

Auditorium at 8 p. m., the speakers being Drs. Victor C. Vaughan, Washington, D. C.; William J. Mayo, Rochester, Minn., and William S. Thayer, Baltimore. The guests of honor will be Governor Groesbeck, Senators Couzens and Ferris, Representative Michener, and Drs. Cyrenus G. Darling and Frederick C. Warnshuis, president and secretary, respectively, of the Michigan State Medical Society. There will be clinics at the hospital, November 20, by Dr. Thayer and Dr. Mayo, an inspection of the hospital in the afternoon, and a general meeting in the evening, at which the dean, Dr. Hugh Cabot, will preside and which Drs. Harley A. Haynes, director of the University Hospital, James B. Herrick, Chicago, and Charles P. Emerson, Indianapolis, will address. Saturday morning there will be a continuation of clinics by distinguished physicians of the state of Michigan. Dr. William J. Mayo will deliver the annual Mayo Lecture, in the Natural Science Auditorium, November 19, at 4:15 p. m., on "Splenic Syndromes."

MINNESOTA

Radio Talks.—The Minnesota State Medical Association has arranged for a series of lectures on medical topics to be given by prominent Minnesota practitioners of medicine over the radio from station WCCO. The first six numbers were: Infantile Paralysis, October 9; Pregnancy and Childbirth, October 16; Facts About Insanity, October 23; Blood Pressure, October 30; Your Heart, November 6; and Prevention of Tuberculosis, November 13.

Hospital News.—A delegation from the Sisters of St. Francis, St. Paul, recently inspected the University of Southern Minnesota, Austin, to determine its suitability for conversion into a hospital.——The Bethel Deaconess Hospital, Mountain Lake, is building a nurses' home.——A new cottage for women, having a capacity of seventy-five patients, at the St. Peter State Hospital, was recently opened. The hospital now has a population of more than 1,500.

Society News.—Dr. Leo G. Rigler addressed the Hennepin County Medical Society at a noonday meeting, October 28, on "Roentgen-Ray Visualization of the Gallbladder," and Dr Claude C. Kennedy on "Volvulus of the Small Intestine."——The annual meeting of the Hennepin County Medical Society will be at noon, November 18. At the noonday meeting, November 4, Dr. Arthur A. Wohlrabe spoke on "Diagnosis and Treatment of Duodenal Ulcer," and Dr. Verne S. Cabot on "Surgical Treatment of Duodenal Ulcer."——At the regular meeting of the Minnesota Academy of Medicine, which was held at Rochester, November 12, Dr. Charles H. Mayo gave clinical demonstrations of cancer of the right colon; Dr. Plummer, the use of iodin in toxic goiters; Dr. Edward C. Rosenow, studies in poliomyelitis; Edward C. Kendall, Ph.D., progress in study of thyroxin, and Dr. Frank C. Mann, studies in liver function. There was a dinner at the University Club Rooms at the Kahler in the evening.——Dr. Samuel E. Sweitzer gave a lantern demonstration of skin diseases before the Hennepin County Medical Society, November 11, and Dr. John F. Curtin spoke on "Antrum Infection in Children and Its Treatment."——The headquarters of the Minnesota State Medical Association has been moved to 11 West Summit Avenue, St. Paul, the new home of the Minnesota Public Health Association.

MISSOURI

Hospital News.—The new $400,000 Christian Hospital at Carter and Newstead avenues, St. Louis, was recently opened.

State Board Awaits Decision in Test Case.—The action to be taken by the state board of health on citations pending against "physicians" to show cause why their license should not be revoked for alleged fraud will be determined largely by the decision in the test case now before the state supreme court. The new president of the board, Dr. William A. Clark, Jefferson City, said, according to the St. Louis *Post Dispatch*, that the board is tied up by various injunction proceedings but that it will push the remaining cases if it has jurisdiction. The case testing the jurisdiction of the board of health now before the supreme court grew out of a suit filed by Dr. Clara W. McGrew, St. Louis, to enjoin the board from proceeding with its case involving her license. The board then obtained a "preliminary of prohibition" in the supreme court to prevent the circuit judge in St. Louis from proceeding with the injunction case. The issue now before the supreme court is whether the writ shall be made permanent; if so, the ruling would uphold the jurisdiction of the board.

Dr. Adcox Confession.—The St. Louis *Star* is publishing serially the confession of Dr. Robert Adcox, who is under federal indictment and sentenced to serve two years in the Missouri penitentiary for his connection with medical diploma mills. Adcox relates how he arranged to secure high school certificates from public school officials in several states, and how he sold them to illiterate or poorly educated students for the purpose of entering certain low-grade medical schools. In future instalments, he says he will tell how "he dabbled in medical diplomas." The only other name involved thus far in the confession is that of Owen T. Owen, Chicago (The Journal, July 5, 1924, p. 46). In his testimony, November 4, in quo warranto proceedings brought by the state to revoke the charter of the St. Louis College of Physicians and Surgeons, Adcox testified that Dr. Waldo H. Briggs, dean of the St. Louis College of Physicians and Surgeons, had appointed him a solicitor of students for the school with the understanding that whatever was collected from the applicant in the way of tuition was to be equally divided between them. Adcox said that he charged the student in proportion to what he had and according to how badly he wanted to graduate, and that this amounted sometimes to as much as four times the regular tuition fee. Adcox said that his students frequently entered the St. Louis College of Physicians and Surgeons as late as Christmas and got credit for attending classes from the beginning of the term in October. There were plenty of cases, he said, in which students matriculated in October, went right home and got their degrees the next spring without ever having attended a class. Adcox said that sometimes he would take his students to the school where Dr. Waldo H. Briggs, the dean, would have his secretary make out cards showing attendance at the school for the freshman, sophomore, junior and senior years, and then the student would get a diploma. A student by the name of Draser, for example, attended the St. Louis College of Physicians and Surgeons for one semester, bringing with him credits for four years' work from the defunct Pacific Medical College. Draser obtained from Briggs "indefinite leave," then went home and did not return; a diploma was mailed to him in California, and it cost him between $500 and $600.

MONTANA

"Dermatologist" Arrested.—W. M. de Orgler, who claimed to be a dermatologist from Denver and to have a medical degree from Vienna, and a permit from the Montana Medical Board, is said to have gone to Billings recently to practice dermatology. He made arrangements with a local druggist and advertised in the newspaper. One of the first patients sent to de Orgler was from the assistant county attorney, whereupon he was arrested for practicing without a license and paid a fine of $50. De Orgler left for Worland, Wyo.

NEBRASKA

Hospital News.—The Pioneer Memorial Hospital, Dalton, which is in charge of Drs. Axel E. Hedlund and Guy F. Zarbaugh, was opened to receive patients, October 15.

NEW HAMPSHIRE

Society News.—Dr. James B. Woodman, Franklin, was elected president of the New Hampshire Surgical Club at the annual meeting at Portsmouth; Dr. Eugene B. Eastman, Portsmouth, vice president, and Dr. John F. Holmes, Manchester, secretary-treasurer. Dr. Eastman was toastmaster at the annual banquet. The clinical meeting next spring will be at Nashua.

NEW JERSEY

Personal.—Dr. Henry Wallace, Glen Ridge, director of the cardiac department, Mountainside Hospital, Montclair, has resigned and moved to New York City.

Hospital News.—The new nurses' home of the Nathan and Miriam Barnert Memorial Hospital, Paterson, the gift of Nathan Barnert, was dedicated, October 8.

Typhoid Bacilli in Potato Salad.—An investigation of a recent outbreak of typhoid in Barnsboro following a supper given by the local fire company in September disclosed, it is reported, that the outbreak was due to the eating of potato salad which had been prepared by a typhoid carrier. Three persons died as a result of the outbreak.

NEW YORK

Hospital News.—The board of governors of the New Rochelle Hospital, White Plains, announce a drive for $1,000,000, beginning November 21, for the expansion of the hospital.

Personal.—Dr. Carl Boettiger, Forest Hills, was elected vice president of the Queensborough Tuberculosis Association at the sixth annual meeting, October 28.——Dr. Donald C. Smelzer, assistant to the superintendent of the Buffalo General Hospital, Buffalo, has resigned to become superintendent of the Charles T. Miller Hospital, St. Paul, to succeed Dr. Karl H. Van Norman.

Site for Veterans' Hospital.—The U. S. Veterans' Bureau purchased, November 2, the 550 acre Holmes estate near Northport, L. I., as a site for a 1,000-bed hospital for mentally infirm veterans. Nearby are the Central Islip and Kings Park hospitals, also for mental patients; *New York Medical Week* says that the state of New York is building an additional $3,000,000 group of buildings on the Kings Park grounds for veterans from the state who are mentally ill.

New York City

Personal.—Holmes C. Jackson, Ph.D., professor of physiology, University and Bellevue Medical College, has been appointed dean of the New York College of Dentistry.

Hospital News.—The cornerstone of the extension to the Staten Island Hospital, New Brighton, S. I., was laid, October 17, by Edward C. Bridgeman, president of the Staten Island Savings Bank, who has been a trustee of the hospital for more than fifty years.——The annual benefit performance for the Hospital for Ruptured and Crippled will be "The Vagabond King" at the Casino Theatre, November 16.——The cornerstone of the new Caledonian Hospital, Brooklyn, was laid, November 8, and a campaign to raise $200,000 to complete the structure was begun the following day.

Society News.—At a recent meeting of the Manhattan Dermatological Society, Dr. Benjamin F. Ochs, the sole surviving charter member, and Dr. Ludwig Weiss, were made honorary presidents; Dr. George C. Andrews, Jr., chairman; Dr. Joseph J. Eller, vice chairman, and Dr. David L. Satenstein, secretary-treasurer.——Dr. William E. Preble, Boston, will address the Clinical Society of the Hospital for Joint Diseases, November 24, on the medical aspects of "Chronic Arthritis," and Dr. William Russell MacAusland, Boston, on the surgical aspects of that subject, with moving pictures of arthroplasty. Physicians are invited.

Lectures on Mental Hygiene.—The following series of lectures on mental hygiene will be given at the New York Academy of Medicine, beginning November 10:

Edwin Grant Conklin, Ph.D., professor of biology, Princeton University, "Development in the Light of Eugenics and Heredity."

Dr. Thomas W. Salmon, professor of psychiatry, Columbia University College of Physicians and Surgeons, "Some of the Emancipation Problems of the Adolescent."

Dr. C. Macfie Campbell, professor of psychiatry, Harvard Medical School, "New Concepts of Mental Ill Health."

Dr. Adolf Meyer, professor of psychiatry, Johns Hopkins University, Medical Department, "Individualism and Mental Health."

Dr. William A. White, medical director, St. Elizabeth's Hospital, Washington, D. C., "Psychological Methods of Cure, Psychanalysis and Suggestion."

Dr. Ira S. Wile, New York, "The Mental Health of the School Age Child."

Dr. Augusta F. Bronner, "Juvenile Delinquency and Mental Hygiene."

Paul Klapper, Ph.D., dean, School of Education, College of the City of New York, "Mental Tests—Their Uses and Interpretation."

Dr. Abraham Myerson, professor of neurology and neuropathology, Tufts College Medical School, "Inheritance of Mental Diseases."

Dr. R. Foster Kennedy, professor of clinical medicine, Department of neurology, Cornell University Medical College, "The Relation of Nervous Disorders to Functional Disease."

Dr. Patty Hill, professor of education, Teachers' College, Columbia University, "Nursery Hygiene and the Nursery School."

Dr. Douglas A. Thom, instructor in psychiatry, Harvard Medical School, Boston.

OHIO

Physician Sentenced.—Dr. Frank J. Sofge, Cincinnati, was sentenced to three years in the federal penitentiary at Atlanta, October 19, by U. S. District Judge Hough, following his plea of guilty to violation of the Harrison Narcotic Law, it is reported.

Hospital News.—The Deaconess Hospital, Cincinnati, is conducting a drive for $500,000 for new construction.——The citizens of Fostoria will soon vote on a $50,000 bond issue, the proceeds of which will be used to convert the Emerine property into a hospital.——Alterations are being made on the McKinley Hospital, Columbus; it will be operated as an open hospital by a group of general practitioners. The head of the new organization is Dr. William H. Cleveland.

Cincinnati Dermatologists Organize.—The Cincinnati Dermatological Society was recently organized with Dr. Augustus Ravogli, president; Dr. Elmore B. Tauber, vice president, and Dr. H. Jerry Lavender, 715 Provident Bank Building, secretary-treasurer. Meetings will be the first Wednesday evening of each month except in summer, and visitors will be welcome. The secretary requests that dermatologists from other cities inform him at any time of their intended visits in or near Cincinnati.

Society News.—Dr. Charles A. Langdale has been elected president for the ensuing year of the Cincinnati Academy of Medicine, Dr. Victor Ray, president-elect; Dr. Alexander G. Drury, treasurer, and Dr. Elmer A. Klein, secretary——Dr. George W. Crile, Cleveland, addressed the Columbus Academy of Medicine, September 28, on "Problems Relating to the Liver and Biliary Tract," illustrated by lantern slides.——Dr. John A. Riebel gave a surgical demonstration before the General Practitioners Medical Society at the new McKinley Hospital, Columbus, October 29, of the new Gerad-Bassini herniotomy; Dr. Benjamin W. Abrahamson presented a case of epidemic encephalitis.——T. Wingate Todd, Henry Willson Payne professor of anatomy, Western Reserve University School of Medicine, Cleveland, addressed the November meeting of the Academy of Medicine of Toledo and Lucas County on "Royal Mummies."——Dr. Clarence D. Selby, president, Ohio State Medical Association, addressed the Harrisburg (Pa.) Academy of Medicine, October 6, and the Academy of Medicine of Toledo and Lucas County, October 21.

Personal.—Dr. Tedrow S. Keyser, Springfield, has been appointed head of the medical staff of the Clark County Tuberculosis Sanatorium, to succeed Dr. Clarence E. M. Finney, resigned. Dr. Keyser will take up his duties about December 1; he is a graduate of Johns Hopkins University Medical Department, Baltimore, and served in Germany and Roumania during the World War as a tuberculosis examiner.——Dr. Charles W. Conley has resigned as a member of the medical staff of the Ohio Industrial Commission and will be succeeded by Dr. Austin H. Seeds, Columbus; Dr. David P. Young, Dayton, has been added to the medical staff of the commission.——Dr. William H. Banner, Tiffin, has been appointed jail physician to succeed the late Dr. Charles W. B. Harbour.——Dr. Samuel P. Carter, West Manchester, has been appointed assistant surgeon for the American Rolling Mills, Middletown.——Dr. Henry T. Sutton, Zanesville, has been reelected president of the staff of the Good Samaritan Hospital.——Dr. Harold S. Cohn has resigned as medical examiner of the U. S. Veterans' Bureau at Cleveland.——Dr. Maurice I. Miller, Troy, has been appointed county physician to succeed the late Dr. Charles A. Hartley.

PENNSYLVANIA

Personal.—According to the Pittsburgh *Post*, Dr. John R. Conover was elected secretary of the newly organized Allegany County Health Association, October 30. Board of health officials from all parts of the county outside Pittsburgh were present and among the speakers were Dr. Charles H. Miner, state health officer, Dr. Samuel R. Haythorn of the University of Pittsburgh and Dr. Carey J. Vaux, health officer of Pittsburgh.

Physical Examinations for State Employees.—Governor Pinchot recently announced that the state department of health is prepared to make physical examinations of all employees of the executive departments. The examination of employees is voluntary except when they are absent from duty on sick leave for five consecutive days in a month, or for eight days in two consecutive months, or for employees who are believed by the health department to be a menace to the health of others and except all new employees.

Philadelphia

Personal.—George H. Meeker, Ph.D., dean of the Graduate School of Medicine of the University of Pennsylvania received the degree of doctor of laws from LaFayette College at the Founder's Day exercises, October 21.——Dr. Solomon Solis-Cohen, for many years professor of clinical medicine, Jefferson Medical College, was elected to membership on the board of education at the meeting of the board of judges, November 6.

Welfare Drive Continued.—To allow the 4,000 workers to reach persons whose names they have but whom they have been unable to canvas, the Welfare Federation Campaign for $3,157,000 will be continued for a week longer. The tabulating of final reports of the drive, which was to have ended at the close of the eight-day period, showed that the total subscribed was $2,527,944, or more than $600,000 less than the goal.

Society News.—Dr. Theodore H. Weisenburg has arranged a symposium on "Nervous Diseases," which will be presented at the next scientific meeting of the Philadelphia County Medical Society, November 26, at the College of Physicians.——The Board of Directors of the Philadelphia County Medical Society, Room 1208 Central Medical Building, desire information concerning certain founders of the society, and if possible photographs for historical classification. However slight, any information will be welcome concerning Drs. William Curran, William H. Tingley, Robert Foster, Thomas Hobson, James McCulloh, Frederich A. Martin, John M. Pugh, Neville C. Reid; ex-presidents, Drs. Benjamin Horner Coates-1859, George Hamilton-1868, and Francis M. Perkins-1903.

RHODE ISLAND

Smallpox at Woonsocket.—It is reported that the outbreak of smallpox at St. Francis Orphanage, Woonsocket, had affected eighteen children, October 31, and that there were fourteen cases in the orphanage when the outbreak was discovered; only two cases were severe, and these patients are convalescent.

Society News.—Dr. Jeffrey J. Walsh has been elected president of the Rhode Island Ophthalmological and Otological Society; Dr. John J. Gilbert, vice president, and Dr. Francis B. Sargent, secretary-treasurer. The society voted at this meeting to subscribe to the eye, ear, nose and throat journals for the medical library and to make the usual contribution in funds to the Rhode Island Medical Library Fund.

State Society Sponsors Radio Talks.—Through its committee on education, the Rhode Island Medical Society is sponsoring a series of health talks over the radio from Station WJAR, on Friday evenings at 8:50. The series began, October 16, and November 13 will be "Prenatal Care," Dr. Herbert G. Partridge; November 20, "The Baby: Its Proper Food," Dr. Henry E. Utter; November 27, "The Preschool Child," Dr. Harold G. Calder; December 4, "The School Child," Dr. Ellen A. Stone; December 11, "Tuberculosis in Childhood," Dr. John I. Pinckney; December 18, "Tuberculosis in Adults," Dr. Harry L. Barnes.

SOUTH CAROLINA

Personal. — Dr. Louis L. Williams has been appointed county health officer at Georgetown.——Dr. James B. Beeler, *Columbia, a member of the staff of the State Hospital*, has been elected superintendent of the Spartanburg General Hospital.

Society News.—The Greenville County Medical Society held a meeting, October 5, in honor of Dr. Robert S. Cathcart, Charleston, president of the South Carolina Medical Association. Dr. Cathcart spoke on "The Progress of Surgery" and on the work of the state medical association.

WASHINGTON

Increase in Death Rate.—The Department of Commerce announces that the 1924 death rate for Washington was 1,001 per hundred thousand of population, as compared with 966 in 1923. The increase is largely accounted for by increases in death rates from diseases of the heart, measles, nephritis and diphtheria.

Society News.—Dr. James Tate Mason addressed the King County Medical Society, Seattle, November 2, on "Some of the Pertinent Problems of Goiter," and Dr. William M. O'Shea, on "Vomiting [illegible]" Dr. William H. Axtell, Bellingham, add[illegible] County Medical Society, October 5, on "[illegible]" and Dr. Lyle A. Greenwood, Bellingham, on "Observations on Blood Sugar."

WISCONSIN

Society News.—The Marathon County Medical Society, Wausau, gave a dinner in honor of Dr. Joseph F. Smith at the Wausau Club, October 21. Dr. Smith was recently elected president of the Wisconsin State Medical Society.

Personal.—Dr. Adolf Gundersen, La Crosse, a regent of the University of Wisconsin, has been awarded the Knighthood of St. Olaf by the king of Norway.——Dr. Mynie G. Peterman, associate in pediatrics, Mayo Clinic, Rochester, Minn., has accepted the position of director of laboratory and research at the Children's Hospital, Milwaukee.——Drs. E. Evans, LaCrosse; John W. Coon, Stevens Point; Charles D. Boyd, Kaukauna, and Gustave Windesheim, Kenosha, were reelected directors of the Wisconsin Anti-Tuberculosis Association at the eighteenth annual meeting, Milwaukee, October 30, and Dr. Michael R. Wilkinson, Oconomowoc, was elected as a new director.——Dr. Lawrence F. Dugan has resigned as house physician of the Emergency Hospital, Milwaukee, and has been succeeded by Dr. Harry T. King.

GENERAL

Prize for Health Work in Schools.—The American Child Health Association announced, October 11, that the $1,000 prize offered in its study of health programs in secondary schools of this country had been divided between the Jacksonville Consolidated School, Jacksonville, Ark.; the New Trier Township High School, Kenilworth, Ill., and the DeWitt Clinton High School, New York. More than fifty schools took part in the contest.

Section Meetings Discontinued.—The American Roentgen Ray Society, at the recent annual meeting in Washington, D. C., decided to discontinue sectional meetings. It has been evident for several years, the journal of the society says, that meetings devoted to roentgenology and radium therapy had become so frequent as to impose a burden on those required to attend them. The Radiological Society of North America previously had discontinued its summer meetings. The editor says that the number of meetings could be still further reduced without interfering with the progress of roentgenology and radium therapy.

Accidents at Coal Mines in September.—There was a loss of 142 lives in accidents at coal mines in the United States, in September, which, according to the Department of Commerce, were all at bituminous mines, work at the anthracite mines being suspended during the month. There were no major disasters reported. The fatalities represented a death date of 3.03 per million tons of coal mined, as compared with 3.76 for the corresponding period last year. The deaths of 1,612 men killed by accidents at coal mines in the United States have been reported to the Bureau of Mines in the first nine months of this year, representing a reduction in the death rate per million tons mined of 16 per cent.

Campaign for The Physicians' Home.—The campaign for an endowment fund for a national home for aged and needy physicians will be inaugurated, November 23, at a banquet at the Waldorf-Astoria, New York. Among those who have been invited to speak are Hon. Chauncey M. Depew, Hon. Elihu Root, Dr. Hubert Work, Secretary of the Interior, Cardinal Hayes, Hon. Samuel Untermyer, Dr. Charles H. Mayo, Dr. Alexander Lambert and Rev. S. Parkes Cadman. Persons desiring to attend the banquet should notify the secretary, Silas F. Hallock, The Physicians' Home, Inc., Twenty-Second Floor, *Times* Building, Broadway and Forty-Second Street, New York, promptly.

Accidents at Quarries.—According to the Bureau of Mines of the Department of Commerce, there were 138 deaths at quarries in the United States during 1924 and 14,777 injuries, as compared with 142 deaths in this industry and 14,990 injuries in 1923. The 1924 fatality rate is the lowest since the Bureau of Mines in 1911 began compiling data for quarries. The industry employed 94,242 men during the year. The employees averaged 269 workdays per man. Accidents inside the quarries killed ninety-six men and injured 8,990, while accidents outside the quarries, at crushers, mills, and rock-dressing plants, killed forty-two and injured 5,787. The principal causes of fatal accidents inside the quarries were falls or slides of rock, explosives, falls of persons, machinery and haulage, while the principal causes of fatalities outside were machinery, haulage, falling objects, falls and burns.

Postgraduate Classes in Stomatology.—The following courses, given under the auspices of the American Stomatological Association, are open to duly licensed physicians and dentists; stomatologic bacteriology, under the supervision of Drs. William H. Park and Charles Krumwiede; diagnosis and focal infection, Drs. George Reese Satterlee, Homer E. Smith, George A. Wyeth and others; stomatologic hygiene, Alfred J. Asgis, D.D.S., and E. B. Hardisty; dietetics in stomatologic practice, Holmes C. Jackson, Ph.D.; clinical dietetics, Dr. Robert H. Rose. Clinical and laboratory courses will be given at Fordham Hospital, University and Bellevue Medical College, Medical Laboratories, Midtown Hospital and other institutions. Information may be obtained from the Director of Classes, Aeolian Hall, 33 West Forty-Second Street, New York.

Women's Clubs Plan Health Surveys.—The department of public welfare of the General Federation of Women's Clubs [illegible] a plan of health surveys in communities [illegible] States. The assistance of other organizations will be enlisted and the data collected submitted to official agencies before publication. A prize will be offered the state showing the greatest interest in this program, and the Metropolitan Life Insurance Company, New York, will supply clubs with an outline by which such a survey may be conducted and furnish statistics whereby results may be compared with work done in other communities and, when the survey is completed and approved by local health officials, will print the report for distribution in the community concerned. All names of women's clubs completing the work should be in the hands of the General Federation chairman by April 1, 1926, if a state desires to compete for the national prize.

Automobile Fatalities.—There were 3,973 automobile fatalities reported to the Department of Commerce from January 1 to October 10 from fifty-nine cities in the United States having an aggregate population of 28,000,000. Reports from thirty-seven cities having a population of 100,000 or more show more automobile fatalities in the four weeks ending October 10 than in the previous four weeks, and that there were no automobile fatalities in the latter period in Grand Rapids, Mich., Kansas City, Kan.; Washington, D. C., and Wilmington, Del. New Bedford, with nine deaths, has the lowest rate (8.4) per hundred thousand of population. Among sixty-five cities in which comparisons are possible for 1924 and 1925, only sixteen reported more automobile fatalities in the period from Jan. 1 to Oct. 10, 1925, than in the first ten months of 1924. New York so far this year has reported 730 automobile fatalities; Chicago, 453; Philadelphia, 226; Detroit, 200; Cleveland and Los Angeles, each 173.

Sanitation in Jails.—A report submitted to the American Prison Association by its committee on jails, of which Dr. Hastings H. Hart, consultant at the Russell Sage Foundation, New York, is chairman, covers a study of 893 city and county jails throughout the country in which federal prisoners are kept. The committee found that many of these jails are overcrowded and insanitary and infested with vermin. It was not unusual at the Cook County Jail in Chicago, for example, to keep five prisoners in a cell intended for one, and similar conditions have existed in Detroit, Cleveland, New York and other cities. The report shows that the United States government is "boarding out" more than 7,000 prisoners to local jails over which the government has no control and many of which are "desperately overcrowded." A large part of these federal prisoners are simply awaiting trial, and a considerable number of them are subsequently legally proved innocent. Since the government has no jails of its own, the committee says, it inflicts a great injustice on the taxpayers in the counties where the prisoners are confined. The government boards its prisoners in various county jails at an average cost of 69 cents a day, and the fees received for federal prisoners go to the sheriff or jailer or to the county, depending on the laws in the state; in some places the income of the local jailer depends on what he can save from the food allowance of the prisoners. The committee says that the present system of boarding out prisoners in county jails is hopelessly unsatisfactory to all concerned, except to a limited number of county sheriffs and jailers.

LATIN AMERICA

Medical Practice in Honduras.—The Facultad de Medicina at Tegucigalpa frames the laws pertaining to the medical profession and examines foreign physicians who desire to practice in Honduras. The right to practice in that country may be obtained by completing a six year course in the department of medicine of the University of Honduras, the only medical school, but physicians from other countries may register their diplomas with the Facultad de Medicina and thereby obtain the right to practice. If a physician from another country has no diploma from a recognized school, he must take an oral and a written examination; this applies to dentists and pharmacists also. Certain formalities should be observed in order to avoid loss of time; for example, the signatures on one's diploma should be authenticated by the secretary of state of the state in which the school is located; the signature of the secretary of state should be authenticated by the Secretary of State of the United States, and his signature in turn authenticated by a Honduras consul in the United States. The diploma then, with the attached documents, is forwarded to Tegucigalpa to the minister of foreign relations, who transmits it to the minister of public instruction for the necessary registration. For those who take the examination in Honduras in order to practice and who do not speak Spanish, the Facultad de Medicina appoints a translator.

FOREIGN

Trachoma Epidemic in Germany.—The public schools in various sections of the Palatinate (a part of Bavaria) have been closed on account of an epidemic of trachoma, according to the New York *Times;* eighty-five school children have been placed in hospitals in the Hassloch district.

Medical Officer for London County.—Dr. F. N. Kay Menzies, director of the hospital and medical services department at the Red Cross of London, will succeed Sir William Hamer as chief medical officer for the County of London, Jan. 1, 1926, when Dr. Hamer will retire, after having served the council for nearly thirty-four years.

Vacant Professorships in Medicine in Ireland.—Dr. John Mallet Purser has resigned the chair of Regius professor of physic in Dublin University, and the vacancy will be filled in December. According to the *Lancet,* Dr. Purser has recently been in ill health. Dr. Joseph O'Carroll has resigned the chair of medicine in University College, Dublin, National University of Ireland, to which he was appointed in 1912.

Warning Against Studying Medicine.—The Prussian state authorities have issued a public warning against taking up the study of medicine in the next few years. Among the reasons given are that the outlook for physicians is the worst conceivable while the training in medicine is the most expensive of all the academic professions. The *Klinische Wochenschrift* adds that the warning was issued at the initiative of the officers of the organized medical syndicates, the Aerztekammern.

Annual Dinner at "Old Barts."—The annual old students' dinner of St. Bartholomew's Hospital, London, was held again this year in the Great Hall of the hospital, and the chairman was Mr. John Adams, F.R.C.S. Among many others present were Sir John Bland-Sutton, Sir Archibald Garrod, Lieut. Gen. Sir William B. Leishman, Surg. Vice-Admiral Joseph Chambers and Dr. W. Langdon Brown. Plans have been drawn up for the rebuilding of the hospital, which provide for more than 700 beds on the present site and for a paying patients' block with about eighty beds. The historic Great Hall (this hospital is more than 800 years old) will be left undisturbed.

American University of Beirut.—The dean of the Medical Department of the American University of Beirut, Syria, writes that the freshman class this year comprises twenty-five students and that there have been new appointments to the faculty of Dr. Stanley E. Harris as adjunct professor of internal medicine and therapeutics. Dr. Harris graduated from the University of Pennsylvania in 1923. Dr. Lepine, son of the dean of the Medical Faculty of the University of Lyons, France, has been appointed professor of pathology. A former student of Johns Hopkins Medical School, Mr. William Shanklin, is teaching histology, and Stanley E. Kerr, who has done special work at the University of Pennsylvania, is expected to take charge of the new laboratory in biochemistry. This school has its first fifth year class this year of nine men. The dean says that many of the other graduates are taking their year of internship in general hospitals in Palestine, Egypt or the Sudan or at the University of Montpellier in France. A large tract of land in the rear of the University Hospital has been added to the campus for purposes of expansion.

Deaths in Other Countries

James Niven, formerly medical officer of health for Manchester, England, September 30, aged 74.——Dr. **James W. Russell**, professor of medicine, University of Birmingham, September 20, in Devonshire, aged 62.——Dr. **Charles Frederick Sonntag**, anatomist to the Zoological Society of London and author of many papers on comparative anatomy; October 10, aged 38.——Dr. **R. C. Chicken**, consulting surgeon to the Nottingham General Hospital and formerly president of the Nottingham Medico-Chirurgical Society; October 3, aged 75.——Dr. **A. M. Arquellada**, Madrid, president of the Madrid Pediatric Society and surgeon in chief of the Niño Jésus children's hospital.——Dr. **G. Dorner**, professor of internal medicine at Leipzig, committed suicide October 5 in a recurring attack of depression.——Dr. **L. Bardach**, director of the German sanatorium at Nice for twenty-five years.——Dr. **A. Massone**, chief of the hygiene department of the Italian public health service.——Dr. **G. Perna**, professor of anatomy at Bologna and author of numerous works on anatomy.——Dr. **O. van der Stricht**, a Belgian biologist who lectured at various universities in this country during the World War, and whose last important work, on ovogenesis in mammals, was recently published with financial aid from America.

LONDON

(From Our Regular Correspondent)

Oct. 23, 1925.

The Earliest London Woman

At a meeting of the Zoological Society, Mr. Warren R. Dawson and Prof. Elliot Smith exhibited what appear to be the earliest fossilized human remains discovered in London. They consist of the posterior two thirds of the cranium of a woman, estimated to be about 45 years of age from the condition of the sutures. The bony matter was so mineralized that there could be no question of its being the familiar case of a modern skull getting into a pit. The skull was found during recent excavations in connection with building operations in the city, 26 feet below the level of the street. The deposit there is Pleistocene river gravel. Remains of the mammoth had been obtained previously in the same area, both above and below the level at which the skull was found and at a deeper level of the deposit, part of the skull of a woolly rhinoceros had been found. The bed of river gravel is part of the third or lowest level of the Thames Valley, laid down when the river was much wider and deeper than now. From the anthropologic point of view, the horizon is associated with the upper paleolithic ages of human development. The discovery confirms the view that before the age of neolithic culture began in the south of England, there was an indigenous population, living for the most part in caves, ignorant of pottery or of metals, but making accomplished implements of stone, showing a strong artistic sense and living as nomad hunters. These Paleolithic races have belonged definitely to *Homo sapiens,* the species of modern man. Distinct from them and of unknown origin is the low-browed Neanderthal species, remains of which have been discovered in many parts of the world. In the opinion of Professor Smith, the skull in the present case was much flattened and similar to the Neanderthal type.

The Defense of the "Unconscious Mind" Fails in a Murder Case

At the central criminal court, a lad, aged 19 years, was tried for the murder of his aunt by marriage. The crime had very unusual features, for he was the woman's paramour and she had asked him to kill her. In cross-examination the police surgeon, called by the prosecution, admitted that for a humane boy to strangle the woman he loved in the circumstances disclosed showed an abnormal state of mind. He was asked, "If some one had reiterated commands given to him, such as 'Kill me,' might not he, in his state of mind, have done things without appreciating what he was doing?" He replied, "I suppose so." "Suppose a boy very emotionally moved and in a curious condition altogether suddenly loses control of himself, his subconscious mind might take charge of him and make him do something without his appreciating what he was doing?" The police surgeon again replied, "I suppose so." The judge then intervened by saying, "I don't quite understand this. Is the theory that the prisoner's condition of mind was such that his conscious mind ceased to function and he strangled the woman through the action of his subconscious mind?" The lawyer for the defense answered, "Yes." But the police surgeon said, "I do not think the conscious mind was lost in this case. We know the subconscious mind plays an important part, but I cannot say it takes up the work if the conscious mind is absent." Dr. Bronte, the government pathologist, was also cross-examined. He admitted that "calf love" might take a strong hold on a person, and that difficulties might increase that hold. He was asked, "Any one in that condition might be prone to suggestions by a person more mature than himself?" He answered, "Yes." Evidence was given for the defense that the prisoner was of a peculiarly gentle character, and that there had been insanity in the family. The defense was that under the circumstances his mind gave way and the woman's reiterated command, "Kill me! Kill me!" took possession of his subconscious mind and urged him to the act. In summing up, the judge asked the jury to consider whether at the time the prisoner committed the act he had any disease of the mind. If he did not appreciate the nature and quality of his act, or if he knew what he was doing, but he did not know that it was wrong, they could find him guilty but insane. This, of course, is the celebrated McNaghten rule, which recent medical opinion and still more recent legal opinion have declared to be inadequate. The jury found the prisoner guilty but recommended him to mercy.

Hospitals and Road Accidents

The enormous increase of road accidents due to the development of motor traffic has been pointed out from time to time in The Journal. The number of such accidents treated in the hospitals has now become a serious burden. In its last annual report, the British Hospitals Association stated that the number of such accidents treated was much more than formerly, and that there was no legal or other machinery in compensation cases to enable hospitals to reap any financial benefit for services rendered to the injured. Mr. E. W. Morris, house governor of the London Hospital, said that the number of motor accidents constituted a serious problem in that institution. The best treatment was provided, the expense of which was considerable, and the hospital could not legally claim anything for the service rendered to the injured person who was entitled to compensation. "There are insurance companies among our subscribers," he added, "and motorists and others injured have made contributions. But the amount is infinitesimal compared with the expense to the hospital. We do think that the services rendered by the hospital should be considered in compensation cases claims."

The Racial Problem in South Africa

Is white civilization doomed to extinction in South Africa? This question was raised by Dr. J. A. Mitchell, chief health officer of the Union of South Africa, at the Imperial Social Hygiene Congress at Wembley. The fertility of the black race was so enormous, he said, and their adaptation to the climate was such that it had been estimated that within fifty years they would exceed the white out of all proportion. There was an extraordinary tendency to exaggerate the prevalence of diseases among the natives. Statements were made that 50 per cent. and more were infected with venereal disease, but the total for all races was under 2 per cent. Under European rule, intertribal wars had been stopped; law and order were enforced; famine was prevented or checked, and, apart from the world-wide spread of influenza in 1918, there had been no serious epidemic in South Africa during the last forty years. The real racial danger was not that the native population would be reduced or destroyed, but that the Europeans may be elbowed out or swamped and absorbed by natives.

Workshops for the Tuberculous

Health officers from various parts of London attended a meeting at the Holborn town hall in support of the provision of workshops for tuberculous men and women. The borough of Holborn boasts the first workshop of this kind in the country, and the purpose of the gathering was to urge the necessity of establishing similar institutions. The Spero Leather Factory was established in 1922 by the Central Fund for the Industrial Welfare of Tuberculous Persons and is at present subsidized by voluntary subscriptions. The idea is that patients leaving sanatoriums are often able to undertake some work, though not sufficient to yield a living wage. Colonies have been formed for their assistance in the past; but by means of the workshops, such as that in Holborn, the men can remain at home with their families. Wages at Holborn factory vary from $8 to $11 a week. Medical opinions expressed at the meeting were strongly in favor of such workshops.

The Cost of Malaria

Dr. Andrew Balfour, director of the London School of Hygiene and Tropical Medicine, estimates the direct annual cost of sickness and death attributable to malaria in the empire at between $250,000,000 and $300,000,000. A further vast loss is the diminished industrial efficiency due to the disease. The annual world death roll he estimates at 2,000,000.

The Prevention of Scarlet Fever and Diphtheria

In his presidential address to the Society of Medical Officers of Health, Dr. G. F. Buchan, health officer for Willesden, said that since 1875 the death rate of England and Wales had fallen by 46 per cent., and the infant mortality by 53 per cent., while the expectation of life at birth was greater by twelve years. Judged by these figures the health officer had well fulfilled his function, but there are some aspects of public health which did not throw so favorable a light on his work, particularly the continued prevalence of diphtheria and scarlet fever. In 1874 the death rate from diphtheria was 15 per hundred thousand persons and from scarlet fever, 105. Last year the figures were, respectively, 6.4 and 2.3. The total number of deaths from these diseases in 1874 was 3,560 and 24,922, respectivity; in 1924, 2,501 and 888. While the deaths and death rates from diphtheria had not materially changed during the period from 1874 to 1924, the deaths and the death rate from scarlet fever had greatly and progressively diminished. His own experience led him to the conclusion that hospital isolation was not effective as a means of prevention of diphtheria and scarlet fever; that the methods of disinfection in general use were without influence in prevention of the spread of these diseases, and that isolation hospitals; by increasing the length of infectiousness, defeated to some extent the object of prevention for which they were established. Hospital provision for the treatment of diphtheria and scarlet fever cost $15,000,000 per annum, exclusive of the cost of disinfection and other means of prevention. The bulk of this could be saved by the application of the newer methods of prevention revealed by recent research. These included the Schick test, the Dick test and immunization.

The London School of Hygiene and Tropical Medicine

The site for the new building of the London School of Hygiene and Tropical Medicine is near the British Museum. It is not expected that it will be ready for occupation before 1928. One source of anxiety has been removed. The trustees of the Rockefeller Foundation originally promised to provide a sum of $2,000,000, in 1922. This meant a considerably larger sum in sterling at the time than it does now, because of the depreciation of the British currency practically to par. Representatives of the board of management to the Rockefeller trustees have caused the latter to cancel this loss and have undertaken to provide a sum equal in British money to that which their grant would have yielded at the time it was made. The number of students in the tropical division of the school constitutes a record; for the year 1924-1925, it amounts to 227. The widespread benefit of the school is shown by the countries to which its students have gone. These include West Africa, East Africa, South Africa, Egypt, Mauritius, India, Ceylon, China, Hongkong, Federated Malay States, Straits Settlements, Siam, Palestine, the United States, South America, Trinidad, Australia, the Gilbert and Ellice Islands, France, Italy, Denmark and Serbia. With regard to research work, the most important development is the arrangement made between the authorities of the school and the government of Southern Rhodesia for the prosecution of medical research in that colony. Dr. G. R. Ross left England in March to conduct research on blackwater fever in the laboratory at Salisbury and in the field.

Leukemia Following the Use of Radioactive Substances

Articles by Jagić Schwartz and Siebenbrock (1911), Aubertin (1902) and Mostram (1920), show that radiations of short wave length may cause destructive lesions of the blood-forming organs. A number of cases of grave anemia and pernicious anemia have occurred in persons who handle radium and thorium. The therapeutic use of these substances or of too strong or too often repeated doses of roentgen rays has sometimes produced similar conditions. Experimentally, too, acute anemic and hemorrhagic states have been induced in animals. Weil observed recently two civil engineers who had been working in the same laboratory preparing radioactive substances of the thorium group, one of whom succumbed to pernicious anemia and the other to myeloid leukemia. Weil has an interesting article in the *Presse médicale* on leukemia following the use of radioactive substances. Besides his own case, which he reports in detail, he cites from the literature seven other cases of leukemia that developed under similar conditions. Of these seven cases, five occurred in roentgenologists, one in a person who handled radium habitually, and one in a patient who had received roentgenologic treatment. Only two of the cases were published with the details. On the basis of these eight observations, leukemia following the use of radioactive substances seems to be established. This type of leukemia seems to be caused more particularly by roentgen rays, for most of the patients were roentgenologists; but radium and thorium may likewise be incriminated. In all cases the effects were produced through small doses frequently repeated over a long period.

The only case of therapeutic origin was in a patient with uterine fibroma, who was subjected to a single massive application of penetrating rays. Because four years intervened before the appearance of leukemia there is some doubt of a causal relation of the one to the other. If, however, a single massive dose of roentgen rays is capable of producing leukemia after so long an interval, other cases will be reported before long. Application of penetrating rays, now abandoned, was in vogue a few years ago and possibly their untoward effects will be revealed in further cases. The type of leukemia caused by roentgenologic irradiation is not peculiar in any way. It may be either of the lymphatic or the myeloid type.

Leukemia is often very favorably influenced (at least, at the start) by roentgenotherapy, and in that respect it resembles epithelial cancers of roentgenologists, which, although caused by roentgen rays, are nevertheless susceptible to treatment by roentgen rays or radium, in the usual doses.

Since the irradiations act both on the hematopoietic and on the reproductive organs, there is evidence in the patients of atrophy of the ovaries or testes.

The etiology of leukemia has been long in doubt. Some authors have regarded it as "cancer of the blood" or of the hematopoietic organs; others, as a special infectious disease, bringing it into relation with such infections as produce not only an irritation of the hematopoietic organs but also a marked leukocytosis of the myeloid (smallpox, spirillosis in fowls) or lymphatic (malaria, mumps) type.

The fact that irradiations may produce both epithelioma and leukemia in man, together with the fact that irradiations act favorably on both, awakens the idea that the two affections are interrelated. Some progress might be regarded as accomplished if we could produce leukemia experimentally in animals just as skin epitheliomas have been produced by irradiations.

Hospital Intern, Victim of Accident

A number of years ago H. Vadon, a hospital intern in Paris, in puncturing a lymphorrhagic effusion in a patient operated on for cancer of the breast, accidentally pricked a finger of his left hand. At the site of the skin puncture there soon developed an ulcerous skin lesion, which proved rebellious to all forms of treatment and the true nature of which remained for a long time unrecognized. It was only after histologic examination of an engorged gland that the diagnosis of cancer could be made with certainty. The extension of the disease soon made necessary a disarticulation of the shoulder. This operation was courageously borne by the young man, aged 24, and the government has justly conferred on him the rank of knight of the legion of honor.

The Need of Early Diagnosis of Cancer

Cancer patients often do not seek the advice of a surgeon until the disease has spread to such an extent that a radical cure is difficult. The delays that arise before beginning radium therapy, roentgenotherapy or surgical treatment cause many deaths that might have been prevented. A few years ago, the Franco-American League for Combating Cancer endeavored to educate the public by distributing more than 100,000 copies of a small pamphlet entitled, "What You Should Know," which presented the cancer situation as follows: The number of cancers is increasing from year to year. Cancer affects all classes of society without distinction —women somewhat more frequently than men. In persons above the age of 40, it is one of the most frequent causes of death. It kills more than 40,000 persons in France, annually. Its incurability results most frequently from the ignorance of the public, which neglects cancer in its initial stages, since it is not painful during the first period of its development. If operated on early, it can be cured in a great number of cases, because at the start cancer is a local disease. The sick are urged, therefore, to suspect painless indurations of the breast, any abnormal oozing, persistent ulcerations of the tongue or lips, small cutaneous tumors that ulcerate or are increasing in size, persistent troubles of digestion (especially when accompanied by loss of weight), or the appearance of constipation when the stools have been previously normal. In all such circumstances, one should have oneself examined.

The Franco-American league has carried on the same campaign by posters, and its example has been followed by the Association française contre le cancer. The league has also organized lectures, which were attended with great interest. In this way a formal movement was launched. M. Strauss, who was then minister of public health, having presided at one of the general sessions of the league, was immediately won over for this campaign against cancer. Aided by the late Professor Bergonié, who was the most zealous worker in the campaign, he created in France a number of anticancer centers. M. Godart, who succeeded M. Strauss, has continued to give to the work the influence of his authority.

Professor Hartmann, the director of the Hôtel-Dieu in Paris, one of the most frequented anticancer centers, holds the view that, in order to make the crusade more effective, a special appeal should be made to physicians, for, without their cooperation in the movement, all efforts will be in vain. All physicians should familiarize themselves with the initial signs of various cancers, which are not fully explained in the textbooks. In order that physicians may have in a concise form, without burdensome details, descriptions of the beginning characteristic symptoms of cancer, Professor Hartmann, with the collaboration of well qualified colleagues, has edited a series of short articles dealing with the early diagnosis of the principal forms of cancer. These articles are to be published in the *Presse médicale,* and there is no doubt that they will render great service. The first article of the series is by Professor Forgue of Montpellier and deals with the diagnosis of cancer of the lip.

VIENNA

(From Our Regular Correspondent)

Oct. 12, 1925.

Diseases of Metabolism and of the Digestive Tract; the Vienna Convention

The fifth session of the Gesellschaft für Verdauungs- und Stoffwechselkrankheiten was held in Vienna, Sept. 30 to Oct. 5, 1925, under the chairmanship of Prof. Dr. Kuttner of Berlin. This society was founded only twelve years ago but has had a rapid growth. Whereas only 400 members took part in the Berlin session last year, more than 800 members from all parts of Europe were registered this year. At the opening meeting, Professor Wenckebach of Vienna was elected honorary chairman. Every day two papers were presented on some main topic, and, following these, there were shorter papers on the same subject. The opening papers were on "The Variations of Metabolism" and "The Skin in Relation to Metabolism." I can give here only the outlines of the most important papers. Professor Kestner of Hamburg discussed the physiologic bases of variations in metabolism. The correct technic for the determination of gas exchange is particularly important. The examination is made with the patient fasting and the muscles relaxed. Physiologic variations are caused by (1) endogenous factors (size, weight, sex and age) and (2) exogenous factors (temperature, skin irritations, mode of living and geographic location). As a rule, the basal metabolism is constant, but specific dynamic factors may cause a change: hunger, growth, pregnancy, convalescence. The anterior lobe of the pituitary body appears to exert an influence.

Professor Biedl of Prague discussed the variations of metabolism induced by the endocrine glands. Here two factors, both the "hormonal" and the "neural" factors must be reckoned with, but these are often merged. The hormones modify functions of certain organs, or directly affect metabolism. The most important organ, in this connection, is the thyroid. Biedl discussed also myxedema, exophthalmic goiter, and hypothyroidism and hyperthyroidism. In hypothyroidism, basal metabolism may drop to 50 per cent. of normal, or even less; the hair, nails and skin are "abnormal." The ingestion of thyroid substance raises the basal metabolism. Determination of the basal metabolism establishes the differential diagnosis between genuine exophthalmic goiter and forms of hyperthyroidism. It also serves as a guide to treatment, and may throw light on the indications for operation. The thyroid also influences muscular work. Thyroid substance has a direct effect on the body temperature. The parathyroid glands influence calcium metabolism; nothing is known as to the effects of the thymus, and very little about the effects of the gonads. The anterior lobe of the pituitary body affects growth; the middle lobe, metabolism, particularly the metabolism of fat. The "suprarenal system" has an effect on the metabolism of carbohydrates and fats. At the various periods of life, sometimes one system, and sometimes another, exerts the dominant influence, which would explain cyclic fluctuations in men, women and children.

Prof. Dr. Grafe of Rostock discussed metabolism in pathologic conditions. Researches of this nature should be undertaken only in a hospital and not in the patient's home, since no reliance can be placed on a single short observation. In warm-blooded animals, the intensity of metabolism depends on three factors: (1) the metabolism of the tissues themselves; (2) influence of the nerves, and (3) endosecretory processes. Food will increase the metabolism. Fever also will produce marked quantitative changes.

In his paper on "The Skin in Relation to Metabolism," Bloch of Zurich stated that heretofore the connection between these two factors had been known in only a small number of diseases. Sometimes a disease that originates in the skin affects the internal organs and sometimes the reverse is true, dermatoses resulting from disturbance of metabolism. The effects of dermatoses on the internal organs have not been sufficiently investigated. In allergic reactions, the skin appears to act as a protection through the vegetative nervous system or through "cutaneous hormones."

The topic of the second day was "The Genesis and Treatment of Constipation and Diarrhea." Professor Strassburger, internist, of Frankfort, stated that constipation might be of functional or of mechanical origin. Diarrhea—except in catarrh—he considers due to disturbance of motility and of the excretion of fluid by the intestinal wall.

Constipation from the surgical point of view was discussed by Professor Payr of Leipzig. The most frequent cause for surgical intervention was intestinal stenosis (neoplasm), but there were also mechanical causes, such as adhesions. In reflex spastic intestinal occlusion, operation should be postponed until after subsidence of the acute attack. Payr considered also the failures and the complications of such procedures. The roentgenologic aspects of the question were treated by Holzknecht of Vienna. In fluoroscopy one rarely sees movements of the whole intestine. Slight (also reversed) intestinal movements are more frequent. Long-continued constipation may be divided into the dyskinetic, the hypokinetic and the spastic forms. As a rule, one form merges into another, and is often dependent on the constitution and the bodily type of the patient. The roentgenologic aspects of diarrhea are as yet little known. Dr. Bergmann of Frankfort brought out that intestinal function is affected by mental and physical habits; it is a delicate reflex process, which is disturbed by the habits and customs of civilization.

Boas of Berlin presented a paper on chronic appendicitis. There is a form of chronic appendicitis without demonstrable preceding attacks; this form must be carefully distinguished from acute recurring forms. The chronic type has no special characteristics, except pains in the region of the cecum. It is liable to be confused with other conditions. Roentgenologic examination is valuable. Treatment is almost exclusively surgical, and a policy of waiting—especially in children—often leads to disaster. Professor Haberer of Graz approved in the main the statements of Boas, and emphasized that in many patients who were operated on and gave no history of symptoms there were signs of previous inflammation. Grave appendical changes—even empyema—may not be associated with fever.

The third day, papers on "Cirrhosis of the Liver" and on "Diseases of the Spleen and Liver" were read. Sternberg of Vienna discussed the pathologic anatomy of cirrhosis of the liver, and gave a demonstration with lantern slides and preparations. He considered the various forms of hepatitis and pointed out the difference between pigment cirrhosis, or pseudocirrhosis, of the liver and the genuine type. The etiology is still unknown.

The clinical paper on cirrhosis of the liver was presented by Eppingen of Vienna, on the basis of 372 cases, verified by 135 necropsies. Seventy-two per cent of the cases are in men. The disease occurs, for the most part, between the ages of 40 and 50; from six months to eight years elapse before it proves fatal. The history of the patient is important; syphilis, abuse of alcoholic beverages, icterus and dyspepsia are often mentioned. In 80 per cent. of the cases, enlargement and hardening of the liver occur; tumor of the spleen is found in 70 per cent.; icterus, in 50 per cent.; in the duodenal secretions, bile is always found; ascites occurs in 52 per cent. and distended veins in 27 per cent.; esophageal hemorrhages in 10 per cent.; low blood pressure in 76 per cent; pruritus in 18 per cent. (in combating which Eppinger has found calomel very efficacious). Fever occurs only in 33 per cent.; colic (also pseudogallstone colic) is frequent; pancreatitis is observed in 20 per cent.; absence of hair on the arms and legs is a peculiar symptom in 30 per cent. Leukopenia or leukocytosis has been noted in 56 per cent. Examination of the gastric juice, the stools, the urine (determination of urobilin) is important. Also roentgenograms furnish valuable evidence. Coma hepaticum occurs but rarely (in from 5 to 7 per cent.)—with bradycardia and high fever but no acetone. To combat this condition, Eppinger recommends an infusion of glucose. Of the cases examined, 24 per cent. were atrophic, 6 per cent. hypertrophic-cirrhotic, and 70 per cent. partly each. In the Läennec type, alcoholism was present in 61 per cent. of the cases; syphilis, in 8 per cent.; icterus, in 8 per cent., and infectious disease in 6 per cent. Eppinger considers cirrhosis from the standpoint of the double function of the liver, since it affects mesenchymal and epithelial tissues.

Hijmans van den Berg of Utrecht discussed "The Mutual Relations Between the Spleen and the Liver." Little is definitely known concerning the function of the spleen, and therefore little as to its relation to the functions of the liver. It is probable that the spleen prepares the red corpuscles (under normal conditions) for destruction in the reticulo-endothelial apparatus of the liver. But, since in the splenic artery just as much bilirubin is found as in the splenic vein, it appears that the spleen does not normally participate in the production of bilirubin. In pathologic conditions—poisoning, pernicious anemia and hemolytic icterus—the case is different. In animals from which the liver has been removed, bilirubin is found in the blood. Where there is extravasated blood, there is an extra amount of bilirubin formed. In a number of diseases, blood in large quantities flows through the splenic pulp, and the red blood cells are probably partially disintegrated there and thus prepared for the liver. As yet we do not know in which diseases removal of the spleen is advantageous, nor why it should be advantageous. We must rely on the observations of the surgeons for information in regard to the effects on other organs of spleen extirpation. Ranzi of Innsbruck pointed out the rapid compensation following spleen extirpation. Often no marked effects due to the loss of the spleen were noted. To be sure, changes in the blood picture are observed even twenty years later. The results of spleen extirpation are good in hemolytic icterus. In pernicious anemia the patient's condition may improve, but a cure is not effected. A large spleen gives a better prognosis. Ranzi employs blood transfusion before and after the operation, with good effect. The mortality is high in cirrhosis with splenomegaly and the operation is difficult, but the condition of the liver is here more important. Essential thrombopenia reacts very favorably, although leukemia is hard to influence, and in acute yellow atrophy of the liver operation has not effect. Ranzi reviewed the most common operative methods and their complications.

Discussion on the papers was limited to ten minutes. Dr. Snapper of Amsterdam discussed the metabolism of the kidney and its part in the acidosis of diabetes, in which the sound kidney destroys the beta-oxybutyric acid. Professor Singer of

Vienna pointed out the significance of poisonous substances developing in the intestine from putrefaction of proteins. To combat this condition, he recommended intestinal antisepsis, a diet rich in carbohydrates and poor in proteins, and free evacuation to prevent stagnation in the rectum. For conditions involving liver injury he prescribes magnesium sulphate and hexamethylenamin. Raab of Prague studied in dogs the hormonal and nervous regulation of metabolism and found that the pituitary body plays a leading part in metabolism; its function is closely associated with the function of the vegetative midbrain centers. The cerebral fat center is identical with the heat regulating center. Glaessner of Vienna reported good results in the treatment of skin diseases from the use of glycocoll. He prescribes from 5 to 10 gm. daily; he secures increased diuresis and relief from edemas, and relief of itching in icterus and eczema. Pulay discussed the disturbances of mineral metabolism (defective distribution of blood calcium); he has cured urticaria by the administration of calcium lactate. Porges incriminated typhilitis (putrefaction due to mucus in the cecum) as the cause of many dermatoses. Singer has found that sclerodermia results not only from thyroid disturbances but also from ovarian and pluriglandular affections—often in connection with intestinal disturbances. Ehrmann of Vienna, Lichtwitz of Altona, and Stümpke of Hanover dealt with disturbances of metabolism in skin diseases, while Liebesny of Vienna discussed hypophysial and thyrogenic obesity. Mendel of Berlin recommended insulin (from 4 to 8 units daily) in exophthalmic goiter. Holzknecht emphasized again the close relation between bodily build and intestinal activity. Lenz of Bern, Schindler of Munich, and Strauss of Berlin discussed problems of local impaction. Professor Borgbjaerg of Copenhagen and Zweig of Vienna treated of suppurative colitis, in which sometimes autovaccines and sometimes surgical intervention produced favorable results. Good roentgenograms of diseased appendixes were shown by Gottheimer of Berlin. Professor Mühsam of Berlin spoke favorably of the diagnosis by means of contrast mediums. Dr. Einhorn of New York presented a new method for the roentgenographic representation of the gallbladder. He introduces tetrabromphenolphthalein sodium directly into the biliary ducts by a duodenal tube, instead of injecting it. Glaessner of Vienna uses in chromoscopy of the stomach a 5 per cent. solution of neutral red, which is excreted in the stomach ten minutes after its intramuscular injection. Glaessner and also Wittgenstein have found this method very useful in masked ulcer and many cases of achylia. Bergmann of Frankfort presented a new method for testing the function of a cirrhotic liver. He injects bilirubin solution intravenously. A healthy person shows a normal color index within half an hour, whereas in liver disease an abnormal coloration persists for some time. Pick of Prague demonstrated that intestinal activity varies in the two sexes. In men, flatulence occurs under conditions which in women cause atonic constipation. Müller of Vienna, however, denied that atonic constipation existed.

A protracted discussion arose on the subject of Gaucher's disease, in which Pick of Berlin, Epstein of Vienna, Lieb of Graz, and others, participated. Gaucher's disease is a familial (not hereditary) affection involving the spleen, the bone marrow and the other blood-forming organs. It often develops in infancy, and takes a chronic course. Splenic puncture assures the diagnosis.

Balint of Budapest dealt with gastric ulcer. He has found that the tissues in ulcer patients contain more acid than those of healthy persons and therefore are much more sensitive. Alkan of Berlin emphasized a relation between the parathyroids and ulcer (frequency of tetany in connection with ulcer). The surgical treatment of gastric ulcer was discussed particularly by Finsterer of Vienna, who has performed total resection under local anesthesia or splanchnic anesthesia; and also by Eiselsberg of Vienna, who expressed himself as strongly in favor of surgical treatment. Fränkel of Berlin, Csaki of Budapest, and Haberer of Graz took part in the discussion and touched on many new factors of the pathology and physiology of gastric ulcer. For its diagnosis Glaessner recommended the ingestion of calcium lactate, followed by a lactic acid test of the urine.

Landsberg of Warsaw recommended insulin for the treatment of slowly healing wounds in nondiabetic patients; he employs insulin also to improve the appetite of convalescents, which makes forced feeding possible.

Reicher of Frankfort presented a treatment for gallstones which causes stones of considerable size to be passed. The method requires, however, critical testing.

This review of the transactions can only suggest the character of the papers presented. Berlin was chosen for the next meeting in 1926, and Professor Bergmann was elected chairman by acclamation.

Oct. 17, 1925.

The Medical Lectures in Essen

With the beginning of the period of inflated currency, scientists here were forced to struggle for their very existence. When, in 1920, the depreciation of the currency was commencing to affect the progress of scientific research, German learned societies and institutions of higher learning founded the so-called *Notgemeinschaft der Deutschen Wissenschaft,* with headquarters in Berlin, the object of which was to prevent collapse of German scientific research. During the four years and a half in which it functioned, it was able, with the help of funds furnished from domestic and foreign sources, but particularly with the aid of federal appropriations and contributions from the several states, to relieve the tension in many quarters and to make possible the carrying out of many plans of research. The four annual reports of the society show that many German scientific journals were kept going; many books, published during the war and postwar periods, and lacking in scientific libraries, were purchased; many important investigations in natural science and medicine were made possible, and many young scientists were given necessary financial aid.

Recently the Notgemeinschaft received a request from the mining companies in the Ruhr to hold a series of lectures for the workmen on the present status of medical research. Accordingly, the Notgemeinschaft has organized a course of eight lectures, to be delivered in Essen during the week from October 25 to 31. Invitations will be sent out by the three large leagues of mining companies. Nearly all the tickets will be reserved for them. The following topics will be discussed: the value of physical exercise as a means of avoiding tuberculosis, Bier of Berlin; the operative treatment of pulmonary tuberculosis, Sauerbruch of Munich; recent researches on human performance of labor (manual labor, fatigue, capacity), Rubner of Berlin; self-control of the body, Thomas of Leipzig; the theory of nutrition on the basis of war observations and recent researches, Müller of Munich; how we can remain healthy: prevention of infectious diseases, Krehl of Heidelberg; the value of necropsies and animal experiments with reference to public health and public welfare work, Aschoff of Freiburg, and the circulation of the blood, His of Berlin. Following the lectures, an opportunity will be given to ask questions of the speakers.

Incomes and Property Holdings of German Physicians

Some time ago, the statistical department of the Leipzig Verband or League sent out a questionnaire to all its members in regard to the relative status of physicians' incomes and property holdings in 1913 and in 1924. Replies were received from 19,781 physicians, including 4,214 specialists. Of this number, 5,620 were postwar physicians, including 1,735 specialists. The league comprises at present 38,000 members, 8,000 of whom are officials or hold definite posts; very few of the 8,000 sent in reports. The statistical material was sent in, therefore, by about 65 per cent. of the physicians in the country. Table 1 gives a comparison of the total incomes before and since the war.

TABLE 1.—*Comparison of the Total Incomes Before and Since the War*

Marks	General Practitioners, 1913, per Cent.	The Same Physicians, 1924, per Cent.	Postwar General Practitioners, 1924, per Cent.	Specialists, 1913, per Cent.	The Same Physicians, 1924, per Cent.	Postwar Specialists, 1924, per Cent.
Below 12,000.........	55	78	78	43	61.6	71
Below 20,000.........	34	19	20.5	30.7	25	21.42
Over 20,000..........	11	3	1.5	26.3	13.4	7.58
	100	100	100	100	100	100

It is readily apparent that, since the war, the number of incomes amounting to more than 12,000 marks (about $3,000) has markedly decreased. The incomes of the specialists have not been affected to the same extent as those of the general practitioners, owing to the general deterioration of public health and the fact that many members of health insurance societies are being treated as private patients, especially by dermatologists.

Table 2 shows the incomes from panel practice before and since the war.

TABLE 2.—*Incomes from Panel Practice Before and Since the War*

Marks	General Practitioners, 1913, per Cent.	The Same Physicians, 1924, per Cent.	Postwar General Practitioners, 1924, per Cent.	Specialists, 1913, per Cent.	The Same Physicians, 1924, per Cent.	Postwar Specialists, 1924, per Cent.
Below 12,000.........	93.5	94	92.5	94.8	94	94
Below 20,000.........	5.8	5.6	6.2	5	5.64	5
Over 20,000..........	0.7	0.4	1.3	0.2	0.36	1
	100	100	100	100	100	100

Table 2 disproves the assertions of the *Krankenkassen* with reference to the "enormous" incomes of the panel physicians. Before and since the war, the majority of the incomes (more than 90 per cent) were below 12,000 marks (about $3,000) per annum.

Table 3 shows the property holdings as based on the reports of 12,602 prewar physicians. Here one sees the destructive effects of the inflation of the paper currency The holdings consisted for the most part of cash, mortgages, war bonds and personal and professional effects.

TABLE 3.—*Property Holdings of Prewar Physicians Before and Since the War*

Year	No Property, per Cent.	Below 20,000 Marks, per Cent.	Below 50,000 Marks, per Cent.	Below 100,000 Marks, per Cent.	Below 200,000 Marks, per Cent.	Below 500,000 Marks, per Cent.	More than 500,000 Marks, per Cent.
1913.........	8.3	15.4	19.2	21.1	20	13	3
1924.........	37.6	37.9	17.4	5.8	0.9	0.4	0

Table 3 reveals that, before the war, 57.1 per cent. of the physicians owned more than 50,000 marks, or approximately $12,000, in property; in 1924 the proportion was only 7.1 per cent.

Marriages

ROBERT OGDEN DU BOIS, New York, to Miss Elizabeth Harsen Chisolm of Ridgefield, Conn., October 11.

LEE SPOTTSWOOD LIGGAN, Callao, Va., to Miss Alice Elizabeth Hechler of Richmond, September 9.

MILTON EDWARD BEITENMAN, Cascade, Iowa, to Miss Kathryn Dolan of Omaha, October 11.

ROBERT BEEBE HAUVER, Cleveland, to Miss Katherine Carlson of Warren, Pa., October 28.

FRANK C. HENRY, JR., Perth Amboy, N. J., to Miss Beatrice Brennig of New York, October 11.

JAMES EDWARD FITZGERALD, Chicago, to Miss Dorothy Dow of Lockport, Ill., November 3.

HENRI ERNEST ABEL, Elizabeth, N. J., to DR. ALICE STEARNS GIBB of New York, October 24.

WILLIAM J. GOREY, Columbus, Ohio, to Miss Mary Faas of Springfield, September 16.

LUCIUS H. FOWLER, Minneapolis, to Miss Rachel Wilson of Stillwater, Minn., in October.

FRANK J. PETERSON to Miss Jane Adler, both of New York, October 7.

Deaths

Cassius Marcellus Riley, St. Louis; Miami Medical College, Cincinnati, 1870; professor of chemistry and toxicology, Beaumont Hospital Medical College, 1886-1892, and Barnes Medical College, 1892-1907; dean, Barnes College of Pharmacy, 1904-1907; formerly director of the American Research Laboratory; aged 81; died, October 18.

Joseph William Legault, Oakland, Calif.; University of Montreal Medical Faculty, Montreal, Que., Canada, 1890; member of the California Medical Association; on the staff of the Merritt Hospital; aged 58; died, October 22, of a self-inflicted bullet wound.

Hickman Ray ⊕ Durham, N. C.; University of Maryland School of Medicine and the College of Physicians and Surgeons, Baltimore, 1915; formerly secretary of the Durham Orange County Medical Society; aged 36; died, October 17, at the Watts Hospital.

Louis Eben Poole ⊕ Union City, N. J.; Jefferson Medical College of Philadelphia, 1902; served in the M. C., U. S. Army, during the World War; on the staff of the North Hudson Hospital, Weehawken, where he died, October 25, aged 56.

James Monroe Turner, Northwilksboro, N. C.; University of Louisville School of Medicine, 1881; member of the Medical Society of the State of North Carolina; aged 67; died, October 18, at the Long's Sanatorium.

Charles Henry McKain ⊕ Vicksburg, Mich.; University of Michigan Medical School, Ann Arbor, 1878; Bellevue Hospital Medical College, New York, 1882; aged 74; died, October 21, of cerebral hemorrhage.

George H. Chapman, Chicago; Rush Medical College, Chicago, 1874; member of the Illinois State Medical Society; local surgeon to the Illinois Railway; aged 74; died, November 1, of pneumonia.

William D. Groves, Ursa, Ill.; Missouri Medical College, St. Louis, 1883; member of the Illinois State Medical Society; aged 62; died, October 24, at St. Mary's Hospital, Quincy, of heart disease.

Charles A. Hartley, Troy, Ohio; Eclectic Medical Institute, Cincinnati, 1871; member of the Ohio State Medical Association; aged 78; died, October 21, of edema of the lungs and heart disease.

John R. Cowherd, Vine Grove, Ky.; Hospital College of Medicine, Medical Department Central University of Kentucky, Louisville, 1903; aged 57; died, October 10, of heart disease.

John Dargavel, Minneapolis; Victoria University Medical Department, Toronto, Ont., Canada, 1892; aged 67; died, October 16, at St. Mary's Hospital, of acute dilatation of the heart.

Vienna pointed out the significance of poisonous substances developing in the intestine from putrefaction of proteins. To combat this condition, he recommended intestinal antisepsis, a diet rich in carbohydrates and poor in proteins, and free evacuation to prevent stagnation in the rectum. For conditions involving liver injury he prescribes magnesium sulphate and hexamethylenamin. Raab of Prague studied in dogs the hormonal and nervous regulation of metabolism and found that the pituitary body plays a leading part in metabolism; its function is closely associated with the function of the vegetative midbrain centers. The cerebral fat center is identical with the heat regulating center. Glaessner of Vienna reported good results in the treatment of skin diseases from the use of glycocoll. The Medical Lectures in Essen

With the beginning of the period of inflated currency, scientists here were forced to struggle for their very existence. When, in 1920, the depreciation of the currency was commencing to affect the progress of scientific research, German learned societies and institutions of higher learning founded the so-called *Notgemeinschaft der Deutschen Wissenschaft*, with headquarters in Berlin, the object of which was to prevent collapse of German scientific research. During the four years and a half in which it functioned, it was able, with the help of funds furnished from domestic and foreign sources, but particularly with the aid of federal appropriations and contributions from the several states, to relieve the tension in many quarters and to make possible the carrying out of many plans of research. The four annual reports of the society show that many German scientific journals were kept going, many books, published during the war and postwar periods, and lacking in scientific libraries, were purchased, many important investigations in natural science and medicine were made possible, and many young scientists were given necessary financial aid.

Recently the Notgemeinschaft received a request from the mining companies in the Ruhr to hold a series of lectures for the workmen on the present status of medical research. Accordingly, the Notgemeinschaft has organized a course of eight lectures, to be delivered in Essen during the week from October 25 to 31. Invitations will be sent out by the three large leagues of mining companies. Nearly all the tickets will be reserved for them. The following topics will be discussed: the value of physical exercise as a means of avoiding tuberculosis, Bier of Berlin; the operative treatment of pulmonary tuberculosis, Sauerbruch of Munich; recent researches on human performance of labor (manual labor, fatigue, capacity), Rubner of Berlin; self-control of the body, Thomas of Leipzig; the theory of nutrition on the basis of war observations and recent researches, Muller of Munich; how we can remain healthy: prevention of infectious diseases, Krehl of Heidelberg; the value of necropsies and animal experiments with reference to public health and public welfare work, Aschoff of Freiburg, and the circulation of the blood, His of Berlin. Following the lectures, an opportunity will be given to ask questions of the speakers.

Incomes and Property Holdings of German Physicians

Some time ago, the statistical department of the Leipzig Verband or League sent out a questionnaire to all its members in regard to the relative status of physicians' incomes and property holdings in 1913 and in 1924. Replies were received from 19,781 physicians, including 4,214 specialists. Of this number, 5,620 were postwar physicians, including 1,735 specialists. The league comprises at present 38,000 members, 8,000 of whom are officials or hold definite posts; very few of the 8,000 sent in reports. The statistical material was sent in, therefore, by about 65 per cent. of the physicians in the country. Table 1 gives a comparison of the total incomes before and since the war.

Table 1.—*Comparison of the Total Incomes Before and Since the War*

Marks	General Practitioners, 1913, per Cent.	The Same Physicians, 1924, per Cent.	Postwar General Practitioners, 1924, per Cent.	Specialists, 1913, per Cent.	The Same Physicians, 1924, per Cent.	Postwar Specialists, 1924, per Cent.
Below 12,000	55	78	78	43	61.6	71
Below 20,000	34	19	20.5	30.7	25	21.42
Over 20,000	11	3	1.5	26.3	13.4	7.58
	100	100	100	100	100	100

It is readily apparent that, since the war, the number of incomes amounting to more than 12,000 marks (about $3,000) has markedly decreased. The incomes of the specialists have not been affected to the same extent as those of the general practitioners, owing to the general deterioration of public health and the fact that many members of health insurance societies are being treated as private patients, especially by dermatologists.

Table 2 shows the incomes from panel practice before and since the war.

Table 2.—*Incomes from Panel Practice Before and Since the War*

Marks	General Practitioners, 1913, per Cent.	The Same Physicians, 1924, per Cent.	Postwar General Practitioners, 1924, per Cent.	Specialists, 1913, per Cent.	The Same Physicians, 1924, per Cent.	Postwar Specialists, 1924, per Cent.
Below 12,000	93.5	94	92.5	94.8	94	94
Below 20,000	5.8	5.6	6.2	5	5.64	5
Over 20,000	0.7	0.4	1.3	0.2	0.36	1
	100	100	100	100	100	100

Table 2 disproves the assertions of the *Krankenkassen* with reference to the "enormous" incomes of the panel physicians. Before and since the war, the majority of the incomes (more than 90 per cent) were below 12,000 marks (about $3,000) per annum.

Table 3 shows the property holdings as based on the reports of 12,602 prewar physicians. Here one sees the destructive effects of the inflation of the paper currency The holdings consisted for the most part of cash, mortgages, war bonds and personal and professional effects.

Table 3.—*Property Holdings of Prewar Physicians Before and Since the War*

Year	No Property, per Cent.	Below 20,000 Marks, per Cent.	Below 50,000 Marks, per Cent.	Below 100,000 Marks, per Cent.	Below 200,000 Marks, per Cent.	Below 500,000 Marks, per Cent.	More than 500,000 Marks, per Cent.
1913	8.3	15.4	19.2	21.1	20	13	3
1924	37.6	37.9	17.4	5.8	0.9	0.4	0

Table 3 reveals that, before the war, 57.1 per cent. of the physicians owned more than 50,000 marks, or approximately $12,000, in property; in 1924 the proportion was only 7.1 per cent.

John R. Cowherd, Vine Grove, Ky.; Hospital College of Medicine, Medical Department Central University of Kentucky; Louisville, 1903; aged 57; died, October 10, of heart disease.

John Dargavel, Minneapolis; Victoria University Medical Department, Toronto, Ont., Canada, 1892; aged 67; died, October 16, at St. Mary's Hospital, of acute dilatation of the heart.

Zadok Thornton Daniel ⊕ Rushville, Neb.; Bellevue Hospital Medical College, New York, 1870; formerly health officer of Rushville; aged 76; died, October 21, at a hospital in Omaha.

Elijah Miller, Camden, N. J.; University of Pennsylvania School of Medicine, Philadelphia, 1886; aged 67; died at the Millville (N. J.) Hospital, October 7, of cerebral hemorrhage.

DeWitt C. Huff, Christiana, Tenn.; Vanderbilt University Medical Department, Nashville, 1877; member of the Tennessee State Medical Association; aged 79; died, October 17.

Julius Noll, Kerrville, Texas; University of Texas Department of Medicine, Galveston, 1912; member of the State Medical Association of Texas; aged 37; died, August 16.

Julius London, New York; Cornell University Medical College, New York, 1905; formerly on the staffs of the Mount Sinai and Lebanon hospitals; aged 41; died, in October.

Herbert P. Barton ⊕ Los Angeles; Jefferson Medical College of Philadelphia, 1890; physician in charge of the Clara Barton Hospital, where he died, October 15, aged 59.

Clair Scofield Campbell, Wauseon, Ohio; Detroit College of Medicine and Surgery, 1894; served in the M. C., U. S. Army, during the World War; aged 53; died, October 21.

Joseph Howard Buffum, San Francisco; New York Homeopathic Medical College, 1873; aged 76; died, September 15, at the Wakefield Hospital, of chronic nephritis.

Marcellus Clinton Carpenter, Fairfield, Iowa; Rush Medical College, Chicago, 1882; member of the Iowa State Medical Society; aged 68; died suddenly in October.

Cyrus K. Ritchie, Velva, N. D.; Barnes Medical College, St. Louis, 1903; member of the North Dakota State Medical Association; aged 67; died, September 29.

Ernest Shillito, Marcellus, Mich.; Kentucky School of Medicine, Louisville, 1888; aged 61; died, October 9, of chronic nephritis and cerebral hemorrhage.

Laban H. Shank, Empire, Mich.; University of Michigan Homeopathic Medical School, Ann Arbor, 1889; died suddenly in October, of heart disease.

Mary C. Ford, Dover, N. J.; New York Medical College and Hospital for Women, New York, 1875; aged 89; died, October 17, at Essex Falls.

James A. MacMahon, St. Catharines, Ont., Canada; University of Toronto Faculty of Medicine, Toronto, 1887; aged 63; died, October 29.

William Van Doren ⊕ Scranton, Pa.; Medical Department of the University of the City of New York, 1885; aged 67; died in September.

Alexander Raymond Harvie, Orillia, Ont., Canada; Victoria University Medical Department, Toronto, 1885; aged 65; died, September 28.

James Hiram Eastland ⊕ Mineral Wells, Texas; Vanderbilt University Medical Department, Nashville, 1903; aged 49; died, October 21.

Stephen B. Harmon, Meridian, Miss.; University of Louisville (Ky.) School of Medicine, 1881; aged 75; died, October 10.

Johann H. William Meyer ⊕ La Porte, Ind.; Rush Medical College, Chicago, 1876; formerly a druggist; aged 72; died, October 21.

Robert N. Herbert, Aspen Hill, Tenn.; University of Nashville Medical Department, 1867; aged 82; died in October.

James Grant Hainline, Denver; Keokuk Medical College, 1892; aged 63; died, October 21, of cerebral hemorrhage.

James D. Beer, Wooster, Ohio; Starling Medical College, Columbus, 1889; aged 66; died, October 20, of pneumonia.

William Henry Dunham ⊕ Cincinnati; Cincinnati College of Medicine and Surgery, 1880; aged 79; died in October.

Millie Elizabeth Ellis, Brooklyn; Boston (Mass.) University School of Medicine, 1903; aged 54; died, October 24.

James Osborn Davis, Middletown, N. Y.; Albany Medical College, 1875; aged 78; died, October 18, of pneumonia.

Thomas Manly Dillingham, New York; Boston University School of Medicine, 1874; aged 74; died, October 26.

Joseph Cuneo, Denver; University of Naples, Italy, 1887; aged 69; died, October 16, following a long illness.

Patrick J. Watters ⊕ Indianapolis; Medical College of Indiana, Indianapolis, 1879; aged 73; died, October 21.

J. S. Abernethy, Charlotte, N. C.; College of Physicians and Surgeons, Baltimore, 1878; died recently.

The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE JOURNAL'S BUREAU OF INVESTIGATION, OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER GENERAL MATERIAL OF AN INFORMATIVE NATURE

MORE MISBRANDED NOSTRUMS

Abstracts of Recent Notices of Judgment Issued by the Bureau of Chemistry of the United States Department of Agriculture

Grandma's Compound Sarsaparilla.—About one hundred bottles of "Grandma's Compound Sarsaparilla" shipped from San Antonio, Texas, by the Park Laboratory Co. of that city to California in September and November, 1922, were seized by the federal officials on the charge that the product was misbranded. The preparation was analyzed in the Bureau of Chemistry which reported that it consisted essentially of potassium iodid (0.3 per cent.), alcohol (2.6 per cent.) with plant extractives including a laxative drug, sugar and water, flavored with sassafras oil. The preparation was declared misbranded, first because the label declared the presence of 10 per cent. of alcohol when actually there was only about 2½ per cent.; further, because it was fraudulently claimed to be a specific for all diseases of the blood, syphilis, rheumatism, erysipelas, pimples, boils, ringworm, female weakness, general debility and all constitutional diseases. In February, 1924, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment No. 12658; issued February, 1925.*]

Hooper's Anodyne.—The O. P. Hooper Chemical Company, Chester, Pa., shipped in June, 1922, a quantity of "Hooper's Anodyne" from Pennsylvania to New York. The federal authorities seized the product on the charge that it was misbranded. When analyzed in the Bureau of Chemistry it was reported to consist essentially of morphin hydrochlorid, glycerol, sugar, salicylic acid and water, flavored with spearmint. The following claims were printed on the bottle:

> "Administered To Children Suffering From Colic Summer Complaint or Teething It Produces A Most Wonderfully Beneficial Effect . . . for Violent Colic . . . in Teething."
>
> "For Babies Relieves Colic, Aids Digestion . . . makes Teething Easy . . ."
>
> "Invigorates The Stomach and Bowels, Prevents Vomiting, Also Inflammation Of The Stomach and Gives Tone and Energy To The Whole System."
>
> "Will almost instantly Relieve . . . Colic."

In other words, this preparation belonged to that vicious group of nostrums sometimes spoken of as "baby killers." The stuff was declared misbranded because the claims made for it were false and fraudulent. In September, 1924, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment No. 12755; issued March 13, 1925.*]

Ark-A-Lu.—The Vawter Drug Stores, Monroe, La., in June, 1923, shipped a quantity of "Ark-A-Lu," which the federal authorities declared was misbranded. The Bureau of Chemistry reported that analysis showed the stuff to consist essentially of Epsom salt, iron chlorid, nitric and hydrochloric acids, and water, with wintergreen flavoring. The label stated in effect that the preparation was an effective remedy and cure for stomach, liver and kidney diseases, rheumatism, piles, "Blood Diseases, Chills, Fever, Ague and Nervousness." These claims, naturally, were declared false and fraudulent and in October, 1924, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment No. 12766; issued March 13, 1925.*]

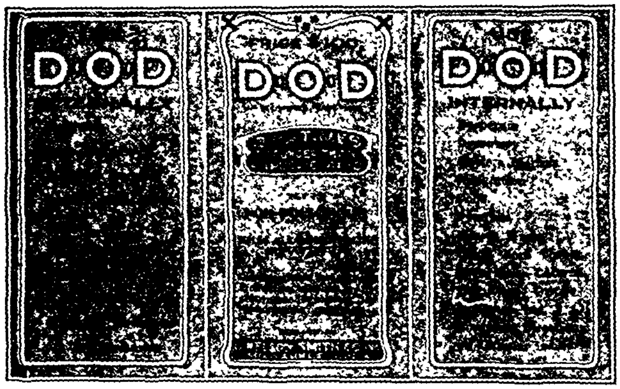
Sanita.—The Newer Novelties Co., Los Angeles, Cal., are alleged to have shipped in interstate commerce in October, 1922, a quantity of "Sanita." When analyzed by the Bureau of Chemistry it was reported that the product consisted essentially of capsules of cocoa butter and tannin with a trace of boric acid. The product was sold under the following *claims:*

> "Sanita . . . the most effective agent for the cure of Leucorrhoea . . . Ulceration and Inflammation of the Womb or Cervix, painful or suppressed menstruation, vaginitis, and to relieve the painful tenderness so frequently following the menses. . . . Weaknesses which manifest themselves by falling of the womb, etc., soon yield to the wonderful curative properties of Sanita."

These claims were declared false and fraudulent, and in May, 1923, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed. —[*Notice of Judgment 13314; issued July, 1925.*]

D-O-D.—One R. Burbach of West Allis, Wis., is alleged to have shipped into Ohio a quantity of "D-O-D," which the government declared misbranded. Analysis of a sample of the article by the Bureau of Chemistry showed it to consist approximately of 93 per cent. baking soda, 6 per cent. potassium permanganate, and a small quantity of Epsom salt. Some of the claims made on the label for this product were:

> "Guaranteed, when used according to directions, to relieve any disease caused by poison or Bacteria or money refunded."
>
> "It Kills All Poison in the human system."
>
> ". . . a remedy has been discovered that will kill poison and bacteria in the human system wherever it can be reached, regardless of the disease—and that remedy is D-O-D . . . provides permanent relief to sufferers from every disease that is caused by poison . . . most all diseases are caused by poison in the human system . . . taken internally will kill the poison in the stomach and bowels which is responsible *for* . . . Dyspepsia, Dysentery, . . . Cholera Morbus, Ulcers, Ptomaine Poison and many other kindred ailments . . . Gangrene . . . Eczema, Piles, . . . Rashes, . . . and other skin diseases."



There were many other claims even more ridiculous and fraudulent than those quoted. In July, 1923, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment No. 12770; issued March 13, 1925.*]

The files of the Bureau of Investigation contain a good deal of material on D-O-D. From this it appears that the stuff was put out by C. Nelson Smith Co., Inc., Milwaukee. Part of the advertising issued in 1923—at the time the federal seizures were made—are to the effect that the large Allis Chalmers steel plants at West Allis, Wis., "used D-O-D exclusively"; a testimonial purporting to be from the general works manager of that concern formed part of the advertising puffery.

Rose's Whooping Cough Remedy.—Aschenbach & Miller, Inc., of Philadelphia are alleged to have shipped in May and August, 1924, from Pennsylvania to Maryland, a quantity of "Dr. J. S. Rose's Whooping Cough Remedy." The Bureau of Chemistry reported that analysis of a sample showed this preparation to contain syrup, potassium nitrate, arsenic and cyanid. This dangerous mixture was sold under the claim that it was a cure for whooping cough—a claim that was declared false and fraudulent. In April, 1925, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment No. 13317; issued July, 1925.*]

A. D. S. Special Kidney and Bladder Pills.—More than twenty-five hundred packages of A. D. S. Special Kidney and Bladder Pills shipped by the American Druggists' Syndicate from New York to California in November, 1924, were declared misbranded. The Bureau of Chemistry analyzed samples of the preparation and reported that the pills consisted of hexamethylenamine and extracts of plant drugs, including small quantities of resins and volatile oils mixed with magnesium carbonate. They were coated with sugar and chalk and colored blue. The label declared that the pills were a treatment for simple inflammatory conditions of the kidneys and bladder. These claims the government declared false and fraudulent and in January, 1925, the American Druggists' Syndicate of the Pacific Coast, having appeared as claimant, judgment of condemnation and forfeiture was entered, and the court ordered that the product be released to the concern on payment of costs and the execution of a bond conditioned in part that the preparation be relabeled so as to be brought into compliance with the law.—[*Notice of Judgment No. 13015; issued April 5, 1925.*]

Correspondence

"PIGMENTED MOLES"

To the Editor:—In The Jounal, October 31, is a note on "Pigmented Moles." I do not think that the treatment recommended is radical enough. The time to stop a horse from running away is just before he starts, and if we wait with pigmented moles until they begin to grow, the damage is already done.

In The Journal, July 9, 1904, is a paper which I read before the Section on Surgery and Anatomy of the American Medical Association on "The Danger of Allowing Warts and Moles to Remain Lest They Become Malignant," and gave the history of twenty-five cases as a warning. Among the cases reported, some of them had existed for thirty, forty and even fifty years, and at last suddenly became malignant. In every case the entire thickness of the skin should be removed with the mole itself.

As an incident connected with that paper, I always remember that the next morning, on meeting Osler, he said to me, "From brain tumors to warts and moles—the first evidence of senility!" How characteristic of him!

But, soberly speaking, I think the advice that I gave in that paper is wise—that all such moles should be removed; for when they have once started on their malignant course, it is almost certain to be too late. Moreover if on an exposed part of the body they are a blemish. By an intracuticular suture there will be an almost invisible scar.

W. W. Keen, M.D., Philadelphia.

PERSPIRATION AND THE ELECTRIC FAN

To the Editor:—In The Journal, October 31, page 1420, a correspondent asks as to the employment of an electric fan for the surgeon in the operating room who is given to perspiration. His question is partially answered by Kirschner, on page 1439 of the same issue. He distinctly advises the use of electric fans to play on the operating staff above the table.

For a good many years I have used in the operating room a pretty fair sized electric fan, tilted at such an angle that the breeze strikes the head and shoulders of myself and my assistants, but is above the level of the patient. The experience has been in every way exceedingly satisfactory, as such a fan adds materially to the comfort and well being of those within reach. There has not been the slightest evidence of any ill effect on the patients.

J. F. Baldwin, M.D., Columbus, Ohio.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed Every letter must contain the writer's name and address, but these will be omitted, on request.

DECIDUOUS TEETH

To the Editor —A healthy boy, aged 4 weeks, developed a second incisor tooth, which was attached to the soft parts only, without root, and was easily removed with dressing forceps The tooth is only a shell of a crown but is well formed At 6 months he developed a similar first incisor, which the mother removed I have them both. He is now 9 months old and has three normal teeth, but no sign of tooth in the left upper whence these two early teeth were removed Kindly inform me whether this is unusual and worth reporting

W E. Brenneman, M D, Chicago

Answer —Many cases have been reported in which the deciduous tooth erupts before a sufficient amount of the root has been formed to hold it in place In such cases the crown becomes loose and may easily be removed with the fingers. The child will doubtless be short the two teeth mentioned in the deciduous set.

DIFFERENTIAL STAINING OF MYELOCYTES

To the Editor —Please furnish me with directions for differential staining of myelocytes from cells of lymphoid series by means of alphanaphthol and of dimethylparaphenylendiamin

Lloyd Jonnes, M D, Circleville, Ohio.

Answer —A Simpler method

1. The slides are fixed with 4 per cent formaldehyd solution for from twenty to thirty minutes.
2. They are put for about three minutes into a 1 per cent solution of alphanaphthol in water containing 1 per cent of potassium hydroxid
3. The slides are transferred without drying or washing into a 1 per cent. solution of dimethylparaphenylendiamin (base) until they are blue.
4. They are dried with a filter paper.

Both solutions 2 and 3 may be diluted with a little water.

B The stain keeps longer with the following method:

1. One gram of alphanaphthol is heated in 100 c.c. of water until it boils, and then concentrated solution of potassium hydroxid is added until the naphthol is completely dissolved. The supernatant fluid is used after cooling. This should be kept in a dark bottle
2. A 1 per cent solution of the dimethylparaphenylendiamin base in water should be prepared without boiling. This is used after a few days of standing.
3. Equal parts of 1 and 2 are mixed and filtered.
4. The slide is kept for two hours in a solution of formaldehyd (40 per cent), 1 part, and alcohol, 3 parts
5. The slide is kept in Mixture 3 until the leukocytes are distinctly blue.
6. The slide is washed quickly with water
7. It is put for three minutes into 1 part of compound solution of iodin and 2 parts of water.
8. It is kept for twenty-four hours in water with the addition of some lithium carbonate.
9. It is stained with alum-carmin, and perserved in glycerol-gelatin.

TROPIN, TUBERCULIN AND IRON CACODYLATES

To the Editor —1 Has tropin been tried in acute glaucoma? 2. What is the status of tuberculin in the treatment of consumption? 3 What is the status of cacodylates of iron as a tonic? Are they worth while or questionable?

D. H P., California

Answer.—1. No mention of the use of tropin in glaucoma has been found According to Cushny (Pharmacology and Therapeutics, 1924), "atropin and its congeners are contraindicated when there is any suspicion of glaucoma, as, owing to their action on the intra-ocular pressure, they may either aggravate the disease already present or precipitate an acute attack."

2. The following statement is made in the Handbook of Therapy (Osborne and Fishbein, 1923). "Tuberculin is not in itself curative, but it is, at most, a stimulant to the curative efforts of the organism. Many observers are of the opinion that it is of value in selected cases of tuberculosis. . . . Its administration requires careful selection of the case, close observation of the patient and appropriate regulation of the dose."

Also, in this connection, our correspondent is referred to: "Ponndorf Vaccination," Queries and Minor Notes (The Journal, October 31, p. 1421).

3. Ferric cacodylates have the properties of iron and of cacodylates. In 1923 the Council on Pharmacy and Chemistry omitted iron cacodylate from New and Nonofficial Remedies because it had become convinced that this drug represents an irrational and useless method of the administration of iron and arsenic. The Council held that "a much more rational method of administration of these two drugs would be separately, in which case a better control of the dosage is possible."

INDICATIONS FOR SPINAL PUNCTURE

To the Editor —Please give me the most essential clinical (physical) signs (not diseases) that a patient or patients may show which are absolute indications for the attending surgeon to perform an exploratory lumbar puncture. Furthermore, in which diseases of the central nervous system is such lumbar puncture contraindicated?

Louis M. N. Federici, M D, Springfield, Mass.

Answer —Exploratory lumbar puncture is indicated in paralysis or paresis, the cause of which is unknown; convulsions, the etiology of which is not clear, and rigidity of the neck when combined with Kernig's, Brudzinski's and Babinski's signs.

Suspected tumor of the brain, especially of the cerebellum, is considered by some clinicians a contraindication for lumbar puncture, because of the possibility that a sudden release of cerebrospinal fluid may produce a herniation of the brain. However, when a manometer is used or when care is taken not to release the cerebrospinal fluid too suddenly or to collect too much fluid at one sitting, lumbar puncture may be resorted to even in cases of brain tumor.

LACTIC ACID MILK

To the Editor —Regarding lactic acid milk, are the cultures sold by the various laboratories of any marked therapeutic value? Are they of more value than milk sugar? What is the established therapeutic value of bile salts?

C E. Eaton, M D, Seattle.

Answer —The article "Lactic Acid-Producing Organisms and Preparations" (N. N. R., 1925, page 191) brings out that there is considerable evidence in favor of the therapeutic value of soured milk, particularly of sour milk containing an abundance of living *B. acidophilus*. Whereas the administration of *B. acidophilus* has for its object the implantation of living *B acidophilus*, there are reports which indicate that the administration of milk sugar may produce the same results through promoting the growth of aciduric bacteria normally present in the intestinal flora.

An estimate of the value of bile salts appears in New and Nonofficial Remedies, 1925, page 71.

HAIR DYE

To the Editor —I have been asked whether there is a reliable and noninjurious hair dye If question is published, please do not mention name

M D., New Jersey.

To the Editor —One of my patients has black hair, which is turning gray, and for good reasons she wants to dye it What can I recommend that will be the least harmful?

Amy Weiss, M D., Chicago.

Answer —The least dangerous black dye is the old combination of iron salts and tannic and gallic acids The hair is washed thoroughly, dried, and then washed with:

	Gm or C c.	
Ferrous sulphate	0|6	gr. x
Glycerin	32|0	oz i
Water to make	500|0	O i

The hair is allowed to dry and is then brushed thoroughly. This procedure is repeated each day for three days. Then, with a fine comb, this solution is applied:

	Gm. or C c.	
Gallic acid	0|25	gr. iv
Tannic acid	0|25	gr iv
Water to make	50|0	oz. jss

One should avoid touching the scalp with this, or a temporary stain may result. As further color is required, the two solutions may be used on the same day, always allowing the hair to dry, and brushing it, after the first one, then waiting an hour or more before applying the second. There are other more brilliant black dyes, but all are more or less dangerous.

Illinois June Examination

Mr. V. C. Michels, superintendent of registration, of the Illinois Department of Registration and Education, reports the written and practical examination held at Chicago, June 23-26, 1925 The examination covered 10 subjects and included 100 questions. An average of 75 per cent. was required to pass. Of the 160 candidates examined, 145 passed and 15 failed. Fifteen candidates were licensed by reciprocity. Four reciprocal candidates failed on clinical examination. The following colleges were represented·

Book Notices

LE TRAITEMENT DE LA SYPHILIS PAR LES COMPOSÉS ARSENICAUX ET LES PRÉPARATIONS BISMUTHIQUES AVEC L'EXPOSÉ DES NOUVELLES MÉTHODES DE LABORATOIRE Par le Dr. Lacapère Avec la collaboration du Dr. Ch Laurent, Medecin des hôpitaux de Saint Etienne. Fourth edition Paper Price, 16 francs. Pp 341. Paris: Masson et Cie, 1925.

This deals particularly with the use of arsenical and bismuth preparations in the treatment of syphilis. One also finds the necessary information regarding the use of mercury and potassium iodid. A portion of the book is devoted to the laboratory measures employed in the diagnosis and surveillance of this disorder. The last section has to do with the applied therapeutics of syphilis, dealing with prophylaxis, primary and secondary syphilis, tertiary syphilis and the congenital form In connection with the last named variety, rules are laid down for the marriage of syphilitic patients and also for treatment during pregnancy. The author prefers arsphenamin but believes that neo-arsphenamin can be made almost as efficient by combining it with bismuth. He adheres to the principle of small doses at first, gradually increasing to the maximum amount. These arsenicals are best given intravenously Of the bismuth preparations the hydroxid and bismuth quinin iodid are especially recommended. Mercury he believes to be largely supplanted by bismuth. Sulpharsphenamin, given intramuscularly, is favored for the treatment of congenital syphilis The irreducible Bordet-Wassermann reaction should be attacked by arsphenamin plus an insoluble bismuth salt Lacapère, however, mentions satisfactory results in such cases following a series of lipiodol injections. The arsphenamins, intravenously, represent the best agents for immediate sterilization or for the cure of a grave lesion. In a generalized syphilitic infection the association of arsenic and bismuth gives durable results When the clinical and humoral symptoms have been mastered, bismuth is particularly indicated as the basic treatment by reason of its long continued action Potassium iodid is recommended in the cerebral lesions of tertiary syphilis and also in the attentuated forms of congenital syphilis characterized by dystrophic lesions due to endocrine involvement (Hutinel). In those intolerant to potassium iodid, Lacapère adds to it a little tincture of belladonna or else gives the patients epinephrin by mouth, in 20 minim (1.25 c c) doses, two, three or more times daily, thus neutralizing the vasodilator effects of the iodid. On account of the same tendency, he does not give the iodid during a course of arsenical treatment. The Bordet-Wassermann and Hecht tests ought to be done together, since reliance should not be placed on the Hecht alone Vernes' flocculation test is simple but lacking in sensitiveness. Lumbar puncture is best performed during the fourth year of infection, as Ravaut has suggested. The colloidal benzoin test of Guillain and his collaborators is recommended as being much simpler than the colloidal gold test. The internal use of arsenical derivatives as prophylactic agents is discussed, and stovarsol is accorded considerable praise No mention is made of the intravenous use of sodium thiosulphate for the dermatoses due to the arsenicals, but it is recommended for local injection when a portion of the arsenical drug has been given extravenously All in all, this is a comprehensive and practical summary of the subject from the pen of a well known French clinician. A fourth edition within seven years attests to its popularity. It is to be highly recommended to those interested in this subject.

SURGICAL TREATMENT OF PULMONARY AND PLEURAL TUBERCULOSIS By J Gravesen, M D, Medical Superintendent, Vejlefjord Sanatorium, Denmark, with a foreword by S Vere Pearson, M D, M R C P., Resident Physician Mundesley Sanatorium Cloth Price, $3 50 Pp 155, with 87 illustrations New York: William Wood & Co, 1925

In the last few years there has been a growing interest in the treatment of pulmonary tuberculosis by surgical intervention. Artifical pneumothorax has been the chief method employed by the majority of men interested in this special field. Since the World War, a great tendency has developed to go one step farther and collapse a lung by those methods as first advocated by Brauer and Sauerbruch. Gravensen's treatise comes at a most opportune time. He discusses at length the various procedures used in the surgical treatment of pulmonary tuberculosis. Especially clear cut are his indications and contraindications for those methods especially advocated by him. No less clear are the successive steps needed in the operative technic; at the same time, he calls our attention to the important fact that medical treatment must be instituted along with such surgery as may be indicated in each individual case. Under the caption of collapse therapy, Gravensen describes artificial pneumothorax, thoroscopy with cauterization, extrapleural thoracoplasty, pneumolysis and apicolysis and phrenicotomy. This is followed by a section on the surgical treatment of pleural tuberculosis. Here he deals with serous effusions, empyema and spontaneous pneumothorax. The volume is ably written. No question is left as to what to advise patients as to proper treatment. While not all would agree with him that the internist should also be trained in the surgical field, one cannot close this book without feeling that it is well worth while and that Dr. Gravensen has added much of value in his presentation of the subject.

Pathology and Bacteriology of the Eye. By E. Treacher Collins, F.R.C.S., Consulting Surgeon to the Royal London Ophthalmic Hospital, and Stephen Mayou, F.R.C.S., Surgeon to the Central London Ophthalmic Hospital. Second edition. Cloth. Price, $10. Pp. 731, with 310 illustrations. Philadelphia: P. Blakiston's Son & Co., 1925.

The conception of this work is unique in ophthalmology in that it presents pathologic changes in the eye not as alterations of this or that tunic but as disturbed physiologic conditions and, again, in that it is not primarily a study of disease affecting the eye but a study of the organism, taken often as a whole, in one or another stage of its evolution or life history as influenced by untoward circumstances. Thus, there are no chapters on keratitis or iritis, but chapters on aberration in development, derangements of circulation, derangements from pernicious mechanical, chemical and other conditions, reactions of the organism to inflammation and, lastly, processes of involution and degeneration. At first the book seems very general and sketchy, but as one reads on the advantages of the method are appreciated, especially the avoidance of useless classification and confusing detail. However, most of us are trained in another school; and many will say that there is really not enough microscopic anatomy, cytology (except in conjunctivitis) and differential diagnosis. The consideration of suppurative disease of the cornea seems especially inadequate in view of an easy correlation of herpetic disease, dry abscess, aspergillus keratitis, disciform keratitis, ulcus serpens and ring abscess. On the other hand, the chapter on obstruction of the central vein is very good, as is that on inflammation in general and, in particular, the one on immunity. The presentation of the anatomic relations of disturbance of lymph circulation is excellent. The work makes no pretense to be encyclopedic, and the fact that it is a treatise on stages of evolution makes it difficult to use as a reference book. This shortcoming, however, is more than made up by the fact that its nature and its perspective render it peculiarly adapted to the use of those who are entering on the study of ophthalmology from the field of general practice or after a general course in medicine and a hospital service. There is no other book in the field of ophthalmology that will so interest and serve one thus placed; it might well become the key-book for the beginner in ophthalmology.

Newer Methods of Ophthalmic Plastic Surgery. By Edmund B. Spaeth, M.D., F.A.C.S., Major, M. C., U. S. A., Chief, Eye Clinic, Walter Reed U. S. Army General Hospital. Washington, D. C. Cloth. Price, $5 net. Pp. 258, with 170 illustrations. Philadelphia: P. Blakiston's Son & Co., 1925.

Plastic surgery is essentially individualistic, and consequently any writing dealing with that subject must treat either with basic principles or else with individual examples. But the latter are so diversified that they cannot assume any great rôle in a textbook. The author has kept these truisms well in mind and has succeded in producing a textbook of ophthalmic plastic surgery that occupies a lone position on the stage of ophthalmic literature. True enough, plastic surgery is touched on in various textbooks on ophthalmology and ophthalmic surgery, but only in a desultory manner; hence, the book devoted to the basic principles and various basic phases of plastic surgery within the realm of the ophthalmologist receives a warm welcome. There is a foreword by Brig. Gen. W. H. Wilmer, M. O. R. C., U. S. Army. Part I contains 106 pages, devoted to the basic principles of plastic surgery, to the types and technics of the various skin grafts, and to the appliances that are used to augment cosmetic correction that has been started through surgical procedure. This part is well illustrated both by diagrams and by actual photographs, and is written in a clear and convincing manner. Part II deals with individual basic operations, such as those aimed at the correction of entropion, trichiasis and other lid deformities, with canthoplasties and tear sac procedures, with the repair of defects from tumor losses, and finally with the various phases of physiotherapy about the eye. The illustrations of the second part are not so good as are those of the first part, but the text is written in just as clear an convincing a manner. The book making is good, and the proof reading has been thorough and careful. All in all, there is much of value in this book that will justify a careful perusal by even the most experienced ophthalmic surgeon.

Ocular Therapeutics. A Manual for the Student and the Practitioner. By Doctor Ernst Franke, A. O. Professor of Ophthalmology, University of Hamburg. Translated by Clarence Loeb, A.M., M.D., Oculist to the Michael Reese Hospital, Chicago. Cloth. Price, $3.50. Pp. 183. St. Louis: C. V. Mosby Company, 1925.

The first ninety pages of this valuable handbook are devoted to the general treatment that only too frequently the oculist has to utilize in conjunction with the local treatment of an ocular complaint. Tuberculosis comes first, and under this the various forms of tuberculin are dealt with at length from a purely practical standpoint. Syphilis is gone into at somewhat greater length and, as the author states, three substances come into consideration: mercury, arsphenamin and iodin. Serotherapy and organotherapy, protein therapy and paraspecific therapy receive somewhat shorter notice, as their value in ophthalmology has not yet been determined accurately. Ray and light treatment and physiotherapy are dealt with at somewhat greater length than is customary in a book originating in this country, and this very fact adds to the value of the book. The second part of the book deals with the local treatment of the eye, both chemical and mechanical, and the action of the various forms is discussed fully. A long list of the drugs that are used locally, with their action and dosage, is included and serves as a handy reference table for the busy oculist. The last part of the book is in the form of a synopsis of the various diseases of the eye and appendages and the usual treatment employed. This is more for the beginner in ophthalmology and, on the whole is the least useful portion. The diction savors somewhat of the "made in Germany" type, but this does not detract from the usefulness of the book.

The Principles of Public Health Engineering. By Earle B. Phelps, B.S., Professor of Sanitary Science, College of Physicians and Surgeons, Columbia University. Cloth. Price, $3. Pp. 265, with 35 illustrations. New York: The Macmillan Company, 1925.

This book is prepared for two classes of students—the health officer who has had little or no engineering training, and the sanitary engineer with little or no knowledge of public health principles. In it are treated such topics as lighting, water supply and sewerage, atmospheric pollution, ventilation of buildings, and pasteurization of milk. The book is compact; the style, clear and concise. The proof-reading might be better, one important error being that on page 142, where aerobic is used for anaerobic. On page 158 "steam" is used in place of stream. There is occasionally a tendency to pedantry, as when "phreatic" water is used as synonymous with ground water. The discussion of air conditioning, including the control of atmospheric pollution, is particularly clear and outspoken. The author declares that "artificial humidification offers no particular advantages in the first place and, as practiced by the evaporation of water in the room from home-made or commercial 'humidifiers,' is generally futile." The dangerous effect of the gases from automobiles does not seem to be mentioned. The book as a whole is sure to be of real use to students of public health. The value of a second edition would be enhanced by the substitution for collateral reading of more recent references than those given at the end of the several chapters.

PERSONAL AND COMMUNITY HEALTH. By Clair Elsmere Turner, Associate Professor of Biology and Public Health in the Massachusetts Institute of Technology. Cloth. Price, $2.50. Pp. 426, with 53 illustrations. St. Louis: C. V. Mosby Company, 1925.

This book has been prepared primarily for college students and will be a welcome addition to the few discussions that ought to be placed in the hands of such students as a part of any general education. Professor Turner's book combines in one volume the two subjects of personal and community hygiene. The first six chapters deal with the health of the individual and include the hygiene of nutrition, action, nervous system and reproduction, and oral hygiene. The material is well presented and adequate for its purpose. Three chapters deal with disease prevention and immunity. It is doubtful whether the theories of immunity should have been included. They are more likely to confuse than interest the general student. The remainder of the book deals with community hygiene. The subjects are logically treated and accurately presented. Perhaps some criticism might be made of the relatively large amount of space devoted to sewage disposal compared to that given to food and water sanitation. The chapter on public health administration should be particularly commended. On the whole, Professor Turner has prepared an excellent and useful book.

THE NATURE OF ENZYME ACTION. By Sir W. M. Bayliss, M.A., D.Sc., F.R.S. Fifth edition. Boards. Price, $3.25 net. Pp. 200, with 8 illustrations. New York: Longmans, Green & Co., 1925.

This edition of Bayliss' monograph is organized like the fourth, but includes numerous pertinent references to work published since the preceding edition appeared. New material included in the text amounts, all told, to about ten pages incorporating significant material obtained from approximately forty new contributions to the field. New work reported has strengthened rather than modified Bayliss' general conclusions, which are expressed identically in the fourth and in this edition. Bayliss teaches that enzymes obey the usual laws of catalytic phenomena, particularly in heterogeneous systems in which reactions taking place are essentially at the surfaces of the colloidal enzymes. The author believes that reactions catalyzed by enzymes are reversible, the equilibrium point being determined by the effective concentration of water. In vitro, water necessarily predominates; hence, nearly complete hydrolysis is reached, whereas in vivo there exist mechanisms for the diminution of the effective concentration of water favorable to synthesis.

SIMPLIFIED NURSING. By Florence Dakin, R.N., Inspector of Schools of Nursing, State of New Jersey. Cloth. Price, $3. Pp. 499, with 77 illustrations. Philadelphia: J. B. Lippincott Company, 1925.

While there are available numerous outlines of nursing methods, few are so direct and practical in their instructions as the simple text presented by Miss Dakin The author has been at particular pains to prepare a book that would be useful for high school classes, home nurses and practical nurses, as well as for trained attendants. She has collected all the essentials and carefully avoided going beyond the point of legitimate nursing practice. Her book is, in every sense of the word, a practical one.

KOMPENDIUM DER TOPISCHEN GEHIRN- UND RUCKENMARKSDIAGNOSTIK. Kurzgefaste Anleitung zur klinischen Lokalisation der Erkrankungen und Verletzungen der Nervenzentren. Von Robert Bing, Professor an der Universität Basel. Sixth edition. Paper. Price, 9,90 marks. Pp. 242, with 102 illustrations. Berlin: Urban & Schwarzenberg, 1925.

Practically no difference is apparent in the text of this edition and the previous one of 1922. However, further improvement has been made in the numerous and excellent diagrams and illustrations. The work is more than ever a standard guide to the difficult paths leading to correct topical diagnosis of lesions of the brain and cord.

Medicolegal

Physician Without Authority to Employ Another

(Johnson et al. v. Roberts (Ala.), 103 So. R. 563)

The Supreme Court of Alabama, in reversing a judgment that was rendered in favor of plaintiff Roberts, says that an employee of the defendants, partners trading as Johnson & Thompson, was injured in his foot or ankle while working at his employment. The employee testified that Mr. Thompson had him removed to a hospital and engaged a physician to attend him, telling the physician that the defendants would pay for his services and not to leave a stone unturned in attempting to save the foot. The physician testified that the defendants never made any deal with him, but kept sending patients to him; that Mr. Thompson brought this injured employee to his office; that he examined the foot, found a fracture, and told Mr. Thompson that he (the physician) would have to take the man to a hospital to find out what was necessary to be done; that Mr. Thompson told him to do everything necessary; that he tried to reduce the fracture, had another physician try to do it, and then called in the plaintiff, to whom he turned over the case. The defendants knew nothing of the plaintiff's services until they received his bill for $360, and they never agreed to or ratified his employment. They refused to pay the bill. He sued them for $360 with interest, and the jury returned a verdict in his favor for $434.40. But the plaintiff had no contract, express or implied, with the defendants to perform the services; he was employed by the other physician, without authority, express or implied, from the defendants, to render these services, and the defendants were not liable for his compensation.

That the physician who called in the plaintiff was employed by the defendants to take care of the injured employee and "to do everything necessary," and "not to leave a stone unturned in attempting to save his foot," gave him no express or implied authority to employ the plaintiff to assist him, nor to turn the case over to the plaintiff and let him perform the operation and services at the expense of the defendants. He had no express authority to employ the plaintiff, and his employment to treat the injured employee and do all that was necessary gave him no implied authority to employ the plaintiff to do so at the expense of the defendants. The physician, in this employment to treat the injured employee, was an independent contractor without any control or suggestion by the defendants as to what he should do for the man, or how he should treat him. He was free to treat the case as he should choose, but he was not the agent of the defendants in so doing, and he was not their agent by this employment and contract.

Right to Show Feeling of Physician as Witness

(Central Lumber Co. v. Porter (Miss.), 103 So. R. 506)

The Supreme Court of Mississippi, Division B, says that on the trial of this personal injury case plaintiff Porter introduced as a witness his physician, who had formerly had a position with the defendant company and who it seemed had been displaced or removed from such position as the company's surgeon by the superintendent of the company. The physician was the only physician and surgeon who testified as to the extent and character of the plaintiff's injuries. The defendant attempted, on cross-examination, to interrogate the physician with reference to the state of his feeling toward the superintendent and the company. The physician was asked in how many cases he had testified in which the superintendent was concerned and his company was defendant; had not he himself sued the superintendent for $100,000, and did he not feel bitter toward him; was it not a fact that he had made application to the superintendent within a short time to be put back on this job, and been told that he could not have it; and was it not a fact that he was unfriendly toward the defendant company? The defendant insisted that it was error to refuse to permit it to propound these questions to the physician; that it had a right to interrogate him for the purpose of showing his feeling, bias, prejudice, etc. It was manifest from the record that the physician's testimony was highly important in determining the extent of the injury. Much would depend on his attitude as to fairness and his unbiased attitude in the case. The value to be given to testimony of this kind depends to a great extent on the attitude and fairness of the witness. The supreme court thinks that the questions should have been permitted, and that it was error for the court below to exclude them. It could not be said what effect this might have on the amount of the verdict. It was important on the measure of damages; wherefore the judgment in favor of the plaintiff is reversed as to the amount of the damages, and the case is remanded for a new trial as to damages alone.

Value of Last 10 Per Cent. of Vision

(Chicago Bridge & Iron Co v Industrial Commission et al (Ill), 147 N E R 375)

The Supreme Court of Illinois, in affirming a judgment which affirmed an award of compensation by the industrial commission, says that the award was for the loss of the sight of an eye by an employee of the company. It was admitted that the award would be correct if it were not for the fact that the employee had received compensation for the permanent loss of 90 per cent of the use of the same eye resulting from another injury, incurred three years before, while in the employ of the same company. The company contended that, because only 10 per cent of vision remained, its liability was limited to a payment for the loss of that fraction. The workmen's compensation act of Illinois provides that an employee shall receive "for the loss of the sight of an eye or for the permanent and complete loss of its use 50 per centum of the average weekly wage during 100 weeks." There is no requirement in the act that the eye be perfect, nor is there any provision for reducing the amount of compensation in the proportion the vision is defective The compensation fixed by the act is for the loss of a member of the body, and the same compensation is due and payable whether the eye lost is the eye of a youth or of an old man, an eye with perfect vision or one imperfect by reason of natural defects or a previous injury. The fact that the same employer has paid compensation to the injured employee for a loss arising out of another injury has no bearing on the amount of compensation to be paid for the loss arising out of this injury, and the same rule applies when the payments for the first injury were made by a different employer. A sightless eyeball is not an eye, as that term is used in the act, and an award for a disability caused by an injury which required the removal of a sightless eyeball would be made under paragraph (c) and not paragraph (e) of Section 8

It was conceded that the employee had at least 10 per cent of vision when he received his last injury, which necessitated the removal of the eyeball—that is, he could see with his defective eye at a distance of 20 feet what a person with normal vision could see at a distance of 200 feet. For many purposes this amount of vision was as useful to him as normal vision. It is impossible for any human agency to measure the value to an individual of the last 10 per cent. of vision remaining in his eyes. Whether the defect in vision is caused by disease or accident or is natural, the reduced amount of vision is all the vision the individual has, and when it is destroyed the use of his eye is destroyed. The legislature has fixed an arbitrary amount to be paid as compensation in such cases, and that amount is due and payable whenever a functioning eye is lost, though the eye may be infirm.

Failure to Protect Bandages Against Urination

(Lolli v. Gray (N. J), 128 Atl. R 256)

The Court of Errors and Appeals of New Jersey, in reversing a judgment which the plaintiff obtained for $5,000 for his daughter, aged 12 years, and for $360 in his own behalf for his expenditures in endeavoring to have his daughter cured of her ailment, says that the daughter fell over a stump and injured her left leg near the hip. She was taken to a hospital, and the defendant was called to attend her. He diagnosed the injury as a fractured femur and treated it accordingly. Several days after the operation, the patient involuntarily urinated one night and wet the bandages. Immediately thereafter the defendant redressed the wound, taking off the soiled bandages, putting on clean sterilized ones and using antiseptics. The case on the argument seemed to narrow down to the question of whether the defendant was negligent in not protecting the bandages on the injury with a rubber cloth to prevent infection from urination. However, as the child did not wet herself by urination but once, and that was twelve or fourteen days after she had been in the hospital, and several days after the operation, the defendant doubtless was not required to anticipate that she would do that thing. She was beyond the age when involuntary urination is apt to take place Furthermore, the defendant testified that there was a disadvantage in using rubber cloth over bandages. All the medical testimony, and that of the nurses, was that the defendant's treatment was in accordance with standard medical and surgical practice. The conclusion of the court is that the motion which was made for the direction of a verdict for the defendant should have been granted, and that its refusal was error. A physician and surgeon, in the absence of express contract, is required to exercise only the skill and care ordinarily possessed and exercised by others in the profession.

Liability for Injury Aggravated by Treatment

(Fright v Blakeslee et al. (Conn.), 128 Atl. R. 113)

The Supreme Court of Errors of Connecticut, in holding that the defendants had no reasonable ground of appeal from the denial of a motion to set aside a verdict that was rendered in favor of the plaintiff in this personal injury case, says that the defendants offered in evidence the complaint in an action by this plaintiff against a physician who treated her for the injury for which she here sued, in which complaint she alleged that the physician did not use due and proper skill and care in such treatment, the defendants contending that this tended to prove that the plaintiff's condition was due to the physician's negligence. The allegations were in the nature of admissions by the plaintiff, and hence an instruction was incorrect which excluded from the consideration of the jury the allegations made in such complaint against the physician. But it was not an error which could have prejudicially affected the defendants' case. If the jury found the defendants legally responsible for the accident to the plaintiff, they were responsible for the injuries proximately resulting therefrom to her. If she exercised reasonable care in selecting a physician to treat her, and his treatment added to the injuries resulting from the accident, the defendants would be liable for all such injuries from which she suffered as a result of his treatment which had not been materially contributed to by the plaintiff

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL for a period of three days. No foreign journals are available prior to 1920, nor domestic prior to 1923. Periodicals published by the American Medical Association are not available for lending, but may be supplied on order. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested).

Titles marked with an asterisk (*) are abstracted below.

American Journal of Tropical Medicine, Baltimore

5: 319-384 (Sept.) 1925

Comparative Helminthology as Aid in Solution of Ethnologic Problems. S. T. Darling, New York.—p. 323.
*Amebic Abscess of Liver. W. J. MacNeal and P. Klemperer, New York.—p. 339.
Leprosy Problem in Philippine Islands. G. R. Callender, Washington, D. C.—p. 351.
Mosquito Repellents. C. W. O. Bunker and A. D. Hirschfelder, Minneapolis.—p. 359.

Amebic Abscess of Liver.—MacNeal and Klemperer present a case of amebic dysentery with complicating liver abscess and fatal termination, fairly typical in clinical history and course, unrecognized until the necropsy. The disease was apparently contracted in New York.

American Review of Tuberculosis, Baltimore

12: 1-86 (Sept.) 1925

*Symptoms of Intestinal Tuberculosis. R. J. Erickson, Trudeau, N. Y.—p. 1.
*Effect of Ultraviolet Light on Intestinal Tuberculosis. R. J. Erickson, Trudeau, N. Y.—p. 15.
*Healed Tuberculous Ulcers of Intestine and Calcium Chlorid Treatment. E. H. Roberts, Denver.—p. 29.
*Excretion of Specific Substances of Tubercle Bacilli in Urine. L. Dienes and J. Freund, Asheville, N. C.—p. 35.
Resistance of Specific Properties of Tubercle Bacillus to Sodium Hydroxid and Hydrochloric Acid. L. Dienes and E. W. Schoenheit, Asheville, N. C.—p. 41.
Potency of Watery Extract of Saprophytic Acid Fast Bacilli as Tuberculins and as Antigens in Complement Fixation. L. D. Scheff, Asheville, N. C.—p. 45.
*Studies in Tuberculosis. III. Clinical Significance of Constitutional Reactions Following Cutaneous Tuberculin Tests. F. Eberson, San Francisco.—p. 49.
*Molds in Sputum in Pulmonary Tuberculosis. M. E. Lapham, Highlands, N. C.—p. 64.
Resistance of Albino Rat to Infection with Tubercle Bacilli. G. G. Ornstein and M. M. Steinbach, New York.—p. 77.

Symptoms of Intestinal Tuberculosis.—The material analyzed by Erickson consisted of 100 positive cases, and for comparison forty cases of nontuberculous intestinal disease complicating pulmonary tuberculosis. In 59 per cent. of the positive cases this complication occurred by the end of the second year and in 81 per cent. by the end of the third year. A history of previous intestinal symptoms was present in 58 per cent., most common of which were chronic constipation and indigestion. Intestinal tuberculosis had an insidious onset in one third of the cases and a clearly defined onset in two thirds. Abdominal pain was present in 71 per cent. of the positive cases. It occurred most commonly after meals, was cramping in character, was localized in the right lower quadrant and was accompanied by intestinal gas. Diarrhea was present in 47 per cent. of the cases. It occurred at any time of the day but somewhat more frequently in the morning. Bleeding from the intestine occurred in a tenth of the cases, and was a highly suggestive symptom when proved not to be due to hemorrhoids. Nausea was present in 66 per cent. It occurred most frequently after meals, and was accompanied by vomiting in one half of the cases. General digestive disturbances were the most frequent initial symptom and were present eventually in 47 per cent. They were most varied in type, the most unusual being marked loss of appetite or aversion for food, distress after meals and "sour stomach." They thus began early and were persistent symptoms. Constipation was twice as frequent as an initial symptom, and also during the course of the disease, in the positive as in the negative cases. Alternation of constipation and diarrhea was present in 12 per cent. It had no special diagnostic significance. Constitutional symptoms out of proportion to the severity of the pulmonary disease were a highly suggestive feature in 17 per cent.

Effect of Ultraviolet Light on Intestinal Tuberculosis.—In a series of eighty-one cases of intestinal tuberculosis complicating pulmonary tuberculosis reviewed by Erickson, 85.2 per cent. had a favorable result following the use of ultraviolet light, as judged by entire relief or definite improvement in symptoms, and 14.8 per cent. had no result or an unfavorable one. Of these cases, 24.7 per cent. had entire relief of symptoms, 47 per cent. were very much improved, and 13.5 per cent. had definite though less improvement. This symptomatic cure or improvement has persisted in 85 per cent. of the sixty-nine cases for four months, in 50 per cent. for a year or so, and in 12 per cent. for from three to four years. Pain, nausea and vomiting seem to be most effectively relieved, diarrhea is more persistent, and general digestive disturbances are still more persistent. It thus seems that ultraviolet light ray treatment is of definite value for the relief of symptoms in intestinal tuberculosis.

Calcium Chlorid in Treatment of Tuberculous Intestinal Ulcers.—Roberts presents a case of healed ulcers in tuberculous intestine to emphasize the fact that calcium chlorid has a definite place in the treatment of tuberculous enteritis and the treatment in this case extended over a period of 102 weeks in all, consisting of weekly injections of 5 c.c. of the 5 per cent. solution intravenously. This is the second case of healed intestinal ulcers in a patient dying of pulmonary tuberculosis.

Specific Substances of Tubercle Bacilli.—All attempts made by Dienes and Freund to demonstrate the presence of substances possessing a tuberculin effect on tuberculous guinea-pigs, either in the urine of patients with extensive tuberculosis or in the urine of patients receiving during specific therapy considerable amounts of specific substances, were negative. No demonstrable amounts of the specific substances were present in the blood serum and urine of guinea-pigs killed by the injection of watery extract of tubercle bacilli. The specific substances were present in great amount in the urine of normal guinea-pigs injected with the same amount of watery extract. From these observations, and from general considerations concerning the fate of antigens in the sensitized body, it appears to be improbable that tuberculosis patients excrete substances having the biologic effects of tuberculin in amounts accessible to observation, and the skin test observed with the urine of patients cannot be interpreted as a specific reaction.

Constitutional Reactions Following Cutaneous Tuberculin Tests.—A series of forty-one cases was studied by Eberson from the standpoint of constitutional reactions following diagnostic cutaneous tuberculin tests. All of these patients had positive clinical histories, physical and roentgen-ray findings, and a definite history of exposure to tuberculosis. In 90 per cent. of the cases, constitutional reactions occurred after cutaneous tests with tuberculin. Local reactions were usually violent but not necessarily correlated with the intensity of the constitutional reaction. Focal reactions were observed in all cases with lymph node involvement and with tuberculosis of the bones, joints or intestine. In the absence of definite "adult" parenchymal tuberculosis, the constitutional reaction was correlated uniformly with clinical tuberculosis elsewhere in the body. Roentgenologic findings offered confirmatory evidence of the significance of a constitutional reaction in juvenile tuberculosis. All of these young patients had enlarged hilum lymph nodes; tracheobronchial lymph nodes were present in 64 per cent. and primary foci in 36 per cent. An analysis of typical cases in children and in adults suggests that a constitutional reaction means clinical tuberculosis, regardless of the roentgen-ray picture, when the roentgenologic diagnosis of a focal reaction is based solely on a change in the lung tissue. As an aid in the diagnosis of juvenile tuberculosis, it is suggested that the occurrence of a constitutional reaction following a tuberculin test (particularly when the cutaneous technic is used), and the eliciting of a suggestive clinical history warrants a positive diagnosis which points to clinically active disease in some focus-bone, joint, lymph node, intestine or hilum lymph nodes.

Molds in Tuberculous Sputum.—Lapham has found molds seemingly to be responsible for cough and other symptoms suggestive of pulmonary tuberculosis; therefore she feels that every case of tuberculosis should be studied just as much to recognize or exclude the presence of molds as that of tubercle bacilli.

Cerebrospinal Fluid Pressure.—The technic and value of manometric study of the cerebrospinal fluid was studied by Ayer. He says that while initial pressure readings are often of real diagnostic value, increasing interest attaches to the behavior of fluid pressure under the influence of certain physiologic acts, especially when pressure observations include more than one portion of the ventriculosubarachnoid system In this manner pressure studies form the basis of an understanding of the dynamic physiology of the fluid circulation

Tests on Cerebrospinal Fluid.—Four hundred colloidal—gold, benzoin and mastic—tests made by Cockrill show sixteen dissimilar reactions and 384 similar reactions in all three tests. Comparing the colloidal benzoin and mastic with the colloidal gold, the results indicate that the benzoin and mastic are reliable tests of approximately equal value. The technic of the benzoin is simpler This indicates that the benzoin is the colloidal test to use in the routine examination of cerebrospinal fluid In special cases, such as meningitis, and multiple sclerosis, requiring the original benzoin test of sixteen tubes, the colloidal gold is preferable

Source of Cerebrospinal Fluid.—The secretion theory of the cerebrospinal fluid holds that this body fluid is largely elaborated by the choroid plexus The excretion or absorption theory, in contrast, holds that the fluid comes from the tissue fluids of the brain The secretion theory is mainly based on experimental and anatomic data, which may equally well be explained by the excretion theory. The latter renders understandable the changes in the subarachnoid spaces and choroid plexus in various lesions of the brain or cord As the secretion theory does not explain the relationship between the brain and subarachnoid changes, Hassin says, it must be assumed that the cerebrospinal fluid is produced by the brain tissues themselves, the villi of the choroid, like those of the arachnoid, being organs, not of secretion, but of excretion or absorption of the waste from the spinal fluid

*Papilledema of Otitic Origin L E White, Boston —p 371
Acute and Chronic Suppurative Otitis Media Including Acute Infection of Blood Stream S J Kopetzky, New York —p 379

Bacteremia Due to Tonsillectomy.—Dabney reports a case which presented every classical symptom of a sinus thrombosis in pronounced degree (temperature range of 97 2 to 104.4 F., chills, sweats, otorrhea, history of recurrent earache, bacteremia), and yet there was no such condition. On the other hand, a mastoidectomy was definitely indicated and justified in the light of the pathologic changes found in the bone at operation.

Papilledema as Diagnostic Aid.—White shows that when present in meningitis, brain abscess and lateral sinus infection, papilledema is a valuable diagnostic aid but its absence does not exclude intracranial involvement. There was papilledema in 58 per cent. of the cerebellar abscesses, in 60 per cent. of the temporosphenoidal abscesses, in 44 per cent. of the meningitis cases and in 40 per cent. of the lateral sinus infections The fundi were normal in 50 per cent. of the meningitis cases with spinal fluid under pressure. Streptococci were the only bacteria present in the cases with papilledema As a preliminary to a lumbar puncture on a patient with marked papilledema, the intracranial pressure should be lowered by drainage of the lateral ventricle. Increasing edema of the optic nerve is usually an unfavorable symptom

Infarction of Myocardium.—Two cases of acute coronary obstruction are reported by Willius in which recovery occurred, and in which detailed electrocardiographic study was carried on from the time of the occlusion throughout the period of convalescence.

Suppurative Orchitis.—A résumé of the case reported by Haines and Mumey would suggest that the condition began after an infectious orchitis, following influenza. Its rapid onset and insidious character, accompanied by a suppurative process, made the diagnosis a difficult task, which, after all, did not interfere with the speedy removal of a very malignant tumor three and one half weeks from the time of discovery. The patient is in good health, and there has been no recurrence eighteen months after operation.

Treatment of Scarlet Fever with Antitoxin.—Blake and Trask conclude from their experience that scarlatinal antitoxin in proper amount is a specific and prompt cure for uncomplicated scarlet fever. It indirectly benefits septic complications during the acute stage of scarlet fever, presumably by curing the specific toxemia. It has not been possible to demonstrate that it possesses any therapeutic value in postscarlatinal sepsis after the rash has faded. To be therapeutically efficient in reasonable dosage, an antiscarlatinal serum should contain at least 12,500 minimal blanching doses of antitoxin per cubic centimeter or be able to neutralize at least 10,000 skin test doses of toxin per cubic centimeter. The amount of antitoxin required to cure scarlet fever promptly and with certainty by intramuscular injection varies from 3,000 units to 12,000 units (30 to 120 c c. of a serum which neutralizes 10,000 skin test doses of toxin per cubic centimeter) depending on the size of the patient and the severity of the disease. To obtain the best therapeutic results, the full amount of antitoxin required in each case should be estimated and given at once as soon as diagnosis is made.

Congenital Syphilis as Cause of Mental Deficiency.—A review made by Dayton of 9,183 patients with mental defect given the Wassermann test, revealed 497 with a positive reaction, a percentage of 5.4 supposedly due to syphilis. A review of 16,156 cases of nondefective children given the Wassermann test revealed 699 with a positive reaction, or 4.3 per cent. In the 1756 cases at the Wrentham State School tested by the same means, sixty, or 3.4 per cent., reacted positively. From these statistics it would appear that congenital syphilis is not of great importance as a causative factor in mental deficiency.

Mental Wounds. C. A. Bonner.—p. 729.

Coma in Diabetes.—Coma is the chief cause of death in diabetes in Massachusetts, Joslin says. It occurs so frequently and yet can be so successfully treated that the number of coma deaths should be greatly reduced. Cardiorenal complications stand next to coma in importance. Tuberculosis still claims a certain percentage of the deaths, probably about 6 per cent., but no more than the standard rate for tuberculosis in the community at large. The onset of tuberculosis is usually unsuspected, so slight are the symptoms and insignificant the signs. Deaths from carbuncles are pathetic. Most fatalities could be avoided with early energetic treatment carried out in a hospital by surgeons who will work in close conjunction with physicians. The mortality is distressing in cases treated at the office and in neglected cases. Crucial incisions must reach to the sound tissue, the flaps should be turned up and the necrotic tissue scarified repeatedly so that after a few days of packing with poultices of normal saline solution sloughing can easily ensue. Ultraviolet rays help in the convalescence.

Glucose and Insulin in Preparation of Poor Surgical Risks.—Fisher and Mensing cite two cases. One of these shows how a severe preoperative acidosis requiring immediate surgery was quickly transformed into a good risk by the use of glucose infusions and insulin. The second case is a typical example of the preoperative preparation of a patient in shock.

Appendical Lithiasis.—In Vermooten's case the appendix contained four calculi, composed largely of calcium phosphate but containing small quantities of cholesterol, some silica and a trace of bile pigment.

Acute Appendicitis During Labor.—The case cited by Barber and Miller was one of mild but definite acute appendicitis occurring at the onset of labor in which a routine appendectomy, followed by breech extraction under ether, gave very satisfactory results.

Vitamin Potency of Salmon Oil.—It is evident from the results obtained by Holmes and Pigott that the vitamin A potency of the salmon body oil is not comparable with that of medicinal cod liver oil made by the steam process.

Prevalence of Goiter in Illinois.—On the basis of 15,154 physical examinations of which 10,829 were men and 4,325 were women high school graduates distributed over Illinois, it was found by Beard that the mean average of thyroid enlargement of the women for a five year period was 24.5 per cent.; the men, 4.6 per cent. The attempt is made to indicate the prevalence of endemic goiter in Illinois. The statistics presented are based on the work of forty or more well trained doctors, experienced in the making of physical examinations. Simple goiter is very common among boys and girls of high school age in Illinois. Approximately 5 per cent. of the former and 25 per cent. of the latter have some hypertrophy of the thyroid gland. In Illinois, the incidence of goiter tends to decrease from the north southward and from the east westward. In this state there seems to be some tendency for goiter prevalence and population density to show coincident rise and fall. There is not much difference in the prevalence of goiter in rural and urban sections. Although the greatest population density is in the northern part of the state, the section with the highest goiter incidence, fewer women in the city than in the country have goiter. This fact, taken in connection with the decrease in thyroid enlargement in both men and women in the tier of counties containing Cook County, may be an expression of food variation, greater accessibility to sea food, and better medical attention to be found in cities. In the comparison of the occurrence of goiter in men and in women in the city and in the country, it is not apparent why, in each instance, the prevalence in men should be the reverse of that in women, who are peculiarly susceptible to iodin deficiency. There may be some dietetic difference not evident.

Nature of Blood Glucose in Diabetes and Glycosuria.—Out of eleven examinations made by Lundsgaard and Holbøll on ten patients with severe or moderately severe diabetes mellitus, new glucose could not be detected in the blood in nine. This substance, however, was found in two patients at the conclusion of the treatment. In five of the patients in whose blood new glucose could not be detected, it was present in the blood two hours after the administration of insulin. In two patients with benign glycosuria, new glucose was found in the blood. In all the patients in whom new glucose was detected in the blood, a removal of glucose from the blood stream could at the same time be demonstrated during its passage through the capillaries, while this was not the case in diabetics where new glucose could not be detected in the blood. The authors, therefore, assume that new glucose is an essential link in normal carbohydrate metabolism and probably first, and that insulin exerts its action in the organism in conjunction with a substance always or usually present in the muscles, by transforming α, β-glucose into new glucose which can then be further broken down in the organism

Determination of Sugar in Urine.—Sumner now prepares his dinitrosalicylic reagent by adding to it both phenol and sodium bisulphite and asserts that it is exceedingly delicate in its action.

Carbohydrate Metabolism of Tumors.—On comparing the sugar and lactic acid contents and the carbon dioxid combining power of the plasma of blood drawn from the right and left wing vein of normal chickens, identical values were obtained by the Coris. If a tumor was growing on one wing, the blood that had passed through the tumor contained, as an average, 23 mg less of sugar and 16.2 mg. more of lactic acid than the blood that had passed through the tissue of the normal wing. The plasma obtained from the blood of the tumor side showed on saturation with alveolar air 3.7 volumes per cent. less of carbon dioxid than that of the normal side The plasma of blood that had been collected under oil contained as an average only 0.7 volume per cent. less of carbon dioxid when compared with that of the normal side.

Effect of Operations on Cervical Sympathetic.—The effect of the removal of the complete cervical sympathetic nervous system of both superior and of both inferior cervical ganglions and a small portion of the cervical sympathetic nerve in the rabbit was studied by Pearce and Van Allen in relation to the character of a malignant disease induced by a transplantable neoplasm. It was found that the general character of the disease which developed in the groups of animals in which operation was done was more severe than that of a similar sized control group Comparisons of the mortality rate in the several groups, of the animal incidence of metastases, the number of metastatic foci, and the distribution of these secondary growths all showed this to be the case There appeared, furthermore, to be differences in malignancy among the groups themselves in which operation was performed The more severe disease occurred in the group in which a portion of the sympathetic nerve only was removed (sympathotomy), that in the complete sympathectomy and superior sympathectomy groups was slightly less malignant, and that in the inferior group was much less so These results have been interpreted as due to a less effective animal resistance the mechanism of which has been interfered with in some way by the interference with the sympathetic nerves The reasons for the difference in malignancy exhibited by the several groups in which operation was done are undetermined A tentative explanation is suggested on the basis of coordinating favorable or deleterious functions subserved by the cervical sympathetic nervous system

Local Immunization to Cutaneous Infection.—Bacterial filtrates were prepared by Mallory and Marble by the methods described by Besredka, but these never developed any specific growth-inhibiting factors Such filtrates produced a strictly local immunity of the areas of the skin infiltrated, but such protection was never greater than that produced with the broth from which they were prepared This immunity was manifest within eight hours and persisted at least fifteen days Transcutaneous treatment by moist dressings soaked in either filtrate or broth were entirely ineffective Sites of healed cutaneous lesions show a strictly local and nonspecific immunity for a period of from five to six weeks Repeated intracutaneous infection with virulent staphylococci failed to produce a general cutaneous immunity

Distribution of Lytic Principle—The experiments reported on by Bronfenbrenner and Korb confirm the fact that lytic principle is distributed in active solution in a state of indivisible units This permits its quantitative evalution by serial dilution, as well as by plating on agar

Experimental Rickets—Rickets has been produced experimentally in rabbits by Goldblatt and Moritz by the administration of diets deficient in the antirachitic organic factor and phosphorus but with a high calcium content Cod liver oil added to these rickets producing diets prevented the development of rickets in rabbits

Spiral Organisms of Rats and Rat-Bite Fever—The spiral organism isolated from a wild rat has proved identical with that from a human case of rat-bite fever in Mexico City studied by Mooser Rabbits can easily be infected with these organisms The subcutaneous inoculation of them is followed after from three to five days by a local edema, induration and inflammation—primary lesion About eight days after the appearance of the primary lesion, edematous swellings and inflammation appear on the head and genitals—secondary lesions The organism can be transmitted from rabbit to rabbit by coitus Protective antibodies are to be found in the blood of infected rabbits at a time when the local lesions are still active The peculiar character of certain of the lesions is probably due to the escape of the antibodies from the blood stream The organism belongs to the genus Treponema

Prevention in Pediatrics—Whether the health of school children is a primary responsibility of the school commissioners or the health department, whether these children shall be called school children or children of school age, is still debatable, but in any case, says Knox, all matters pertaining to the health of children in schools should be directed by a physician interested and skilled in this field of work He should pass on the construction of the building, the air space, ventilation, lighting, washroom and toilet facilities, the type of desks and seats, blackboards and lockers, the school lunches and other arrangements that have to do with the hygiene of the school life Competent medical authority should supervise the instruction in health given to all grades and advise as to school hours, rest periods and the recreation of the children In cooperation with the teacher, the nurse or physician should arrange for the daily inspection and occasional examination of the children and direct the precautions to be taken to prevent the spread of communicable disease, and with the family physician should advise as to the care of the malnourished or otherwise physically handicapped child

Mental Hygiene of Child—Thom believes that the mental health of the child just as the physical health is to a very large degree in the hands of the general practitioner, and not the specialist, and in assuming the responsibility he should utilize as one of his important instruments the knowledge which has gradually been collected under the subject of mental hygiene

Value of Oxygen in Pneumonia.—While Binger does not regard oxygen therapy as being specific in these cases, he believes that it removes one of the obstacles which a sick patient must surmount on his road to recovery, and when it is properly given one may look usually for improvement in cyanosis, improvement in the patient's psyche, slight reduction in his pulse rate, and at times in his rate of respirations This may be just sufficient to tide the patient over his critical days until he has established a sufficient immunity to handle his infection, often, to be sure, it may simply prolong his life by a few days when the bacterial infection is such as to overwhelm him

Teratomas, Ovarian and Retroperitoneal.—Gordon holds that the term dermoid, as applied to ovarian neoplasms, is inaccurate. So-called ovarian dermoids should be referred to as cystic ovarian teratomas. The histogenesis of ovarian teratomas is highly speculative. There are two seriously considered theories as to their origin, one the so-called blastomere theory of Marchand and Bonnet, and the other the germ cell theory of Wilms. Cystic teratomas or dermoids are one of the commonest ovarian neoplasms. In a series of 125 ovarian tumors at Bellevue Hospital, they comprise 8 per cent. of the cases. Bilateral cystic teratomas are comparatively common, occurring in from 2 to 14 per cent. of the cases. Malignant changes in cystic teratomas are rare, the most frequent type being squamous cell carcinoma. The ratio of development of carcinoma is usually given as from 3 to 5 per cent. Ovarian resection is justifiable in cases of bilateral cystic teratomas in young women in whom subsequent pregnancies are desired. Solid teratomas are among the rarest of ovarian neoplasms. There is no case in the records of Bellevue Hospital in which the gynecologic admissions average 1,800 cases a year. So-called struma ovarii may be benign or malignant. Retroperitoneal teratomas are unusual tumors. There is no case of solid retroperitoneal teratoma recorded in the literature. Gordon reports a case of cystic retroperitoneal teratoma weighing 11 kg.

Chronic Pancreatitis.—Hinton believes that some of the recurrent attacks of upper abdominal pain following cholecystectomy seem to be due to acute exacerbation of a chronic pancreatitis. This diagnosis should be arrived at by a very careful process of elimination. Some of these cases spontaneously cure themselves if given the opportunity. Surgery employed in these cases does not seem to cure the condition or prevent subsequent attacks.

Cerebrospinal Fluid in Spinal Cord Tumors.—Stookey and his associates insist that in suspected spinal cord neoplasms manometric readings of the cerebrospinal fluid through lumbar puncture should be a routine procedure. Examination is incomplete without a manometric study. Manometric studies of the cerebrospinal fluid through lumbar puncture (without cistern puncture) may indicate complete subarachnoid block, incomplete subarachnoid block, or the presence of a free, unobstructed subarachnoid space. In all patients operated on, in whom the manometric tests indicate complete subarachnoid block, some form of spinal cord neoplasm was found In all patients in whom the manometric tests indicated incomplete subarachnoid block, either a spinal cord neoplasm or some other form of subarachnoid block was found. Negative manometric readings were found in two patients having an early symmetrical enlargement of the cord, presumably an intramedullary tumor, which, however, did not interfere with the free circulation of the cerebrospinal fluid. In all others exposed the manometric findings were substantiated at operation. Combined lumbar and cistern puncture is indicated when manometric studies through the lumbar puncture alone do not permit of definite conclusions being drawn. In the authors' experience combined lumbar and cistern puncture was indicated in only three cases out of fifty suspected spinal cord tumors.

Deltoid Paralysis Following Shoulder Injuries.—Smith and Christensen report two cases of nonpenetrating injury to the shoulder, resulting in paralysis of the deltoid, both showing the typical area of anesthesia and both showing no tendency of the humerus to fall away from the glenoid. One case was uncomplicated by any other nerve injury, and in the other case there was a concomitant injury to the branches of the radial supplying the triceps muscle but with no demonstrable lesions of the first three primary divisions of the plexus. In both cases, a definite lesion (solution of continuity) of the circumflex nerve was demonstrated at operation. In both cases, there was no roentgen-ray evidence of bone injury. The exact mechanism of injury was also obscure but in at least one case was probably due to a subglenoid dislocation of the upper end of the humerus. These two cases apparently demonstrate that even common injuries of the shoulder without crushing, penetration, or laceration may result in definite solution of continuity of the circumflex nerve with resulting complete and permanent paralysis of the deltoid muscle.

Glycosuria in Surgical Patient.—In a series of forty-seven cases treated before insulin, there were twenty deaths (42 5 per cent.), and four additional patients who left the hospital in a critical condition refusing treatment. In a series of twenty-two cases treated with insulin, there was one death (4.5 per cent.). Urinalysis is performed by Menninger every three hours as long as the patient shows glycosuria, with insulin administration based on the findings. Fluid intake is encouraged preoperatively and forced to at least 2,000 daily, postoperatively. The diet given allows 30 calories per kilogram of body weight, with 1 gm. of protein per kilogram of body weight, and the remainder in carbohydrate and fat in the ratio of 1 to 3. Blood chemistry is very desirable in cases of coma, in partial urinary retention, and after glycosuria has disappeared. In the great majority of cases, it is not essential while the patient shows glycosuria and very valuable time is lost, with much increased danger to the life of the patient, in waiting several hours for a blood sugar determination. Alkaline therapy is not used at present. Traumatic glycosuria may be effectively treated, when necessary, with insulin.

Operation for Malposition of Uterus.—Carrington divides the round ligament; the proximal half of the ligament is sutured to the rectus sheath, and the distal half is sutured to the anterior surface of the uterus, thus providing two new supports for this organ.

Malaria Infection in Late Pregnancy.—Blacklock and Gordon state that malaria infection of the placenta occurs in about 36 per cent. of native women in Sierra Leone. These women are practically negligible as a source of danger to the community, so far as gamete production and consequent anopheline infection are concerned. Pathologic effects on the mother may be lacking entirely. The children may in some cases be born and survive, and may appear free from any effects. On the other hand this series contains in other cases proof of a very complete association between maternal infection in the placenta and death of the child in utero, or within a seven day observation period after birth. Examination of a large number of infected placentas showed that severe destruction of the erythrocytes may occur in the umbilical cord in spite of the absence of congenital malaria.

*Nerve Net of Plain Muscle; Its Relation to Automatic Rhythmic Movements. O. W. Tiegs.—p. 157.

Pancreatic Secretion.—According to Horning's observations, the zymogen grains of the pancreatic cells of the guinea-pig are secreted as grains (globules) into the acini, where they are rapidly dissolved. They arise in the cells mainly from the filamentous mitochondria. This suggests the enzymatic nature of the latter. They also seem to contain a lipoidal substance. The zymogen grains may be secreted, not only into the acinar ducts, but also into the pancreatic blood vessels.

Nerve Net of Plain Muscle.—Tiegs has found that a nerve net is always developed in intimate association with plain muscle tissue, never in connection with striated muscle tissue. Nerve fibers arise from the nerve net, and terminate directly on the muscle fibers. Such a nerve net is capable of serving as a basis for simple reflexes, without the intervention of a central nervous system. Automatic rhythmic movements of isolated, deganglionated plain muscle strips always originate in the nerve net, and never directely in the muscle coat. Coordinated action of plain muscle tissue is always neurogenic, never myogenic.

Surgical Treatment of Mitral Stenosis.—Souttar describes a method of approach to the mitral valve for the purpose of cutting it and cites one case in which it was tried successfully, except that no cutting of the valve was done. As the stenosis was of moderate degree, and was accompanied by so little thickening of the valves, it was decided not to carry out the valve section which had been arranged for, but to limit intervention to such dilation as could be carried out by the finger. The patient made an uninterrupted recovery, the freedom from pain or any disturbance which might have been expected to result for the operation being remarkable. Her general condition appeared to be greatly improved, but the physical signs showed little or no change. At the end of the three months she declared that she felt perfectly well, although she still became somewhat breathless on exertion. Souttar asserts that this is the first occasion on which an attempt has been made to reach the mitral valve by this route in the human being, or to subject the interior of the heart to digital examination.

Syphilis and Aortic Aneurysm.—The age and sex incidence and cause of death in aortic aneurysm are discussed by Brockbank as the result of his analysis of fifty-six cases. Of these fifty-six cases, forty-seven were men and nine were women. In fifty-two cases, or 92.85 per cent. (forty-five men and seven women), and in forty-three of the forty-five men (95.5 per cent.), there was a definite history of previous syphilis or a positive Wassermann test. The Wassermann blood reaction was positive in forty out of forty-four cases tested. The ages of the fifty-two patients with positive test or history of syphilis varied in the men from 29 to 68, and in the women from 37 to 70. Of 200 cases of aortic aneurysm found post mortem, the average age at death was 43.87 years. In 42.5 per cent. of all the cases death occurred before 40 years of age and in 75.5 per cent. before 50. Death occurred in these cases from exhaustion and heart failure and rupture of the aneurysm and with virtually equal frequency.

Cases of Atriplicism. S. H. Martin.—p. 808.

Acute Intestinal Obstruction in China.—Thirty-three cases of acute intestinal obstruction are reported by Taylor. Six patients died following operation. In four of these patients gangrene of the bowel, with general peritonitis, was present before the operation. Strangulated hernia was the cause of the obstruction in thirteen cases. Carcinoma was responsible for the obstruction in three cases. Tuberculosis was the cause in three instances. Bolbulus and intussusception were each responsible for one case. Adhesions following gastro-enterostomy caused obstruction to the duodenum and afferent loop of the jejunum in five patients. Adhesions following other operations caused obstruction in three cases.

Sodium Thiosulphate in Mercurial Stomatitis.—Hall reports striking results from the use of sodium thiosulphate in four cases of severe mercurial stomatitis, and one case of tissue reaction due to the leaking of neo-arsphenamin from a vein. All the patients had an extreme degree of stomatitis. In none of the cases was there any gastro-intestinal disturbance, or any involvement of the kidneys. In two cases 0 45 gm. of chemically pure sodium thiosulphate, in 10 c c. of water, was injected as the first dose, and no untoward effect was noted. A third patient, who was suffering considerably from syphilitic bone pain, and in whom it was desired to clear the condition rapidly in order that arsphenamin treatment might be started, was given one dose only of 0 6 gm This was followed in about half an hour by a slight rigor, without, however, any further ill effects The next day the mouth was so much improved that food could be taken with relish. Local treatment in all cases consisted of frequent washing out of the mouth with Dobell's solution. The patient with the arsphenamin in the subcutaneous tissue complained of great pain of a burning character, coming on very soon after injection, and after a few hours had considerable swelling and redness of the whole of the antecubital area. Ten patients received an injection of 10 c.c. of a solution containing 0 6 gm of sodium thiosulphate.

Treatment of Elephantiasis.—For the purpose of establishing lymphatic drainage in the treatment of elephantiasis, Kimura brings normal and affected skin into close contact by planting a pedunculated normal skin flap with its subcutaneous fatty tissues into the affected site. This method is more effective in the penis or scrotum than in the lower extremity. In elephantiasis of the lower extremity, this method, together with Kondoleon's method, and the removal of superabundant tissues, has given better results than any method now in use

*Fecal Enterolith of Small Intestine R. J Morris—p 751.
*Ischemia Cordis Intermittens L Bischoff—p 753.

Fecal Enterolith of Small Intestine.—In Morris' case the conclusion arrived at was that the symptoms of intestinal obstruction were due to malignant disease. At the operation a hard mass was found lying free in the lower portion of the ileum and was successfully removed. It was an enterolith weighing 33.4 gm., 5 5 cm. long, and 3 8 cm in diameter. The enterolith was principally fecal in nature, and it did not originate as a gallstone, a bile acid concretion or a blood clot. The appearance did not suggest that it was an "oatmeal stone," such as has been described by Hammarsten.

Ischemia Cordis Intermittens.—Bischoff describes a group of anginoid phenomena, which he designates as ischemia cordis intermittens. The condition affects patients of about from 30 to 70 years, mostly males, who often, after more or less brisk walking (generally in the open) or climbing, or, in fact, soon after any sort of exercise, feel a disagreeable pain behind the sternum, which passes into a feeling of spasmodic contraction and oppressive sensations of anxiety, culminating in such a feeling of annihilation that the patients are obliged to stop; if they must perforce move on, they can only do so under extreme necessity. It may lead to the complete loss of consciousness. There is no dyspnea with this affection. A rest of a few seconds, or at most of minutes, is sufficient to enable the patient to continue his walk in perfect comfort Soon, however, after the resumption of exercise the pain returns, and rest becomes more necessary. The history of all patients, with slight variations, reveals the same almost stereotyped phenomena. Bischoff cites seven cases.

The Efficiency of Treatment for Syphilis as Revealed by the Cerebrospinal Fluid.—Bernard examined the cerebrospinal fluid of 200 syphilitics who had responded negatively to the Wassermann tests of the blood for periods ranging from six months to several years. The cerebrospinal fluid was normal in eighty-two of the patients, and pathologic in the remaining 118. About 72 per cent. of the subjects with a normal cerebrospinal fluid had been treated with arsenicals and mercury; and only 17 per cent. with arsenicals alone. About 14 per cent. with a pathologic cerebrospinal fluid had been treated with arsenicals and mercury; 63 per cent. with arsenicals alone. The simultaneous use of both drugs seemed to be more effectual than alternating the mercury and arsenical series.

*Idem: Choice of Procedure. V. Le Lorier.—p. 185.

Indications for Operations to Enlarge the Pelvis.—Rossier reviews the indications for pubiotomy and symphyseotomy with reference to the obstetrical literature of the last fifty years. The main indications are contracted pelvis, excessive size of the fetal head, slow dilatation and malpresentation of the head In febrile cases of contracted pelvis, with a true conjugate a little less than 8 cm., pubiotomy should be preferred to cesarean section. With the subcutaneous technic for pubiotomy, fever is not a contraindication, neither is primiparity. The great advantage of these operations to enlarge the pelvis is that they allow carrying expectant treatment to the extremest limits.

Methods of Choice in Operations to Enlarge the Pelvis.—Le Lorier reiterates that the subcutaneous technic is free from the dangers of the open method. The results of subcutaneous pubiotomy seem to be the same as those of subcutaneous symphyseotomy. Intraspinal anesthesia is advisable when rapid delivery, spontaneous or instrumental, can be anticipated.

Etiology and Treatment of Spasm of the Larynx.—Mouriquand considers two types of spasm of the larynx, one from the spasmophilic diathesis, the other associated with enlargement of the thymus. Chvostek's sign appearing only in cases of spasmophilic origin, is important in differential diagnosis. This sign does not occur in infants under 6 months old. About 75 per cent. of all the children with spasm of the larynx presented signs of congenital syphilis; the frequent coincidence with rickets was also evident. Ultraviolet rays are the radical remedy for constitutional spasm of the larynx. Under other treatment, the six children died in the group of six cases with spasm of the glottis, while under ultraviolet rays, all the children recovered in a group of ten thus treated. The first exposure lasts one minute, and is gradually increased to five minutes by the fifth day. Then again a one minute exposure is given. A total of from twenty to thirty sittings, one daily, is required. Improvement is noted after five exposures; disappearance of Chvostek's sign and hypocalcemia after twenty. In spasm of the larynx with an enlarged thymus, the roentgen rays may be indicated. Treatment for syphilis should supplement both kinds of therapy. He reiterates that spasmophilia and rickets are deficiency diseases, the deficiency being in ultraviolet rays.

Ultraviolet Rays in Treatment of Pyodermitis in Young Children.—Chatin emphasizes that suppurating skin diseases may become epidemic in day nurseries and other places where young children are collected. His six years of experience showed stock staphylococcus vaccine to be ineffectual, but eight cases were cured with an autovaccine. Ultraviolet rays appeared to be the most beneficial treatment, inducing a rapid healing of the pyodermitis in twelve cases. The development of folliculitis into pyodermitis was checked under the rays in the already contaminated children. The rays were applied to the back of the child. They are given at one day intervals. The first exposure was for two minutes; the following were prolonged by two minutes, to a total of ten minutes at a sitting. Healing was usually obtained with five or six exposures; sometimes eight or ten were needed. The ultraviolet rays can be counted on to arrest an epidemic under such circumstances.

Transcerebral Ionization Treatment of Hemiplegic Contracture.—Bourguignon applies the positive electrode to the eye on the opposite side from the hemiplegia. The positive electrode is a cotton tampon that just fits into the entrance of the orbit, and is moistened with a 1 per cent. calcium chlorid solution. The negative electrode, moistened with plain water, is applied to the back of the neck. A 2 or 3 milliampere current is used at first, and the maximal strength of 4 or 5 by the third day. Six daily sittings, each lasting thirty minutes, are given the first week, and every second day the second, third and fourth weeks. This is followed by a three weeks' rest. The method was used in patients affected with hemiplegia for two to ten years and even longer. It resulted in a remarkable reduction of the rigidity, restoration of movements, improvement in speech, disappearance of spasms in jacksonian epilepsy, and also attenuation of spasmodic laughing and crying. Calcium ionization proved to be effectual only in spastic hemiplegia, but not in the flaccid type, evidently acting merely on the sclerotic process in the nerves. In syphilitic hemiplegia, calcium may be advantageously substituted by iodin. The ionization treatment appeared to be completely harmless. Faradization of antagonist muscles, with augmented chronaxia, may be a useful adjuvant in combating the contractures.

Leukemia and Pernicious Anemia Consecutive to Occupational Injury from Radioactive Substances.—Emile-Weil reports a fatal case of myelogenous leukemia in a mechanic occupied for several years in the preparation of radioactive substances of the thorium family. Another mechanic, working on the same substances for several years, in the same factory, died from pernicious anemia. Both were robust and of healthy families. On microscopic examination, the lesions of the spleen, liver and bone marrow appeared to be identical with those in ordinary leukemia. It is assumed that irradiations as well as infections may induce changes in the cells in the hematopoietic organs. The author comments on the fact that the same radioactive substance seemed to be responsible for the two quite different blood diseases, probably on account of differing predisposition. He cites another case of fatal leukemia in a woman given a single intensive seven hour application of radiotherapy seven years before.

Rôle of Corpus Luteum in Uterine Hemorrhages.—Castaño's conclusions are based on his experiments on guinea-pigs. He asserts that the corpus luteum is responsible for the whole uterine menstrual cycle; it takes an important part in formation of the decidua and development of the ovum. Hormonal changes from the corpus luteum, and not inflammation of the endometrium, induce the reaction in the uterine mucosa entailing hemorrhages with fibroma and uterine disease.

Hallux Valgus.—Observations of synergisms of muscles, made by Scherb with the aid of the moving sidewalk, revealed surprising individual differences. Abnormities of the action of the long muscles of the big toe may account for hallux valgus. He emphasizes that it is erroneous to endeavor to explain deformities only locally. The functional deviations due in the last instance to abnormal innervation may clear up many conditions. The treatment should be radical.

Hearing Range.—Schlittler tested the apparatus introduced by the state railroads in Switzerland. It was claimed that falling lead balls in the apparatus could be counted by the examined subject at the same distance as he hears the whispered voice. He found that many subjects hear the balls at a much greater distance. He finds that the technic of examination by the whispered voice is simple and more reliable. It should be taught properly in every medical school.

Serologic Reactions in Syphilis.—Schuler examined 5,000 serums with the Wassermann, Sachs-Georgi, Dold and Meinicke turbidity methods. The Wassermann reaction gave the largest number of positive results in syphilis, and the smallest number of false positive reactions. Of the others, the Sachs-Georgi was best, but gave nonspecific results in tuberculosis, arthritis and enteritis. The two other methods gave too many false positive results. They are of use for indicating the advisability of provocation treatment, with all the caution necessary.

Tuberculosis of Male Mamma.—Turco says that the case he reports, in which he amputated the mamma in the young man, is the first of the kind to be published in Italy. He has collected from the literature 200 instances of a tuberculous process in the female breast and eleven in the male.

The Peritoneum and Local Immunity.—Solieri argues that as the peritoneal serosa seems to surpass all other tissues in its power of resisting virulent germs, we are justified in regarding this as an acquired local immunity. He thinks this can be trusted, and drainage avoided, after the cause of the peritonitis has been removed and the serosa cleansed.

Relation Between Biliary Apparatus and Stomach Functioning.—Pietri's research on dogs gave constantly concordant results indicating a functional reflex arc between the gallbladder and the stomach. Partial or total loss of gallbladder functioning depresses gastric secretion, as also malfunction in the bile duct region. Operative measures are unable to restore normal secretory conditions to the stomach.

Gastric Ulcer-Cancer.—In Massa's two cases the women had had gastric disturbances for years. They noted that the pains were recurring oftener and more severe, with more frequent vomiting, and general depression, but the most striking sign of malignant degeneration of the indurated ulcer was the complete lack of any benefit from the usual measures which had previously proved useful.

Postoperative Peptic Ulcers.—Alessandri states that there was no evidence of an excessively acid or potent gastric juice in thirteen of his fourteen cases of peptic ulcer after gastro-enterostomy. The roentgen-ray findings were generally decisive.

Anastomosis Between Gallbladder and Gastro-Intestinal Tract.—Marinelli made a direct communication between the gallbladder and the stomach in twelve dogs and between the gallbladder and the duodenum or the colon, each, in five others. There was irritation and inflammation in every instance, wherever the gallbladder was sutured to the digestive tract, but this reaction was least with cholecystogastrostomy. It was so severe with anastomosis between the gallbladder and the colon that this technic should be discarded entirely.

Experimental Study of Acute Necrosis of the Pancreas.—Calzavara's research was on dogs and a few rabbits—twenty-one animals in all. He injected bile directly into the pancreas. A number of colored plates show the lesions induced. The animals could be saved by operative removal of the exudate, and drainage, provided this was done within the first six hours and if the amount of bile injected had not been too large. When the conditions allow a favorable outcome, the hyperglycemia begins to decline and disappears by the sixth day. When the hyperglycemia persisted, the animals all died. Hence, acute hyperglycemia in necrosis of the pancreas aids not only in differential diagnosis, but also in the prognosis, if it keeps high.

Cancer of Cervix of Myomatous, Assumed Pregnant Uterus.—The patient was supposed to be at the fifth month of her pregnancy but no fetus was found at the operation. This consisted in removal of the uterus and vaginal wall through a laparotomy. She is in good health to date five months later.

Correction of Ankylosis of the Knee.—After Gatti had mobilized the joint by cutting away adhesions and rounding the articulating surfaces, he interposed a free flap of fascia lata (on the head of the tibia). The boy, aged 9, had cut his knee in a fall six months before.

Periarterial Sympathectomy for Painful Trophic Lesions on the Feet.—Durante's contention that the decortication of the artery should be close to the peripheral lesion has already been mentioned in these columns. He here describes in detail his most convincing case: The mal perforant had proved rebellious to stretching of the sciatic nerve and to periarterial sympathectomy on the femur, while it healed promptly after periarterial sympathectomy on the posterior tibial.

Endotoxins and Exogenous Toxins. L. La Porta.—p. 328.

Trophic Affections of the Nails.—Castex and Camauer devote this fourteenth article on the sympathetic nervous system to the influence of the nervous system on the development, growth and nutrition of the nails. In all their numerous patients with urticaria, vasomotor disturbance, vitiligo, etc., and other manifestations of a pathologic condition in the sympathetic system, the nails always presented abnormal findings, from simple parallel longitudinal or transverse lines to the severest forms of onychogryphosis. They insist on the necessity for studying the vegetative nervous balance in every case of disease of any kind accompanied with anomalies in the nails. The factor responsible for the loss of balance in the involuntary nervous system may be of toxic, infectious or traumatic origin, or from emotional stress. It may act directly on the sympathetic or by the mediation of the endocrine system or by regional or remote pathologic reflexes. They describe in detail three extreme cases and the therapeutic deductions therefrom.

Case of Double Uterus. D. Iraeta and C. D. Medina.—p. 360.

Hyperkeratosis and Keratodermia.—This is the fifteenth article of the series, mentioned in the preceding abstract, which aims to reveal the underlying cause—the upset in the balance in the vegetative nervous system—in what seems a purely local affection. The horny changes in the skin in the two cases described were accompanied by signs of sympathetic disturbance. The endocrine system is generally more or less abnormal in such cases of loss of sympathetic balance. To reduce the hyperkeratosis, the causal factors must be determined and combated, in addition to local measures.

Case of Discrete Generalized Tuberculosis. Goyena and Mackinlay.—p. 589.

Hereditary Transmission of Acquired Characters in the Peyton Rous Chicken Sarcoma.—Llambías and Brachetto-Brian confirm that passage of the Peyton Rous sarcoma through a fowl attenuates its virulence. When the malignancy is transmitted to the offspring, it is transmitted in this attenuated form, which they regard as the transmission of an acquired character. The sarcoma may lose all its virulence in this way. Conditions in this respect resemble those with cancer in man and animals—further proof, they say, of the biologic identity of these chicken sarcomas and human cancer.

Acute Suppurating Thyroiditis.—There had been no tendency to goiter apparent in the young woman before the acute onset of the suppuration in the thyroid. It induced severe symptoms from compression, but this subsided after the presumably solitary abscess in the thyroid had discharged its contents into the respiratory tract the tenth day. The vomica occurred spontaneously. The lesion flared up anew a month later, and was relieved again in the same way by a vomica. The roentgen rays showed the small communication into the trachea. Pneumococci and streptococci were found in the pus.

Impalement Injuries.—Madelung's first communication on impalement injuries of the rectum and anus was published in 1890, and he now has collected 276 such cases from the records, including fifty-five children and seven persons over 60. The gastro-intestinal tract had been injured in seventeen cases, and in five cases the impalement had been through the vagina, once by the horn of a steer, goring the woman from the rear. In twenty-nine cases the injury proved fatal in less than two days. Peritonitis became evident in eighty-four cases and proved fatal in fifty-two. All but fifteen recovered of the forty-four treated by a laparotomy. Even mere sitting down on a stake has been known to cause impalement injury opening the peritoneal cavity. The patient should be taken to a hospital at once, even after what seems to be a trivial impalement accident; one never knows how much damage has been done inside. He should be kept sitting up, to keep urine, feces and effusions in the lower part of the pelvis. Although tetanus after such a trauma is extremely rare, a prophylactic injection of the antiserum is advisable at once. Even the mere extraction of the stake may require a major operation, and this may be necessary to correct injury from ill advised attempts to remove the impaling article. Hemorrhage was slight and rare but he warns against rinsing out the rectum with hot or cold water, as has been recommended, and against suturing the tears until after the full extent of the injury has been determined. In Rosenberger's case, the stake had perforated the diaphragm, and the patient died the thirty-seventh day. The advantages of colostomy to supplement the laparotomy are borne out by practical experience. Madelung reviews all this material in detail, and the lessons therefrom, giving eight pages of bibliography.

The Suture in Stomach Operations.—Strauch concludes from his clinical and experimental study of this subject that the same principles apply here as in suturing the skin. All suturing on the stomach must be regarded as in an infected region, and catgut is the material to use. On the adhesion of the serosa depends the stanchness of the suture, and the sheets should be lapped as far as possible.

Surgical Treatment of Angina Pectoris.—Hesse operated on three women in the fifties and one man, all seeking relief for chronically recurring angina pectoris. In one case there were no further pains after the operation, and the radiation of the pains was arrested in all. In these and fifty-eight cases reported by others, no improvement was apparent in 6.8 per cent., but 70.5 per cent. were completely and 22.7 per cent. nearly completely cured. Nine of the patients died in a few hours or days after the operation (heart failure or pneumonia), and three died within six weeks without recurrence of the pains; death occurred suddenly with severe collapse of the heart. One of his own cases was in this group, and is the only one of the kind with necropsy records. The anatomic and physiologic basis for the sympathectomy seems rational, and Jonnescu has two cases with complete cure for seven years and a year and a half to date.

Gastroptosis.—Liek questions whether a sagging stomach should be given operative correction, his impression being decidedly adverse to this. He says that what requires treatment is the whole constitution; the gastroptosis is only one manifestation of this. He has frequently encountered extreme gastroptosis in women quite unaware of their anomaly and free from all disturbance from it. The stomach may display atony on one occasion, and spastic contracture at another time. The common cause should be sought and corrected, not wasting efforts on the shape and size of the organ, which change from day to day. The benefits realized by surgical measures can be obtained with other and safer means, he reiterates.

Dermatologische Wochenschrift, Leipzig

*Behavior of the Tissues in Artificial Phlebitic Thrombosis. G. Nobl and W. Löwenfeld.—p. 1495.
*The Coagulation Time in Dermatoses. J. von Deschwanden.—p. 1499.
Mechanism of Action of Sulphur. L. Görl and L. Voigt.—p. 1504.

The Structure of Artificial Phlebitic Thrombosis.—Nobl and Löwenfeld reproduce the photomicrograph of a small vein that had been injected six days before with a 50 per cent. solution of sugar. There was a relatively slight and tardy reaction on the part of the irritated vessel walls, but it had sufficed to induce a regular and firmly adherent thrombus production. The features of the consolidation, organization and obliteration processes demonstrated the practical impossibility of embolism. They add that the deaths that have been reported after injection of mercuric chlorid in treatment of varicose veins were undoubtedly due to mercurial poisoning or idiosyncrasy. With this artificial thrombus production with the hypertonic sugar solution a long stretch of the vessel is subjected to the same, regular, irritating influence, and the masses of thrombus that form cling evenly to the vessel wall throughout, guaranteeing against embolism. The conditions are entirely different from those with natural thrombosis.

The Blood Coagulation Time in Dermatoses.—The clotting time was found abnormally long in several skin diseases, especially in eczema. In five cases of chronic eczema recurring since childhood, the interval before coagulation ranged from fifty-three to sixty-six minutes. In seventeen normal persons, the range was from thirty-five to thirty-nine minutes.

Herpes and Smallpox.—Gildemeister and Herzberg produced relative immunity of the rabbit cornea against smallpox vaccine by inoculating it with the virus of febrile herpes. The contradictory results of other authors were due to the too large doses of vaccine they used. They discuss the question of herpes virus being a variant of smallpox.

Psychotherapy in Organic Nervous Diseases.—Inglessis deplores the psychotherapeutic nihilism in organic diseases of the nervous system. He reports a case of postencephalitic parkinsonism, the patient not able to write. Hypnosis, combined with suggestion from another patient, restored the faculty.

Prevention of Diphtheria.—Denks reports some untoward effects of a toxin-antitoxin vaccination. Some of the reactions might have been due to the fact that a Schick test had been made fifty days before the immunization. Tuberculous children are most liable to be hypersensitive.

Tuberculin Reaction After Vaccination with Langer's Method.—Fedders obtained positive tuberculin reactions in fifty out of sixty-two infants and children inoculated with Langer's vaccine. The pre-allergic period lasted usually two or three months.

Trypanocidal Substances of Serum.—Leichtentritt investigated with numerous collaborators the occurrence of the trypanocidal action in the serum of children. It was found in healthy infants beginning at least in the sixth to ninth week. It was absent in grave nutritional disturbances (especially from starch) of the avitaminotic type, such as keratomalacia and scurvy, in whooping cough, and in hemophilia. It was also absent in the seemingly healthy mothers of hemophiliac boys. Measles and thrombopenic purpura did not cause any diminution of the substance. Since Rosenthal has found that repeated injection of a protecting serum annihilates its action, it is probable that the serum acts only as a stimulant of the reticulo-endothelial system of the infected mouse. Blocking of this system—either by the large amounts of serum or by other substances (India ink)—exposes the mouse to infection in spite of the presence of the protecting serum. He has also found that certain germs grow poorly or develop pathologic forms in coagulated serum from patients in avitaminosis.

The Posterior Lobe of the Pituitary and Diabetes Insipidus.—Trendelenburg points out that one of the objections to the endocrine etiology of insipidus is the fact that large doses of the extracts are necessary to check the diuresis. If the usual claim, that 1 c.c. of the extract corresponds to 0.1 or 0.2 gm. of the posterior lobe, were true, the normal human pituitary posterior lobe—which weighs around 0.13 gm.—would have to empty its contents completely every day. He found, however, that the best commercial preparations corresponded only to 5-10 mg. of fresh posterior lobe. Therefore a daily secretion of 10-20 per cent. of the substance available would be sufficient. He found no data on the action of exactly titrated extracts in diabetes insipidus.

Hemitetany.—Kehrer analyzes his case and the literature. He concludes that a strictly unilateral tetany does not exist. Only the spontaneous spasms may in rare instances be limited to one side. This is always due to differences in the central nervous system—usually some lesion in the brain.

Action of Oxygen on Blood Pressure.—Simon confirms Loewy's experiments on the effect of oxygen. His patients inhaled daily for from three to eight minutes (sometimes several times daily) about 6 liters of oxygen per minute. In six of ten patients with nephritic or arteriosclerotic hypertension, a permanent lowering of the blood pressure was realized. Normal subjects were not influenced.

Hypoglycemia Without Insulin. — Geiger and Szirtes obtained extreme hypoglycemia by injecting 0.5-1 mg. of atropin per kilogram in rabbits after splanchnicotomy. All of the animals had spasms, but only a few hours after the blood sugar sank to 0.03-0.01 per cent. Injection of glucose or epinephrin had favorable transitory effects, the latter at times in spite of the further lowering of the blood sugar level.

Active Immunization Against Diphtheria. — Kochmann observed three cases of comparatively grave diphtheria in Schick negative infants who were being immunized with toxin-antitoxin. He warns against the danger of the negative phase, especially in Schick negative subjects.

Peptidases in Infections of Paralytics.—Pfeiffer, Standenath and Weeber found an increase of the glycyltryptophan splitting peptidase in the serum during malaria attacks, erysipelas and grave febrile tuberculosis in patients with general paralysis. The amount of the ferment in the urine was diminished during the height of the fever.

Radiation from Man and Animals.—Friedenthal has devised an apparatus to measure the radiation from the body. Emotions have a great influence. The apparatus is sufficiently sensitive to indicate differences in the radiation from the pupil in looking calmly or staring.

Provocation of Seizure by Overventilation.—Mainzer was able to induce a seizure by deep breathing only in two of fourteen patients with epilepsy or hysteria. The experiment was constantly successful in a patient with traumatic epilepsy. The concentration of chlorin in the blood plasma increased 4 per cent. during the hyperpnea. An intravenous injection of a 10 per cent. solution of sodium chlorid also provoked the seizure, as well as an equimolecular solution of sodium acetate, but not of glucose. He believes that an osmotic irritation of the central nervous system and perhaps a specific action of the chlorin ion are responsible.

Diabetes Insipidus and Polydipsia.—Bauer's patient voided from 10 to 20 liters of urine daily. Pituitary extracts lowered the output, but physiologic salt solution substituted without the patient's knowledge had the same beneficial effect. He discusses all the differential symptoms known from the idiopathic diabetes insipidus and polydipsia, and concludes that none of them are decisive, except the result of suggestive treatment.

Acute Leukemia and Sepsis.—Decastello concludes from his own cases and the literature that acute leukemia must not be identified with sepsis, although it follows sometimes septic infections. He emphasizes Petrén-Odin's case, in which a long remission was obtained by injections of arsphenamin (7.2 gm. in 0.6 gm. doses within a month).

Chlorin Metabolism in Disturbances of Gastric Secretion.—Holler confirms in a general way Gundermann's findings. Yet only those cases of duodenal ulcers show an increased diuresis (in the Volhard test) in which there is hyperacidity. With low chlorin content in the stomach, the diuresis is smaller, but the elimination of chlorids is high (ulcers of the stomach). Chronic appendicitis causes frequently gastric hypersecretion and corresponding changes of diuresis. Cancer of the stomach has usually a low elimination of water and of salt, except with extremely high chlorin concentration in the stomach.

Action of Glucose and Insulin on Muscles.—Kollert and John's investigations were made on patients with idiomuscular irritability. This is the formation of a local contraction on mechanical irritation (percussion). The contraction lasts for a few seconds and occurs in fatigue and cachexia. Intravenous infusion of 35 c.c. of a 40 per cent. solution of glucose improved the condition. Addition of insulin enhanced this action, although insulin alone had no effect. The muscles of cachectic carcinomatous patients were most difficult to influence—perhaps because the glucose was absorbed by the tumor. They also think that idiomuscular excitability indicates a disturbance of the carbohydrate metabolism of the muscles.

Spleen and Iron Metabolism.—Lauda found no siderosis in otherwise healthy rats after splenectomy. The contradictory results of other authors are explained by the occurrence of an infectious hemolytic anemia in these animals.

Specific Dynamic Action of Carbohydrates.—Pollitzer and Stolz observed a marked irregularity of the oxygen consumption after the intake of carbohydrates. Bread and glucose acted differently even in the same individual. They explain this by the close connection with the water-regulatory function of the liver. While the majority of subjects did not show any changes of the oxygen intake after drinking water, the metabolism in patients with jaundice decreased. They agree with Gigon that there is no specific dynamic action of the food. They find that the food intake starts the work of the complicated mechanism of maintaining the constancy of basal metabolism, of temperature and of turgor (water metabolism). "We are testing by the specific dynamic action the functional attitude of these systems and the form in which they react."

Iso-Agglutinins in Blood Plasma and Serum.—Starlinger and Strasser found that native plasma from subjects of Group II frequently agglutinated corpuscles of Group III less strongly than the serum from the same subject, while it was the reverse with Group III. They also mention that some of the Group II plasmas agglutinated corpuscles from Groups II and III.

Insulin Treatment. W. Falta. Supplement.—pp. 1-16.

Oncogenic Constipation.—Pollitzer deals with the constipation in fat, torpid women, which he attributes to disturbances of the turgor (Greek, *onkodes*). These patients have a low basal metabolism. In one group the specific dynamic action of the food is high, in the other low. The latter is increased by intramuscular injections of 10 c.c. of physiologic solution of sodium chlorid saturated with hydrogen sulphid. Drinking daily half a glass of a 5 per cent. dilution of such a solution, or sulphur baths, may also relieve the constipation. Thyroid treatment which helps in such cases, probably acts in a similar way on the turgor.

Electrotherapy.—Weiss used successfully cataphoresis of colloidal silver for impregnation of bones from cadavers. The results were sufficiently encouraging for therapeutic experiments in tuberculosis of the bones. The first impression was very good, but he thinks that it is necessary to wait longer with the publication of clinical results.

Medical Thinking.—Greil emphasizes the importance of epigenetic changes. The "wonder world" of teratomas with all its intermediary changes toward univitelline quadruplets is determined in the second week of pregnancy—not at the moment of fusion of the spermatozoon with the ovum. He thinks that the terrorism of the chromosomes has injured clinical biology and the development of medical science more than the terrorism of a one-sided bacterial etiology. The highest triumph of medicine would be to learn enough about pregnancy and the development of the fetus to be able to direct this epigenetic series of reactions, helping, and preventing constitutional anomalies. This "descent to the mothers" is inhibited, he says, by the reign of theories on determinants, gens and germ plasm, which physicians *credunt quia absurdum.* There is no difference in physical chemistry between the determination and realization factors. By this differentiation, Roux produced an abyss between inorganic and living matter which would condemn the physician forever to the rôle of a half ignorant healer-artist. He believes that the theories that the fate of the individual is fixed at the time of fecundation, the theory of gen coupling, lethal factors, etc., are only writing-desk fictions. The sexes have a different significance in heredity, the yolk and middle part of the spermatozoon are important factors—not only the chromosomes. He wants medicine—a science of action—to get rid of the convenient mistakes of the reigning theory of heredity. It is innocuous in zoologists and botanists, but they will, he believes, come in time to learn from the physician, who is conscious of his responsibility to suffering and upward striving humanity.

Influence on Growth of Unphysiologic Food.—Three litters of puppies were fed with a flour gruel such as is used in infant feeding, rich in carbohydrates but without fat. The effect on the development was of the vitamin deficiency type, and it was more serious the younger the animal at the time this feeding was begun. The deleterious influence was most pronounced when the mother animals had been undernourished during the gestation. In addition to the abnormal conditions in regard to growth and development, the puppies showed a peculiar disappearance of the pigment in the ball of the paws, and an abnormal chemical composition of the entire organism, especially of the liver. The entire findings suggest that the action of the vitamins is analogous to catalysis. They throw light on deficiency disturbances and the *Mehlnährschäden* of the pediatricians. The research was aided by a grant from the Rockefeller Foundation.

Import of the Sedimentation Test in Acute Infectious Diseases in Children.—This instalment is devoted to scarlet fever. Büchler noted that the twenty-fifth day was the earliest date in thirty-five cases of scarlet fever at which the sedimentation test gave an approximately normal response. The chart of the test findings shows a gradual slanting rise on a straight line to the twenty-fifth day and then a horizontal line. If the line of the curve drops down, some complication is developing.

Fuel Value of Elements of the Food.—Pirquet and Wagner tabulate under nineteen headings the findings in 386 specimens of animal foods and 542 specimens of foods of vegetable origin. The aim is to estimate the proportional fuel value in each of the protein, fat and carbohydrate content. Each article of food in the diet for diabetics can now be ordered in portions which correspond to the potential energy of the food materials instead of merely their weight. They use nems for their calculations.

Motor Functioning and Acidity of the Stomach in Infants.—Demuth gives over twenty pages of further data to supplement his previous research on this subject. Among the facts emphasized is that the presence in the stomach of bacilli of the colon group is not necessarily pathologic. With acidity less than a p_H of 4.5, these bacilli were found in the stomach in 57 per cent. of the sick infants; in 65 per cent. of the dyspeptic, and in 69 per cent. of the healthy infants.

Infection from Syphilitic Wetnurse.—The child was not thriving on artificial food, and a wetnurse was engaged when the child was nearly 3 months old. She had been obtained through the regular wetnurse institute, but had a "fever blister" on the lip which healed promptly, but a sore developed on the cheek, and the Wassermann test was then positive, and was positive in the infant's blood three months after the wetnurse had been engaged. The case is notable in that the infant developed an arsphenamin dermatitis. Necropsy showed grave syphilitic injury of the liver.

Nonsurgical Treatment of Pylorospasm.—Herz has had eight female infants in his latest series of fifty-two cases of pylorospasm under the age of 18 weeks. He treats it exclusively internally, ten or twelve small feedings of human milk daily, by bottle, spoonful or tube in the nose. The tube in the nose causes least irritation of the nervous stomach centers, and is borne best. In twenty-six cases a cure was realized without drugs. In others, atropin, cocain or papaverin was used besides. The attention the infant gets from the nurse is a potent factor in the outcome; one infant may do better when lying prone after feeding, another when reclining with a sandbag on the abdomen. None of the fifty-two died from the effects of the pylorospasm, and forty-five were partially or completely cured.

Gonococcus Arthritis in Infants.—Hellmann relates that infection had been intra-uterine in one of the two cases he describes. No entering point for the gonococci could be discovered.

The Dick Test in Scarlet Fever.—Nobel and Orel obtained a positive response in only eight of sixty-nine children known positively to have had scarlet fever; in four of twenty-seven supposed to have had the disease, and in 27.8 per cent. of 270 without a history of scarlet fever. Time will show whether any of the negative children develop scarlet fever later; on this depends the usefulness of the test.

Whooping Cough.—This Düsseldorf clinic analysis of 442 cases in infants less than a year old, 423 in older infants, and 199 in children over 3, emphasizes the lack of the whoop in the younger infants. By waiting for the whoop, and not isolating in time, an epidemic may become installed. The infants are extremely restless, and their crying is with rapid breathing, interrupted by frequent coughing. They scratch their faces, bump their heads against the side of the crib, and throw their arms about. Roentgenoscopy may reveal an emphysema partly covering the heart. Attacks of sneezing may initiate or substitute whooping cough paroxysms. In one child, spasms of yawning initiated the paroxysm of coughing. Whooping cough is a serious disease in infants; it may induce fatal closure of the glottis or fatal convulsions from other cause or from the whooping cough paroxysms; in the latter, possibly, by necrosis of ganglion cells. Complications on the part of the lungs are common in infants; the infant may survive a first attack of complicating pneumonia and succumb to a second. Bacteremia was noted in nine cases after whooping cough pneumonia with fatal localizations. No drugs displayed any efficacy in infants, but vaccine therapy seemed to aid in aborting the disease. It had no appreciable effect on the established disease. The main reliance is on "open air" treatment and breast milk. Reduction of intake of fluids helps to reduce secretion; it may be well to give the food in a thick gruel form. The thick food feeding (four a day) has the further advantage that the stomach contracts to a smaller size and does not push up the diaphragm, relieving the respiratory organs to that extent. There is less tendency to vomit with the thick food. Stretching the neck by lifting the chin mechanically shortens the coughing spasm, and venesection in whooping cough pneumonia often tides the infant past the danger point. Of the total 1,064, 38 per cent. died of those under 3; 10.4 per cent. of the 2 to 3 age, and 3 per cent. of the 199 over 3.

Mechanotherapy for Rickets in Infants.—Wimberger is inclined to think that massage of the legs twice a day helped in the treatment of rickets in infants taking cod liver oil, but not in the others.

Familial Polycythemia.—Herz describes four families with a total of thirteen members presenting polycythemia of moderate degree without subjective symptoms. The spleen was not enlarged and the blood pressure was not always high. The erythrocyte count ranged from 5,300,000 to 8,200,000.

"Acute Cerebral Tremor."—A boy, aged 5, was brought to the hospital with the diagnosis of tuberculous meningitis, thirteen days after a fall injuring the back of the head. The fever, diarrhea, somnolency, spasms, contractures and athetotic movements with twisting of the head and tremor continued for some days. The fever subsided the eleventh day, the stupor the next day, and the other symptoms soon after, with complete recovery. Treatment had been merely symptomatic, long tepid baths, and chloral by the rectum the most restless nights. Bottcher regards the case as an instance of a new infectious disease in which the brain is transiently affected. Like the meningism of acute infectious diseases, there was a kind of encephalism.

Serum Sickness After Diphtheria Antitoxin Treatment.—Bienenstein relates that 17.2 per cent. of 235 children developed serum sickness (Vienna).

*Treatment of Gastroptosis. W. R. Braizew.—p. 2245.
*Treatment of Mal Perforant. Bertone.—p. 2248.

Operative Correction of Gastroptosis.—Martin argues that the sagging of the stomach is due to a substandard condition of the cardiac portion. He explains the separate origin of this part of the stomach, and how the lack of elasticity entails the ptosis. His remedy is resection of the cardiac portion, and he describes four cases in which he applied this with excellent results to date, from eight to twelve months since the operation.

Anastomosis Between the Ureter and Spinal Dura to Drain Congenital Hydrocephalus.—Heile has applied this treatment successfully in an infant with progressive hydrocephalus and convulsions. The ureter was cut to include the funnel at the junction with the kidney pelvis. It was then drawn over to the spine, which it reached without traction. Before incising the dura, the retroperitoneal incision was sutured. The sacrifice of a healthy kidney is the drawback of this method. The intervention was borne surprisingly well by the young infant. The child has developed apparently normally during the five months since, and has had no return of the previous spasms. Heile applied this technic further in a case of brain tumor with the spinal fluid under high tension, but the condition was too grave for more than temporary relief and the adult patient died the next day.

Cysts as Regeneration Process.—Gara has induced the formation of cysts in subcutaneous tissue and muscles which seemed to be identical with the congenital and acquired. He is convinced that every cyst must be regarded as the result of an effort at regeneration. Hence the only treatment for it is the complete extirpation of the whole process, with all its walls. Conditions are then provided for healing by some other mechanism than "cyst healing."

Treatment of Varicocele.—Prima insists that varicocele is merely one manifestation of a general substandard condition. The indications are to tone up the whole system. When this is accomplished, the varicocele will spontaneously subside. He protests against local operative measures.

Surgical Treatment of Gastroptosis.—Braizew presents evidence to show that the cause for the sagging of the stomach is generally traction from the sagging of the transverse colon. He corrects this by suturing the mesentery of the transverse colon to the anterior abdominal wall, on a level with the tenth rib. As soon as the drag from the mesocolon is corrected in this way, the stomach regains its normal elasticity and there is no further gastroptosis. He has operated in this way in three cases, with excellent results.

Stretching the Nerve Trunk in Treatment of Mal Perforant.—Bertone has found this constantly effectual in treatment of mal perforant, as applied in about 100 cases at the Venice surgical clinic. Of course the healing left a cavity defect, but this occurs also with excision. The stretching of the sciatic nerve is a simpler procedure than peripheral sympathectomy, while the results seem to be more dependable.

Actinomycosis of the Genitals. F. Horálek.—p. 1411.
*Exophthalmic Goiter. E. Kliment.—p. 1417.

Friedreich's Ataxia.—Jedlička and Henner describe two cases of cerebellar ataxia. The first had spastic flexion paraplegia, the other a loss of vestibular reactions with the cochlear apparatus intact. Photomicrograms of sections from the spinal cord of the first case are added.

Duodenal Stenosis from Adhesions.—Novák discusses his twenty-four cases of stenosis of the duodenum due to adhesions; all of them were confirmed or diagnosed by the laparotomy. The symptoms of obstruction usually arise only with gastroptosis. Roentgen rays are essential for the diagnosis.

Pirquet Test in Infants.—Skalník's twelve cases demonstrate that a positive Pirquet test proves, even in infants, only a tuberculous infection—not necessarily the disease. The negative response is valuable only if the possibility of an ante-allergic or negatively allergic state or deterioration of the tuberculin is excluded.

Exophthalmic Goiter.—Kliment reports favorably on the results of treatment of exophthalmic goiter with ergotamin tartrate.

Korsakoff's Syndrome in Woman with Pancreas Cyst. Bolten.—p. 1342.

Subcutaneous Necrosis of Fat Tissue.—The newly born child developed adiponecrosis subcutanea neonatorum, and died the thirty-ninth day. This affection seems to be a distinct morbid entity, with a special clinical and histologic picture that has nothing to do with sclerodermia, although such cases have probably been classed with the latter or labeled sclerema adiposum. The necrosis and splitting of the fat was accompanied by an inflammatory reaction and resorption. The child had been apparently healthy for three weeks after spontaneous delivery. The location of the patches suggested trauma, possibly during the efforts to resuscitate the child, born in deep asphyxia.

Roentgen Rays in Periesophagitis.—Huizinga and Keijser call attention to the importance of Minnigerode's discovery of a light strip in the roentgenogram corresponding to air that had escaped through a perforation in the esophagus, or gas generated in a suppurating process. They describe four cases, one with spontaneous subsidence of the disturbances after extraction of the swallowed bone. After the swallowing of a foreign body, repeated roentgenoscopy will reveal the first onset of escape of air through perforation of the esophagus wall, and allow intervention in time to ward off serious trouble.

Radiotherapy of Cancer of the Skin.—The cancer research institute at Amsterdam treated 160 cases of superficial cancers 1915-1921, all with radium, curetting the extensive ones to allow closer application of the radium. The histologic structure did not seem to influence the results. There was recurrence in only twenty-five, and the recurrence promptly subsided under renewed application of radium. Every case was cured that did not have metastases when first seen, or special circumstances preventing contact with the radium.

Fatal Pulmonary Embolism.—De Snoo relates that two parturients died recently in his service on the same day from pulmonary embolism. He thinks this is more than a casual coincidence, having noticed the same accumulation of cases on other occasions, suggesting that the bacteria were of a special thrombosis-inducing type. There have been twelve cases of fatal embolism of the lung since 1907, in a total of 10,000 deliveries. The embolus came from the pelvic veins in all but one of the cases. Seven of the women died within a few minutes; two in half an hour, one in thirteen hours, and in the latest case two days had elapsed from the first symptoms of embolism. No instance was known of embolism in the spontaneously delivered women, not even with placenta praevia, eclampsia, syphilis, anemia, heart disease, or other complication. The difference is striking between the 8,200 spontaneous deliveries without a single instance of embolism and the eleven fatal embolism cases in 1,845 artificial deliveries. He insists that every woman with thrombosis should be isolated as infectious. He refuses all except emergency operations during thrombosis epidemics. With severe infection, there is less danger of embolism, as the thrombi stick faster to the vessel wall. In one of his cases a loose thrombus, 40 cm. long, had developed in the femoral vein, which raises the query why embolism is not more common. Possibly the thrombosis-cocci increase the coagulability of the blood, and it may yet be possible to combat this with extract of leeches or other means without danger of after-hemorrhage.

The Fight Against Malaria in Palestine.—The spleen malaria index has fallen from 59 per cent. of 616 children examined in 1912 to zero in 1924 among 829 children. Swellengrebel remarks that the lack of rainfall and other conditions in Palestine facilitate the extermination of malaria.

Acta Chirurgica Scandinavica, Stockholm

Ultimate Outcome of Rectopexy in Children.—Petrén endorses the simplicity, ease and excellent outcome of Ekehorn's method of treating prolapse of the rectum or anus by passing a stout silk thread through the posterior wall of the rectum and tying it over the lower part of the sacrum. The thread is removed after two weeks. Recent reexamination of twenty-six children that had been treated by this means at Lund between 1910 and 1923 showed that it had been permanently effectual in all. The ages of the children ranged from 14 months to 7 years, with the exception of one child of 12. In this latter case the reaction, both general and local, was more severe than in the others, but in six cases the temperature rose to about 39 and in thirteen to nearly 39 C. The stay in the hospital averaged eighteen and a half days. The desired result from the rectopexy was attained constantly, without exception, in the known fifty-eight cases to date in which this technic had been applied. Ekehorn's original description of it is reproduced. The article is in German.

Splenectomy in Banti's Disease.—Brandberg regards splenectomy as indicated in every type of cirrhosis of the liver with enlargement of the spleen, but he has had no experience with actual Banti's disease. In four cases of cirrhosis of the liver with enlargement of the spleen, splenectomy had a beneficial effect, arresting the process in the liver, although a cure is out of the question. One of the four patients died from the progress of the disease, five years after the splenectomy. The others are still in comparative health from nine months to three years since. In two other cases, one patient died from postoperative complications and the other survived only two years. No benefit from the operation was apparent in this case. The microscopic findings in the spleen in splenomegalous cirrhosis seem to be identical with those in the spleen from progressive thrombosis of the splenic and portal veins. The disturbances in both are therefore probably of the same nature, the result of extreme venous stasis. In a group of three other cases, the spleen findings were quite different; there was hyperplasia of cells and lack of any tendency to fibro-adenia. The spleen in these three women was larger than in the liver cirrhosis cases and all were benefited by the splenectomy. There was a possible suggestion of lymphatic aleukemia in one case and of lymphogranulomatosis in another. The latter patient died from pneumonia six months later. The third patient was well for a year after the splenectomy, but then chronic nephritis developed. This thirty-four page article is in English, and the ten splenectomy cases are described in detail.

Traumatic Separation of the Gallbladder.—Andersson's patient, a boy, aged 4, recovered after the gallbladder—partially separated by a fall from a wagon—had been replaced. The bleeding from the bed of the gallbladder was arrested with a couple of catgut sutures, and tampons were packed in the angle between the gallbladder and the liver. Eleven somewhat similar cases are summarized from the records. The symptoms are similar to those from contusion in general. The gallbladder itself was torn only in one instance, and there was not much hemorrhage in several.

Contusion of Biliary Apparatus.—Andersson's study of this subject is based on twenty-four cases of subcutaneous rupture of the liver and two of rupture of a bile duct.

Human Horns.—The horn in the case described was on the abdomen, just below the umbilicus. It was 34 cm. long and measured 14 cm. around the base. The patient was a woman of 55.

Ugeskrift for Læger, Copenhagen

Ambidexterity. C. Gram.—p. 828.

Deep Action of Silver Nitrate.—Haxthausen concludes from his extensive experience that there is no experimental or clinical basis for the assumption that organic preparations of silver have any greater efficacy than silver nitrate in injection treatment of gonorrhea. The latter diffuses to a greater depth in the tissues than the others. Comparative tests in fifty cases of acute uncomplicated gonorrhea showed invariably a better effect from silver nitrate.

Tendon Transplantation to Restore Function to the Peroneus Muscle.—Berntsen's illustrations show how he lengthens the Achilles tendon by slitting it lengthwise, bayonet fashion, and then draws it around behind the peroneus muscle to which it is sutured. By this means the flaccid peroneus is activated by traction from above and below and on both sides. In twenty-six of thirty-eight cases the outcome was excellent. The failures were all due to the fact that the Achilles tendon was not so capable as had been assumed.

Embolus in Pulmonary Artery.—Biilmann comments on the fact that all died soon after the embolectomy in the nine cases on record treated by the Trendelenburg technic; only one survived to the sixth day. He has worked out on the cadaver a method which he thinks would be more effectual. It includes slitting the sternum lengthwise and aspirating the embolus through the pericardium. He has been able to complete the whole procedure on the cadaver in a minute and a half.
